Removing the patient from the source of the burn is an obvious first step. Cooling is only effective if performed within the first 2 minutes and should not be continued longer than 20 to 30 minutes. Irrigation of a thermal burn that is older than 30 minutes has little to no benefit. Copious irrigation is indicated for chemical burns but may also be beneficial if molten metals, synthetic materials, or tar adhere to the skin. Irrigation dissipates heat and therefore should be continued until the burning has stopped and the material is cool **Figure 12-7**. In addition, cold inhibits lactate production and acidosis, thereby promoting catecholamine function and cardiovascular homeostasis in the wound. Cooling of the burn also limits the release of histamine, which results in increased vasculature permeability and **thromboxane**, which promotes coagulation in the wound contributing to ischemia. In chemical burns, the irrigation length should be guided by the pH of the wound assessed in the base of the wound. If the CCTP is unable to measure pH using standard litmus paper, copious irrigation should continue for at least 20 minutes. Blisters should be left intact unless they are the result of a chemical burn, in which case they should be broken because they may trap chemicals in the blisters. All clothing and jewelry should be removed because they may also trap chemicals. Wet clothing may contribute to heat loss and cause hypothermia. After cooling or decontamination, the patient should be kept warm and placed in clean, dry linens prior to transport.

Airway and Breathing

Airway management for the burn patient is a difficult challenge. Inhalation injury, c-spine injury, circumferential chest burns, and poisoning from noxious fumes are challenging scenarios. As stated previously, the patient must be assessed for the possibility of inhalation injury and the airway managed with endotracheal intubation if stridor, progressive hoarseness, or any other evidence of airway compromise is present. Because inhalation injuries result in airway edema, the CCTP should anticipate a difficult airway and be prepared to perform a surgical airway intervention should endotracheal intubation fail.

Figure 12-7 Management of the burn patient includes irrigation.

Signs and Symptoms

Inhalation Injury

- Facial burns
- Stridor or progressive hoarseness
- Singeing of the eyebrows and hairs
- Carbon deposits and acute inflammatory changes in the oropharynx
- Carbonaceous (black) sputum
- History of impaired mentation and/or confinement in a burning environment
- Explosion with burns to head and torso
- Circumferential neck burns
- Carboxyhemoglobin level greater than 10% if patient is involved in a confined space fire
- Soot around the nose and mouth
- Increased mucus production
- Impairment of mucociliary function

Transport Management

Inhalation Injury

- Consider performing endotracheal intubation after RSI if the transport time is prolonged; if there is stridor, progressive hoarseness, or any change in the patient's voice; or for any deterioration in the patient's condition.
- Be prepared to perform surgical intervention should intubation fail.
- Consider administering humidified oxygen (in the absence of wheezing) using a nebulizer with normal saline only and no bronchodilators.

For patients who require endotracheal intubation, RSI should be performed per local protocol.

If the patient's oxygen saturation drops at any point, you have no choice except to ventilate (slowly). If the patient is hemodynamically unstable, you must judge whether sedation is appropriate or whether the risk of profound hypotension is too great to sedate the patient.

Although succinylcholine is the drug of choice in RSI, it is contraindicated in patients with burn injuries greater than 48 hours old or in patients with known rhabdomyolysis secondary to their burn injuries because it may cause an extremely dangerous rise in potassium level. In these situations, a nondepolarizing agent such as vecuronium or rocuronium should be used. Because of the extended time of paralysis with this agent, the CCTP should carefully weigh the risk of being unable to intubate the patient with the benefit of intubation. Most often the benefits of intubation outweigh the risk associated with paralytic-assisted intubation with a nondepolarizing agent. The CCTP should also consider sedation-only assisted intubation (with a medication such as etomidate) or awake intubation as an alternative in a patient in whom the administration of succinylcholine is contraindicated.

Airway management in the burn patient can be difficult. Not only can airway edema make intubation difficult but it can foil most airway devices designed for use with failed intubation. Most of these devices rely on the ability to ventilate the patient through a patent glottic opening, which may not be present in the burn patient with inhalation injury. It is imperative therefore that the CCTP be prepared to surgically manage the airway if orotracheal intubation has failed.

Initial ventilator settings on the burn patient should be standard with the exception of the addition of positive end-expiratory pressure (PEEP) to aid in oxygenation and to treat pulmonary edema.

Carbon monoxide poisoning, asphyxiation, and cyanide poisoning are a major concern; most early fatalities are a result of carbon monoxide poisoning. Poisoning may be suspected from historical information such as burn injury in an enclosed space. An elevated carboxyhemoglobin level may be diagnosed via an arterial or venous blood gas determination or by using an oximeter capable of measuring carboxyhemoglobin (SpCO). Chapter 20 covers the treatment of carbon monoxide poisoning and cyanide poisoning.

Cyanide can be produced from the burning of any substance that contains carbon and nitrogen. The treatment for cyanide poisoning is described further in Chapter 20, but good supportive care in the absence of antidote can save many cyanide poisoning victims.

If any of these conditions are suspected, the patient should be treated with 100% oxygen via nonrebreathing mask. In most burn patients, oxygen, preferably humidified, should be administered immediately. High-flow oxygen may be used in patients with chronic pulmonary disease, but the patient's condition should be monitored closely for evidence of hypoventilation and the CCTP should be prepared to manage the airway. Patients who are known to have COPD and carbon dioxide retention should receive enough supplemental oxygen to maintain their baseline oxygenation or a saturation of 90% to 95%. Providing the patient supplemental oxygen prevents hypoventilation and respiratory acidosis, which occur with oxygen saturations that are above the patient's baseline in COPD. Attempts to oxygenate the patient to supra-baseline oxygenation levels (his or her normal saturation level) can result in carbon dioxide retention, acidosis, arrhythmias, and respiratory arrest; however, oxygen should never be withheld from a hypoxic patient.

Patients with inhalation injury from cyanide or carbon dioxide exposure require immediate intubation. Cricothyroidotomy should be performed in the event of an unsuccessful intubation because the use of airway rescue devices such as laryngeal mask airway, King, and Combitube are not likely to be successful secondary to airway edema. An unsuccessful intubation is defined as three attempts by the most experienced person.

Circulation

The essentials of circulatory management include early, aggressive, sustained fluid management. This management is unique to burn patients. Burns can result in large intravascular fluid losses as a result of the loss of the protection against desiccation and evaporation. In addition, circulating inflammatory mediators cause fluid from capillaries to leak into the interstitial space (neither in the vasculature nor the

cell). The inflammatory process at the site of injury results in plasma "weeping" into the burned area. The larger the surface area involved, the greater the fluid loss. Burns that are deep second degree or larger can cause hypotension and therefore fluid resuscitation should begin immediately via large-bore IV catheter. If possible, obtain IV access through unburned skin; however, access through burned skin is acceptable if necessary.

There are numerous fluid resuscitation formulas for the first 24 hours after a burn. The most commonly used is the **Parkland formula**, which recommends resuscitation with lactated Ringer's solution (normal saline is an acceptable substitute) of 4 mL/kg/%BSA burned; half this amount should be given over the first 8 hours (from the time of injury), one fourth of the total amount should be given over the second 8 hours, and one fourth of the total amount should be given over the third 8 hours. All calculations are determined from the time of the injury, and therefore fluid boluses may be necessary to correct deficits in fluid resuscitation becasue of either a delay in presentation or underresuscitation. It may also be necessary to administer fluids more aggressively if the patient is in shock with unstable vital signs. The goal for all fluid replacement is to maintain a urine output of 0.5 to

For children, the calculation of fluid resuscitation becomes a little more complex. The **Galveston formula** **Table 12-2** uses BSA burned and TBSA of the child (for maintenance fluids) as opposed to weight to calculate fluid needs. The Galveston formula is as follows: 5,000 mL/m^2 burned + 2,000 mL/TBSA m^2, with half of the amount of fluid given in the first 8 hours after injury and the second half over the next 16 hours. The problem with this approach, however, is that calculating m^2 burned while preparing to transport a critically burned child is not easily done, making this approach somewhat impractical. Therefore, for the acute phase and immediate transport, the Parkland formula is adequate until conditions allow the calculation of more precise fluid resuscitation rates.

The formulas used to calculate a burn patient's fluid requirements should serve only as a guide. The patient's overall perfusion status, mental status, urine output, and lung sounds should be monitored. If the patient is too aggressively hydrated, pulmonary or cerebral edema may result. If the patient is not adequately resuscitated, inadequate perfusion of the kidneys or mesentery may worsen organ system damage. The best monitor of fluid replacement is urine output with a goal of a minimum of 30 mL/h (0.5 mL/kg/h) for adults, 1 mL/kg/h in children, and 1 to 2 mL/kg/h for neonates. The urine output should serve to guide the subsequent fluid replacement rates beyond the initial 24 hours after injury. If urine output is above or below the normal range by one third for more than 3 hours, the hourly infusion rate is increased or decreased by one third. If the urine is dark brown or red, which means it contains hemochromogens, titrate the fluids to maintain a urine output of 1.0 to 2.0 mL/kg/h in adults and 2 mL/kg/h in children, until the pigments have cleared and the urine is straw colored. Burn centers often want to participate in the calculation of fluid requirements for children. Know the preference of the receiving facility or contact them prior to transport to discuss fluid resuscitation strategies. When assuming responsibility for a patient, the CCTP should check all fluids and infusion rates to make sure they are appropriate, inventory the fluid given already, and reconcile urine output since injury. It is a good idea for the CCTP to empty the Foley bag at the time you assume care to allow for accurate measurement of urine output during transport **Figure 12-8**.

TABLE 12-2 Galveston Resuscitation Formula

Lactated Ringer's solution (5% Dextrose in children < 2 years)	
First 24 hours	**Second 24 hours**
5,000 mL/m^2 burned +	3,750 mL/m^2 burned

2,000 mL/m^2 TBSA m^2	1,500 mL/m^2 TBSA
Provide half this amount in the first 8 hours, and the second half in the next 16 hours.	
Abbreviation: TBSA, total body surface area.	

Special Populations

Children are much more sensitive to fluid shifts than adults. The CCTP must be very careful with fluid administration in children, who have a much larger surface area relative to body mass and can lose body heat much more easily.

Wound Management and Dressings

Wound management is critical, especially when burn injury compromises the skin as a barrier to infection and regulator of the body's temperature. Proper dressings help reduce infection, decrease pain, and prevent heat loss. After cooling, irrigating, and decontaminating, the wounds should be dried and dressed with *dry*, clean dressings **Figure 12-9**. A common mistake when caring for burned patients is using wet dressings, which contribute to heat loss and are ineffective barriers to infection. Bulky dressings may be used to pad pressure points and sensitive areas. No ointments or creams are necessary, but if wounds are already dressed with ointments or creams they may be left in place. All wounds should be examined to confirm that the BSA and the fluid resuscitation calculation are accurate.

Figure 12-8 Empty the indwelling catheter bag at the time you assume care to allow for accurate measurement of urine output during transport.

Figure 12-9 Wounds should be dressed with dry, clean dressings. Do not use wet dressings.

The debridement of most wounds will be performed at the receiving burn unit. As a general rule, blisters are left intact unless they are caused by a chemical burn. Blisters from chemical burns should be broken during decontamination as they may trap the causative agent and worsen the extent of injury.

Tar and asphalt burns can represent a challenge in the area of burn wound care. When tar that is heated to form a liquid comes in contact with skin, heat transfer occurs, causing a burn injury. Asphalt cements become a liquid at lower temperatures (275°F to 300°F) compared with tar, which requires a higher temperature to remain in a liquid state (450°F to 500°F). Therefore, more serious burns occur with tar than asphalt. As tar or asphalt cool, they solidify and adhere to hair. There is little direct bonding between the tar and skin. The tar or asphalt should be cooled with water until hardened and cool. After the tar is cooled, the patient may be transported to the burn center. If an attempt at removal is made prior to transfer to the burn unit, several ointments and solvents may assist in the removal process. Tar must be removed because it would serve as an occlusive dressing and cause infection. Naphthalene, hexane, and other carbon solvents may be useful for removing asphalts, whereas coal tars respond to aromatic hydrocarbons (benzene, toluene, or naphthalene) only. Unfortunately, these solvents can be absorbed, producing toxic side effects; therefore, a specific type called long-chain aliphatic hydrocarbons (hexanes or pentanes) should be used, or removal of coal tars may need to be delayed until reaching the burn center. Sunflower oil, butter, baby oil, and commercial surface active agents such as polysorbate 80 have been shown to be highly effective and inexpensive for tar and asphalt removal.

Transport Management

Burn Wounds

- Dry and dress wounds with dry, clean dressings.
- Use bulky dressings to pad pressure points and sensitive areas.
- Do not use ointments or creams, but if wounds are already dressed with ointments or creams, leave them in place.
- Examine all wounds to confirm that the body surface area and the fluid resuscitation calculation are accurate.

As a general rule, wound debridement should not be performed by the CCTP except in the setting of chemical exposure and blisters formed by chemical agents. Wounds must generally be debrided to remove dead skin, which can serve as a source for infection and prevent healthy tissue from repairing the burned area. Wound debridement consists of removing any dead or nonviable tissue from the wound. The treatment of blisters is somewhat controversial. On the one side, exposing a broken blister can result in local wound infection, and on the other side, fluid confined by necrotic skin can result in a closed-space infection. The debridement of burned skin is best left to the burn specialist.

Wound Infections and Treatment

Wound infections do not occur during the first few hours after a burn and therefore there is no role for antibiotic prophylaxis by the CCTP. Early antibiotic administration without proven infection may select for resistant bacteria, which makes fighting future infections difficult. Topical antibiotic preparations are generally used to dress wounds. Agents such as bacitracin or a combination preparation of neomycin

sulfate and polymyxin B sulfate (Neosporin) are generally used on the face and areas of thin skin, whereas silver sulfadiazine (Silvadene) is commonly used on other parts of the body. Silvadene should never be used on the face as it can cause skin discoloration. The exception to early wound infection is with tetanus. Patients who have not had a tetanus booster in 5 years require 0.5 mL of diphtheria and tetanus toxoids intramuscularly. Patients who have not had the primary series of three immunizations (more commonly found in immigrants or visitors from developing countries) will require tetanus immunoglobulin in addition to starting the primary immunization series. Patients at highest risk for tetanus are immigrants from developing countries and older patients who have not had a booster in many years.

Pain Control

Burns can be excruciatingly painful, and pain control in the burn patient must be taken seriously. An opioid such as morphine sulfate, in doses of 4 to 8 mg IV (0.1 mg/kg), is the agent of choice in patients who are not allergic, and may be repeated until adequate pain control is achieved. Alternative agents such as fentanyl (Sublimaze) or hydromorphone (Dilaudid) may also be used. Pain should be assessed and treated every 10 minutes until the patient is comfortable. Burn victims may require large doses of narcotics for adequate pain control, so if patients say they are in pain, the pain should be treated. Titration of narcotics should be based on the patient's perception of pain, with additional doses withheld in cases of altered level of consciousness, respiratory depression, or hypotension. The patient should be reassessed often and treated as needed. Morphine sulfate may also be used for children. An initial dose of 0.1 mg/kg up to a maximum of 5 mg/kg per dose should be given. Individual requirements for narcotics are different, and the CCTP should take care to ensure that the pain is not under-medicated or overmedicated.

CCTPs should also be careful not to confuse sedation and analgesia. Sedatives such as lorazepam (Ativan) do not have analgesic properties, and patients who are receiving ventilation will likely require sedation in addition to analgesia. The patient's condition should be monitored closely to prevent oversedation. The CCTP should remember that oxygenation does not equal ventilation, and patients who are oversedated will have a rise in the partial pressure of carbon dioxide long before there is any drop in the partial pressure of oxygen. Therefore, clinical assessment of the patient's ventilatory status or end-tidal carbon dioxide level must be used as the gauge to assess for oversedation. All medications should be given IV and never intramuscularly unless special circumstances exist. Long transports may require large quantities of medication, and the CCTP should make sure enough medication is available for sedation and pain control during transport.

Other Issues

Hypothermia

As mentioned earlier, every effort should be made to maintain a normal body temperature. The patient's temperature should be measured prior to transport. Removal of wet clothing, dressings, and linens is essential. Dry sheets and blankets are preferred. Warmed IV fluids should also be used, especially if large volumes are going to be infused.

Gastric Decompression

Patients with greater than 20% BSA burned are prone to ileus (loss of intestinal motility) because of the systemic inflammatory response that occurs with large burns. The administration of narcotic pain medications decreases gastric and intestinal motility and therefore increases the likelihood of an ileus developing. An ileus can cause abdominal distension, discomfort, and vomiting. Therefore, nasogastric tubes should be placed in these patients. Decompression of the stomach with low intermittent suction will

reduce distension, discomfort, and vomiting. Patients who have been endotracheally intubated also require orogastric tube placement to evacuate the stomach and prevent regurgitation.

Signs and Symptoms

Ileus

- Abdominal distention
- Discomfort
- Vomiting

Transport Management

Ileus

- Perform gastric decompression.
- Use nasogastric tubes.
- Place an orogastric tube in patients who have been intubated.

Figure 12-10 shows an algorithm for the management of a burn patient.

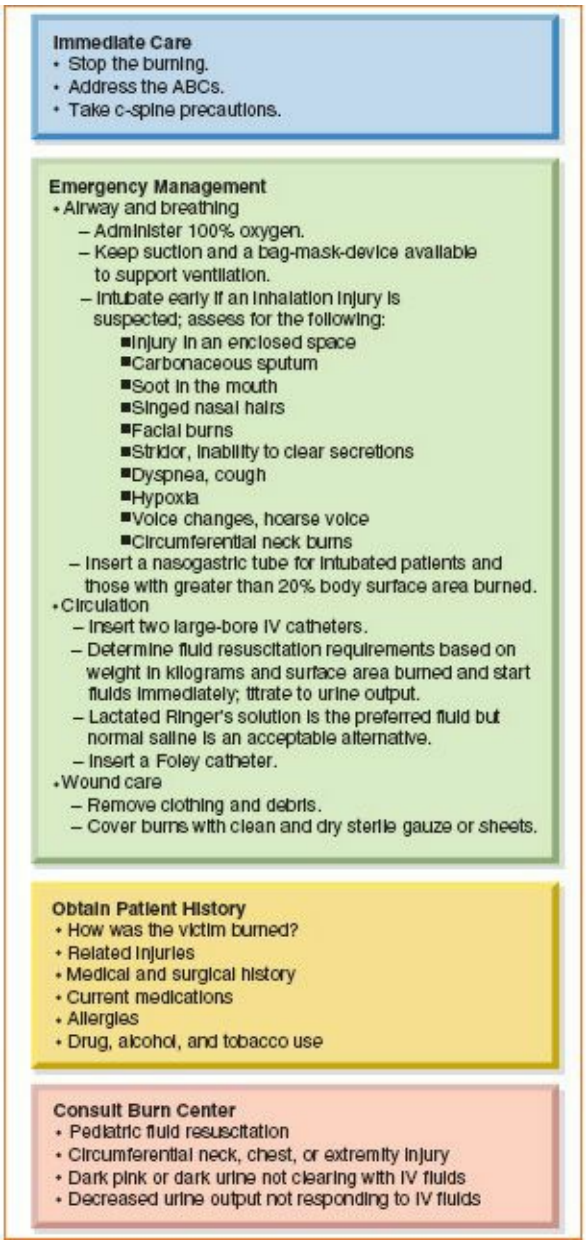

Figure 12-10 Algorithm for the management of a burn patient.

Special Situations

Burn centers provide care and expertise for many different types of injuries. A basic knowledge of these special situations is important to prevent further injury and provide appropriate treatment during transport.

Renal Failure and Rhabdomyolysis

Despite adequate fluid resuscitation, urine output may not be adequate. Given that urine output is the best indicator of adequate fluid resuscitation, patients with inadequate urine output can be extremely challenging for any health care provider. There are several common reasons for inadequate urine output. Severe shock may have caused kidney damage or the patient may have preexisting renal failure. The patient may also have renal dysfunction as a result of the mobilization of muscle proteins impairing filtration, a condition known as **rhabdomyolysis**. Rhabdomyolysis occurs most often with crush injuries, electrical burns, or large full-thickness burns. Specific proteins from the destruction of muscle may accumulate in the blood and urine as a result of tissue damage, causing the urine to become pink, dark red, or rust colored. This potential complication usually improves with appropriate fluid resuscitation, and

appropriate early resuscitation may prevent it from occurring. If urine output is inadequate or if there is urine discoloration that does not clear with the administration of IV fluids, increase the fluid rate, add sodium bicarbonate, and consider a diuretic such as mannitol. The dosage of mannitol and sodium bicarbonate varies somewhat based on physician preference, but typical orders are for three ampules of sodium bicarbonate in a liter of 5% dextrose, and 25 to 50 g of mannitol added to each liter of resuscitation fluid. For severe rhabdomyolysis, the patient may require emergent dialysis.

Patients with preexisting cardiac and renal dysfunction may develop pulmonary edema and congestive heart failure as a result of aggressive fluid resuscitation. In the absence of comorbidities, complications from fluid resuscitation are less likely than are complications from underresuscitation, and therefore it is better to err on the side of overresuscitation rather than underresuscitation. Patients may require ventilatory and inotropic support if fluid resuscitation is too aggressive. In addition to pulmonary edema, patients with renal failure are at increased risk of electrolyte abnormalities such as hyperkalemia. Potassium-containing fluids, including lactated Ringer's solution, should be avoided in the patient with renal failure or insufficiency and normal saline used instead. Always communicate closely with the burn center regarding fluid management in such patients.

Signs and Symptoms

Rhabdomyolysis

- Pink, dark red, or rust-colored urine that does not clear with IV fluids

Transport Management

Rhabdomyolysis

- Increase the fluid rate.
- Add sodium bicarbonate and consider a diuretic such as mannitol.
- When performing RSI, use a nondepolarizing agent such as vecuronium or rocuronium. Succinylcholine is contra–indicated in patients with known rhabdomyolysis secondary to burn injuries.
- Consider sedation-only assisted intubation with a medication such as etomidate or awake intubation as an alternative.
- Err on the side of fluid overresuscitation, but if fluid resuscitation is too aggressive, provide ventilatory and inotropic support.

Ocular Burns

Every burned patient should have a thorough eye exam. Corneal abrasions and corneal burns may occur from many mechanisms. Friction burns from auto airbags, blast injury, thermal burns, and chemical burns are common sources of injury. In awake and alert patients, eye injuries are rarely overlooked because the patient complains of pain or visual changes. If the patient is sedated, is unconscious, or has distracting injuries, clinical suspicion must remain high to avoid missing injuries. Because facial edema may develop quickly, early intervention is important. After the eyelids swell, it may be difficult to open the eyes for an exam or treatment **Figure 12-11**. Copious irrigation is indicated for chemical burns, and airbag injuries should also be irrigated. Airbags may cause friction burns because the bag impact deploys faster than the

eye can react and close to prevent the injury. In addition, the propellant that inflates the bag can release heat or chemicals that can burn the eyes. Corneal injuries can be very painful and should be treated with appropriate IV narcotics. Instillation of topical anesthetics such as tetracaine may alleviate the pain from corneal injuries and aid in irrigation, although topical anesthetic drops should not be used repeatedly.

Figure 12-11 Examine the burn patient's eyes early; facial edema may develop quickly and make assessment difficult.

If chemical burns of the eyes are present, the eyes should be irrigated with copious amounts of water for at least 20 minutes or until the conjunctival sac pH has returned to 7. Irrigation of the eyes can be difficult at best if attempted manually. Morgan lenses—contact lenses with tubing connected to IV fluids—should be placed to facilitate irrigation. Lactated Ringer's solution is better tolerated as an irrigation fluid than normal saline, but either is acceptable. Topical anesthetics should be instilled prior to placement of the Morgan lenses.

For the critically burned patient with nonchemical burns to the eyes, application of topical ophthalmic preparations (if patient care demands allow) will suffice as temporizing treatment until more definitive examination and treatment at the receiving facility can be undertaken.

Transport Management

Ocular Burns

- Treat corneal injuries with appropriate IV narcotics.
- Chemical burns of the eyes: irrigate with copious amounts of water for at least 20 minutes or until the pH of the conjunctival sac has returned to 7.
- Nonchemical burns to the eyes: apply a topical ophthalmic preparation.

Facial Burns

Facial burns require special attention. Ocular and airway injuries are the major concerns and significant facial burns suggest airway injury. Rapid and repeated airway evaluation is crucial. Early intubation should be considered for any airway injury. As mentioned earlier, the face develops edema quickly. Therefore, an early eye exam is important. To help reduce facial edema, the head of the stretcher should be elevated 30° if spinal injury is not suspected.

Transport Management

Facial Burns

- If no spinal injury is suspected, elevate the head of the stretcher 30° to reduce facial edema.

Ear Burns

Ears are also prone to significant swelling. The ear canal and ear drum should be examined before edema develops. Discuss this with the transporting or receiving physician prior to departure. Prevent additional trauma by avoiding pressure dressings and do not use a pillow. Only large, dry, bulky dressings are required.

Transport Management

Ear Burns

- Use large, bulky dressings.
- Avoid pressure dressings.
- Do not use a pillow.

Circumferential Burns and Compartment Syndrome

Burns that encircle the chest, an extremity, or the penis present a difficult challenge. Chest burns can cause respiratory impairment because of eschar limitation of chest excursion. Edema in the extremities and penis may result in vascular compromise. These injuries may require an **escharotomy**, a procedure in which an incision is made through the stiff edematous burned skin to restore mobility to the chest or circulation to an extremity **Figure 12-12**. Again, most burn specialists discourage the use of field escharotomy unless absolutely and immediately necessary to preserve life or limb.

The equipment needed to perform an escharotomy includes the following:

- Scalpel
- Pain medication
- Sedation
- Sterile dressing
- 4″ × 4″ gauze pads

An escharotomy may be necessary in the following circumstances:

- Circumferential burns
- Full-thickness burns
- Compartment syndrome

Figure 12-12 An escharotomy, in which an incision is made to restore circulation in the context of a circumferential extremity burn.

- Thermal burns
- High-voltage electrical burns
- Tissue pressure measurements greater than 35 mm Hg (obtained by placing a needle into the compartment in question, usually done by an orthopaedist)
- Complications of an escharotomy include:
- Bleeding
- Infection
- Nerve damage
- Limited range of motion due to improper technique

Skill Drill 12-1 describes the steps for performing an emergency escharotomy:

1. Prepare your equipment.
2. Administer sedation and pain medications. Burns that cause such injuries are deep and destroy nerve endings; therefore, this procedure can be performed without anesthesia.
3. Maintain an aseptic technique **Step 1**.
4. Determine a well-defined incision pattern. For the chest, an incision is made along both anterior axillary lines and may also be performed transversely. For an extremity, an incision is made parallel to the bone. A single incision may be sufficient for an extremity. The incision should be of sufficient depth for an obvious release in pressure on the skin and for fat to bulge through the incision. For the penis, a single dorsal incision is adequate (the dorsum of the penis is the anterior surface if the penis is pointing toward the feet). Hand escharotomies are performed with incisions in the medial and lateral surfaces of each finger and of the palm.
5. Incise the derma of the burned tissue **Step 2**. Built-up pressure should cause the tissue to open even more.
6. Prepare to manage bleeding **Step 3**.
7. Apply a sterile dressing over the incision.

The most qualified person should perform the procedure; however, situations may arise that make it necessary on an emergent basis to save life or limb. An escharotomy should only be performed after

discussion with the receiving burn center or transport service medical direction (if local scope of practice allows).

Signs and Symptoms

Circulation Problems Due to Circumferential Burns

- Absence of pulses
- Delayed capillary refill
- Mottling and discoloration of an extremity

Transport Management

Circulation Problems Due to Circumferential Burns

- Escharotomy, if allowed per protocol

Controversies

The necessity of prehospital escharotomies is a subject of debate. Many believe that the efficacy of field escharotomies is limited when given a risk-benefit analysis. With field escharotomies, there is the potential for blood loss, severe hypotension, contamination of the wound, and damage to the nerves. Because of the amount of time it takes for an eschar to form, the likelihood of needing to perform an escharotomy in the field is low. However, one must also consider potential benefit of performing escharotomies for interfacility transports of extended length. When performed in a facility as opposed to the field, the benefit may outweigh the risk of the procedure.

Hand and Foot Burns

Burns on the hands and feet can cause significant disability and require specialized care. Circulation is the main concern because edema may impair blood flow to the periphery of the extremity, causing extensive damage. Simple interventions such as elevating the injured extremity above the heart and avoiding constricting dressings are important. Loose, dry dressings that allow easy assessment of the patient's circulation may be used during transport; however, no dressing is required. Do not apply creams or ointments. Do not apply ice packs because they may cause frostbite.

Transport Management

Hand and Foot Burns

- Elevate the injured extremity above the heart.
- Avoid constricting dressings; use loose, dry dressings or no dressing.
- Do not apply creams or ointments.
- Do not apply ice packs.

Genitalia Burns

Burns on the genitalia and perineum should not distract health care providers from life-threatening injuries. However, certain details in the treatment of patients with such injuries require prompt attention. A Foley catheter should be placed immediately before edema develops. The penis should be examined for circumferential burns and monitored for impaired circulation. As mentioned previously, a dorsal escharotomy of the penis may be necessary, but is highly unlikely.

Transport Management

Genitalia Burns

- Place a Foley catheter immediately.
- If a penis has a circumferential burn, monitor for impaired circulation.

Pediatric Burns and Child Abuse

Children present special challenges when burned because their physiology and composition are different than those of adults. Children have relatively more surface area per kilogram, which necessitates higher rates of fluid resuscitation. Infants also have relatively less glycogen stores than adults, making them susceptible to hypoglycemia if deprived of oral intake for several hours. Consideration should be given to the addition of glucose to resuscitation fluids; however, this treatment should be guided by local burn center preference. Some strategies include frequently checking glucose levels and correcting any hypoglycemia as it occurs rather than administering glucose-containing fluids. The blood glucose level should be maintained between 60 and 120 mg/dL.

Skill Drill 12-1

Performing an Emergency Escharotomy

1 Prepare your equipment. Administer sedation and pain medications. Maintain an aseptic technique. Determine a welldefined incision pattern.

2 Incise the derma of the burned tissue.

3 Prepare to manage bleeding. Apply a sterile dressing.

Approximately 25% of all childhood burns are from child abuse and therefore should be considered by the CCTP caring for the child. Children with burns who receive care more than 24 hours after the incident should be suspected of being maltreated and should be reported to child protection authorities. Accidental burns in children most often result from scalding and more commonly occur in the "spill area"—the area of the face and chest that is exposed from a child pulling a container of hot liquid onto himself **Figure 12-13**. Burns to other areas with well-demarcated edges and in a stocking glove distribution should raise the suspicion of abuse **Figure 12-14**. Any suspicion of child maltreatment should be reported to child protection authorities and the receiving facility.

Transport Management

Pediatric Burns

- Consult with a local burn center regarding adding glucose to resuscitation fluids.
- Check blood glucose levels frequently.
- Correct hypoglycemia.

Figure 12-13 An accidental burn.

Figure 12-14 Stocking glove distribution.

Figure 12-15 **A.** An electrical burn entry wound on the shoulder of a patient. **B.** An electrical burn exit wound on the foot of a patient.

Electrical Burns

Injuries from electricity may result from an alternating current or direct current such as lightning. An

alternating current is found in homes and businesses and is the most common source of electrical injury. A direct current is found in automobile electric systems and some lighting systems, and may be found in some industries. Lightning is also direct current.

Electricity releases heat as it travels through or across the body, causing extensive tissue damage. All tissues have a different resistance to current flow, with the nervous system being the least resistant. Bone is the most resistant, but all tissue is susceptible to damage. Electricity may enter and exit the body at any point. The hands are the most common point of entry **Figure 12-15A**, and the feet are the most common point of exit **Figure 12-15B**. The path electricity follows between entrance and exit is erratic and unpredictable. Severe charring frequently occurs at the point of entry and this may be the only obvious injury. Damage to deeper structures may not be evident if the superficial structure such as the skin is uninjured.

Early evaluation of the extent of electrical injury is difficult. There are common patterns of injury, however. Damage to the cardiac conduction system may present as cardiac arrest, and high voltages may lead to respiratory arrest by paralyzing the diaphragm. Alternating current typically causes ventricular fibrillation and is the most common cause of death. Direct current typically causes asystole. Cardiac arrest in the electrocuted victim is treated with standard ACLS protocol. Other arrhythmias may develop at any time after injury, necessitating continuous cardiac monitoring for the first 24 hours because a normal electrocardiogram or rhythm does not rule out injury. Skin burns sometimes occur without deeper structures being damaged. Clothing may ignite without current entering the body. These injuries are treated as other cutaneous burns. Because the electrical current can travel deep to the skin, deep structures such as muscle, bone, tendon, blood vessels, and nerves may be severely damaged, with little evidence on the skin. Massive muscle damage and cell death will release muscle proteins into the bloodstream. Untreated rhabdomyolysis can cause kidney damage and should be treated with increased IV fluids to maintain adequate urine output. As mentioned previously, rhabdomyolysis should be suspected with certain mechanisms of injury or by the development of pink or dark urine. The addition of sodium bicarbonate or mannitol may be necessary to maintain urine output and should be discussed with the burn center or medical direction. Compartment syndrome may develop in the extremities as a result of deep burns. Progressive pain, paresthesias, and decreased circulation are clues to this injury. Consultation with the transferring and receiving physician about fasciotomy should occur before transport. Electric current may also cause violent muscle contractions that break bones. The cervical spine and suspected fractures should be immobilized prior to transport. Care should be taken to protect open fractures from additional contamination.

Lightning injuries are a common source of burns. Patients with lightning injuries may experience any of the injuries already mentioned. They may also experience extensive superficial cutaneous burns in a fern or reticular pattern as electricity passes across the skin **Figure 12-16**. The ear drum may rupture as a result of the pressure wave created by the rapid heating of the surrounding air, and the patient may have displacement to the lens of the eye from the pressure gradient produced.

Chemical Burns

Common household, industrial, and farm products can be toxic and cause significant burns. The active ingredients responsible for injury are usually acids, alkalis, and a few other organic compounds. The extent of damage depends on the type of agent, its relative strength, and the duration of contact. It is crucial to decontaminate patients quickly and thoroughly. Chemicals can settle in clothing, shoes, linens, and jewelry. All patients should be completely disrobed and irrigated with copious amounts of water. Attempts to neutralize one chemical with another can produce an exothermic reaction (producing heat) and worsen the burn; therefore, this should not be attempted. After decontamination, the patient should be

placed on clean, dry linens. Cutaneous burns are not the only risk from chemical exposure because some chemicals may be absorbed systemically, causing organ damage or failure. Injuries may not be apparent for 6 to 24 hours after exposure. Patients with relatively minor-appearing injuries may require transport for observation at a center for specialized care.

Figure 12-16 Fern pattern as a result of a lightning injury.

Transport Management

Electrical Burns

- Treat the same as other cutaneous burns.

Acids are found in drain opener, drain cleaner, bathroom cleaner, swimming pool products, and rust remover. They are also found in hair care products such as hair relaxer. Acids are used extensively in industry for production of other compounds and are found in potent industrial cleaning products. Duration of contact is the main determinant of damage from acids. Rapid, copious irrigation with water is the initial treatment. Acids tend to cause burns that are more self-limiting than alkalis. When acids come in contact with skin, the damage caused is in the form of coagulation necrosis. The coagulum, or scar, limits the penetration of the acid, and thereby limits the damage done. This results in a burn with well-demarcated edges and often in a pattern that suggests liquid spilling. Some acids such as hydrofluoric acid also have other mechanisms of injury and require special attention. Hydrofluoric acid is used in microelectronics, petroleum processing, glass and metal etching, wheel cleaners, rust removal, and many other applications. Hydrofluoric acid is capable of progressive injury despite irrigation. After penetrating the skin, fluoride ions are released and cause nerve damage and severe pain. Calcium binds to fluoride and reduces damage. Therefore, topical calcium gluconate gel should be applied immediately after irrigation. There are commercial preparations of calcium gluconate gels, but mixing calcium gluconate with a water-based, water-soluble lubricant (such as K-Y Jelly) will suffice if commercial preparations are not available. This mixture can be squirted into an exam glove and applied directly to the patient's hand. Intradermal injection of calcium gluconate and intra-arterial calcium gluconate may also be used to alleviate pain. Oxalic acid is not as toxic as hydrofluoric acid but may also require calcium gluconate

therapy. Calcium *chloride* should not be administered intradermally or intra-arterially.

Alkalis are found in many household and industrial products and are capable of producing significant burns. Oven cleaner, drain cleaner, lime, lye, and cement are common alkalis. These agents, when combined with fat, produce soap, and therefore penetrate deeply and rapidly into the tissues. They continue to burn for extended periods of time and require irrigation for more than 20 minutes. Because there is no coagulum to restrict the penetration of alkalis into the tissues, burns caused by alkalis typically have poorly defined edges and diffuse spreading of the injury. Special care must be taken during decontamination to avoid unnecessary heat loss. Because of deep penetration, systemic toxicity is also a significant concern. There are no antidotes. Care of systemic complications is supportive.

Dry lime is a common agricultural product. When combined with water it may also generate an exothermic reaction and cause burns. All dry powders should be brushed away to reduce the amount of chemical before irrigation is performed with flowing water. Fast-flowing water will help dissipate heat, but the higher pressure may cause or worsen tissue damage. When you are using water under pressure, avoid self-contamination from splashing.

Hydrocarbons such as petroleum fuels may cause burns after immersion or prolonged contact. They can also cause significant systemic toxicity if absorbed. Treatment is supportive with copious irrigation and observation. Hydrocarbons (most petroleum products such as gasoline) can cause myocardial depression leading to hypotension and cardiovascular collapse. Halogenated hydrocarbons (chlorofluorocarbons or Freon), such as those used in propellants, are known to cause central nervous system depression or excitability. In particular, the halogenated hydrocarbons (Freon or many solvents like oven cleaner) are best known for potentially creating a fatal arrhythmia.

Transport Management

Chemical Burns

- Decontaminate patients quickly and thoroughly.
- Copiously irrigate until the burning has stopped or the material is cool.
- Irrigation length should be guided by the pH of the wound assessed in the base of the wound.
- If you are unable to measure pH, continue copious irrigation for at least 20 minutes.
- After decontamination, place the patient on clean, dry linens.
- Break blisters.
- Remove all clothing and jewelry.
- Do not attempt to neutralize one chemical with another.
- For burns from hydrofluoric acid, apply topical calcium gluconate gel immediately after irrigation.

After decontamination, management of chemical wounds is the same as for thermal injuries with the exception of applying calcium gluconate gel to hydrofluoric acid burns. Clean, dry dressings are the only requirement.

Toxic Epidermal Necrolysis Syndrome and Stevens-Johnson Syndrome

Toxic epidermal necrolysis syndrome is the most severe form of skin reaction to certain medications, environmental allergies, and other unknown toxins. The medication phenytoin (Dilantin), among others, is well known for causing this reaction. The milder form is called Stevens-Johnson syndrome, which is believed to be an immune-mediated illness causing sloughing of the skin, mucous membranes, and the

cells lining the respiratory system. Stevens-Johnson syndrome and toxic epidermal necrolysis can present respiratory and wound care challenges that are as difficult to manage as severe burns of other types **Figure 12-17**.

The term Stevens-Johnson syndrome is used in conjunction with toxic epidermal necrolysis. The spectrum from Stevens-Johnson syndrome to toxic epidermal necrolysis is as follows:

- In Stevens-Johnson syndrome, epidermal detachment involves less than 10% of the total body skin area.
- Transitional Stevens-Johnson syndrome-toxic epidermal necrolysis is defined by an epidermal detachment between 10% and 30%.

Figure 12-17 Patients with toxic epidermal necrolysis or Stevens-Johnson syndrome can present management challenges that are similar to those presented by patients with severe burns.

- Toxic epidermal necrolysis is defined by an epidermal detachment greater than 30%.

Patients with toxic epidermal necrolysis are frequently managed in burn centers because their wounds are analogous to burn injuries. Treatment is primarily supportive in addition to the skin care.

Summary

Mastering the care of burn patients is a continuous process. Research is ongoing to discover optimal wound management and resuscitation techniques. Additional training is available from various sources. Most burn centers and units also have education programs that are an invaluable resource to local providers.

Case Study

WHILE IN FLIGHT TO A RURAL COMMUNITY HOSPITAL for an interfacility transport, your MedEvac unit is diverted to a scene to care for a victim of a house explosion. While flying to the scene, your communication center advises you of the ground EMS report that states the victim is a 54-year-old woman who is experiencing dyspnea and pain.

During your final approach to the landing zone, you observe a house fully engulfed by flames. As you enter the awaiting ground ambulance to begin your assessment, you find a woman with multiple partial- and full-thickness burns to her arms, chest, abdomen, and face. She is experiencing severe dyspnea and crying out in pain. She is conscious, confused, and difficult to understand because of the hoarseness of her voice. You continue your assessment, while your partner sets up equipment for RSI. The patient is complaining of severe pain throughout the burned areas of her body.

Her vital signs include a blood pressure of 160/100 mm Hg; respirations, 38 breaths/min and labored with audible stridor; and a pulse rate of 150 beats/min. You note singed eyebrows and nasal hairs; soot around the nose and mouth; partial-thickness burns to the chest, abdomen, and arms; and full-thickness burns to the face. You estimate her TBSA of burns to be approximately 30%.

Your partner advises you that he is ready for RSI. You use an established IV line to administer 0.3 mg/kg of etomidate and 2 mg/kg of succinylcholine. You insert the laryngoscope and attempt to visualize the vocal cords; you are unable to visualize the vocal cords or pass the endotracheal tube because of edema. You direct your partner to ventilate the patient using a bag-mask device and 100% oxygen while you prepare the surgical airway kit. You are successful at securing a surgical airway. Upon confirmation of placement, you note decreased breath sounds on the right side as compared to the left side. You quickly cover all burns with dry, sterile dressings and prepare for transport by placing the patient onto your equipment and rapidly performing a hot load (with the engine running and rotors turning) for transport to the closest burn center.

In flight, your patient's vital signs remain stable; you administer 0.1 mg/kg of vecuronium and 1 μg/kg of fentanyl, and you start administering lactated Ringer's solution at 100 mL/h. Approximately 2 minutes from the burn center, your partner, who is ventilating the patient, reports that he is meeting resistance. You assess lung sounds and do not hear anything on the right although you are uncertain because of the amount of noise in the helicopter. Because of the burns and swelling, you are unable to determine whether jugular vein distension or tracheal deviation is present. You confirm that the surgical airway has not moved and then decide to do a needle decompression, which your partner reports makes ventilating much easier.

On arrival at the burn center, you do a hot off-load of the patient and transport the patient to the trauma bay, where you give a report to the trauma team. You and your partner clean your equipment and get the aircraft back in service. Once you return to base, you complete your report for the medical record and discover that you miscalculated the initial IV fluid rate according to the Parkland formula. You notify the nursing staff at the burn unit of the error and complete a protocol deviation form. Finally, you notify the referring EMS agency of the outcome.

1. What should the IV fluid rate have been?
2. What is the rationale for the resistance met during ventilation that led to a needle decompression?
3. According to the American Burn Association, what classification of burns did the patient in the case present?

Analysis

Although there are numerous fluid resuscitation formulas for the first 24 hours after a burn, the most commonly used method is the Parkland formula, which recommends resuscitation with lactated Ringer's solution of 4 mL/kg/% BSA burned. In this case, the initial fluid rate should have been 750 mL/h.

Burn patients may experience significant trauma from explosions or motor vehicle collisions resulting in fires. With the presence of such trauma, the possibility exists that you may overlook conditions such as a pneumothorax or hemothorax while treating the obvious burns. Careful repeated examinations should be aimed at identifying these conditions.

This patient met several criteria for major burn injuries, including partial-thickness burns involving more than 25% of BSA in an adult, burns involving the face, and burns complicated by inhalation injury or major trauma.

Caring for victims of burn injuries requires the CCTP to deploy aggressive critical thinking, assessment, and intervention skills. The CCTP must use an organized, rapid approach to assess,

prioritize, and treat both the burns and any secondary injuries found. Because of the early fluid losses associated with burn injuries, aggressive and sustained fluid management is essential. Determining the severity and extent of burns is important in order to arrange for transportation to the most appropriate treatment facility.

Prep Kit

Ready for Review

- The initial 24 hours of care after a burn are crucial. The CCTP must have an understanding of the common complications of burns that can develop during the transport of the patient to a burn facility.
- The skin, composed of the epidermis and the dermis, is the largest organ of the body and is vital to survival.
- The layers of the epidermis contain pigment cells, immune cells, and capillaries in the lower layers. The epidermis is the first barrier to injury and infection and is constantly repairing itself, as it is injured more often than the other layers, and the outer layer provides a barrier to prevent water loss from deeper structures.
- The dermis lies beneath the epidermis and contains fibroblasts, macrophages, white blood cells, nerve cells, lymphatic vessels, blood vessels, portions of the hair follicles, and oil and sweat glands.
- Proteins such as collagen and fibronectin, which are produced in the dermis, support the continuously reproducing epidermis and play a major role in wound healing, along with fibroblasts, macrophages, platelets, and endothelial cells. The inflammatory response, which is important in the burn healing process, is also responsible for multiple complications.
- The skin has multiple functions, which include protection from infection, maintaining fluid and electrolyte balance, thermoregulation, and neurosensory functioning, which is important for social interaction.
- Burns occur from a variety of mechanisms, including flame/flash, scald (water, grease, etc), contact, electrical, chemical inhalation, radiation, or any thermal source. The size and depth of a burn are determined by the agent, temperature, and duration of exposure.
- The zone of coagulation is the most damaged area of a burn and is the area of skin that came into direct contact with the source of the heat. The zone of stasis has injured tissue and may appear red and hyperemic (filled with an increased amount of blood) initially, but within 24 hours has a stagnant blood flow resulting in ischemic tissues, which by the third day becomes white because it is avascular and necrotic. The zone of erythema, which has increased blood flow, is the outermost area surrounding the zone of stasis, has minimal damage, and will recover.
- Burns of greater than 25% TBSA result in a systemic inflammatory response, which can result in undesirable effects on other tissues and organs, including pulmonary edema, suppression of the immune system, sepsis, and impaired cardiac output.
- The severity of a burn depends on the extent, depth, and location of the burn; the age of the patient; the etiologic agents involved; the presence of inhalation injury; and coexisting injuries or preexisting illnesses.
- The classification of burns includes superficial or first-degree burns, which involve only the epidermis; partial-thickness or second-degree burns, which involve some of the dermis but not the entire thickness of the skin; full-thickness or third-degree burns, which involve all layers of the skin

and perhaps some subcutaneous tissue and muscle; and subdermal or fourth-degree burns, which involve deep structures such as muscle, bone, large blood vessels, and nerves.

- Burn size is also a determining factor of burn severity. A common factor to determine severity is the rule of nines, which is the most common method in the prehospital environment.
- Assessment for burn patients should be similar to any other patient, with attention paid to each organ system, but with special attention paid to the patient's airway, breathing rate and depth, and decreased cardiac output.
- Burn management includes removing the patient from the source of the burn, cooling within the first 2 minutes but not for longer than 20 to 30 minutes, and irrigation but not for longer than 30 minutes.
- Airway management for a burn patient can present difficult challenges because of airway edema resulting from inhalation injuries.
- Aggressive and sustained fluid management is important, because burns can result in large intravascular fluid losses due to the loss of the protection against desiccation and evaporation.
- Wounds should be dressed with clean, dry dressings (never wet dressings), and blisters should be left intact. In general, wound debridement should not be performed by the CCTP.
- Burn victims may require large doses of narcotics for adequate pain control, and pain should be assessed and treated every 10 minutes until the patient is comfortable.
- Other issues of burn management include maintaining a normal body temperature in order to prevent hypothermia and performing gastric decompression.
- Renal dysfunction and rhabdomyolysis should be managed by an increase in the fluid rate.
- Ocular burns can occur from many different sources, including friction burns from auto airbags, blast injury, thermal burns, and chemical burns. A burn patient's eyes need to be examined early, because edema can develop quickly and make assessment difficult. Corneal injuries should be treated with appropriate intravenous narcotics, chemical burns of the eye should be treated with irrigation, and nonchemical eye burns should be treated with a topical ophthalmic preparation.
- Ocular and airway injuries are the major concerns of facial burns, and airway evaluation is important, knowing that early intubation may be necessary.
- Ear burns are prone to increased swelling, and an exam should be done before edema results.
- Circumferential burns (burns that encircle the chest, an extremity, or the penis) and the resultant compartment syndrome present a difficult challenge. These injuries may require an escharotomy, a procedure in which an incision is made through the stiff edematous burned skin, in order to restore mobility to the chest or circulation to an extremity as a result of a circumferential burn.
- Hand and foot burns can cause significant disability and should be treated by elevating the injured extremity above the heart and by using loose, dry dressings or no dressing.
- Genitalia burns require placement of a Foley catheter before edema develops, and if a penis has a circumferential burn, the CCTP should monitor for impaired circulation.
- Approximately 25% of all childhood burns are from child maltreatment, and the CCTP should consider this when caring for the burned child. Accidental burns in children often result from scalding and often occur in the "spill area" or the area of the face and chest that is exposed from a child pulling a container of hot liquids onto himself or herself.
- Early evaluation of the extent of injury from an electric burn is difficult. Damage to the cardiac conduction system may present as cardiac arrest, and high voltages may lead to respiratory arrest by

paralyzing the diaphragm. Alternating current typically causes ventricular fibrillation and is the most common cause of death, whereas direct current typically causes asystole. Lightning can cause extensive superficial burns in a fern pattern as electricity passes across the skin.

- Patients with chemical burns should be decontaminated quickly and thoroughly, irrigating until the burning has stopped and the material is cooled, or for at least 20 minutes, taking care to avoid unnecessary heat loss.
- Toxic epidermal necrolysis syndrome, the most severe form of skin reaction to certain medications, environmental allergies, or other unknown toxins, and a milder form, Steven-Johnson syndrome, can present management challenges similar to those presented by severe burn patients.

Vital Vocabulary

compartment syndrome A condition that develops when edema and swelling result in increased pressure within soft tissues, causing circulation to be compromised, possibly resulting in tissue necrosis.

deep partial-thickness burn A burn in which the skin is blistered but not charred and is painful to the touch, usually the result of steam, oil, or flames and involving the deeper layers of the dermis.

eschar The leathery covering of a burn injury, formed after the burned tissues dry out.

escharotomy A surgical incision in an eschar to lessen constriction; sometimes necessary (although rarely performed in a prehospital setting) to prevent edema from building up, impairing capillary filling, and causing ischemia.

fasciotomy A surgical incision into an area of fascia, for example to relieve pressure between two compartments; not usually performed in a prehospital setting.

full-thickness burn A burn that extends through the epidermis and dermis into the subcutaneous tissues beneath, in which skin is pale, painless, leathery, and charred; also called a third-degree burn.

Galveston formula A formula used to calculate fluid resuscitation for children, which takes into consideration the BSA burned and the TBSA of the child, with half of the amount given in the first 8 hours after injury and the second half over the next 16 hours.

hyperemic An increase in blood flow into a tissue or organ; congested with blood.

Lund and Browder chart A detailed version of the rule of nines chart that takes into consideration the changes in body surface area brought on by growth.

major burn A classification from the American Burn Association that includes: (1) partial-thickness burns involving more than 25% of BSA in adults or 20% of BSA in children younger than 10 years and adults older than 50 years; (2) full-thickness burns involving more than 10% of BSA; (3) burns involving the face, eyes, ears, hands, feet, or perineum that may result in functional or cosmetic impairment; (4) burns caused by caustic chemical agents; (5) high-voltage electrical injury; (6) burns complicated by inhalation injury or major trauma; and (7) burns sustained by high-risk patients.

minor burn A classification from the American Burn Association that includes: (1) partial-thickness burns involving less than 15% of BSA in adults or 10% of BSA in children and older adults; and (2) full-thickness burns involving less than 2% BSA that do not present a serious threat of functional or cosmetic risk to the eyes, ears, face, hands, feet, or perineum.

moderate burn A classification from the American Burn Association that includes: (1) partial-thickness burns of 15% to 25% of BSA in adults or over 10% to 20% of BSA in children and older adults; and

(2) full-thickness burns involving 2% to 10% of BSA that do not present a serious threat to functional or cosmetic impairment of the eyes, ears, face, hands, feet, or perineum.

myoglobinuria The presence of myoglobin, a respiratory pigment of muscle tissue, in the urine.

Parkland formula A formula that recommends giving 4 mL of lactated Ringer's solution or normal saline for each kilogram of body weight, multiplied by the percentage of body surface area burned; sometimes used to calculate fluid needs during lengthy transport times.

partial-thickness burn A burn that involves the epidermis and part of the dermis, characterized by pain and blistering; also called a second-degree burn.

rhabdomyolysis The destruction of muscle tissue leading to a release of potassium and myoglobin, which then accumulate in the blood and urine and impair filtration; occurs most often with crush injuries, electrical burns, or large full-thickness burns. The urine becomes pink, dark red, or rust colored.

rule of nines A system that assigns percentages to sections of the body, allowing calculation of the amount of skin surface involved in the burn area.

Stevens-Johnson syndrome A milder form of toxic epidermal necrolysis, in which epidermal detachment involves less than 10% of the total body surface area; causes sloughing of the skin, mucous membranes, and cells lining the respiratory system.

subdermal burn A severe, life-threatening burn involving the deep structures of muscle, bone, larger blood vessels, and nerves; also called a fourth-degree burn.

superficial burn A burn involving only the epidermis, producing very red, painful skin; also called a first-degree burn.

superficial partial-thickness burn A burn involving the epidermis and part of the dermis, but the deeper layers of the dermis are not involved; also called a second-degree burn.

thermal burn A burn caused by heat, contact with hot objects, ignited liquids, steam, or hot liquids.

thromboxane A type of substance that causes blood vessels and bronchial smooth muscles to constrict, and promotes blood coagulation by causing platelets to collect.

toxic epidermal necrolysis syndrome A severe skin reaction to certain medications, environmental allergies, and other unknown toxins, in which epidermal detachment is greater than 30%.

zone of coagulation The center of a burn, usually the deepest and most severe area.

zone of erythema The outermost area of a burn, representing the least severe burned area, usually an area of first-degree burn.

zone of stasis The area found just outside the zone of coagulation, representing a burned area that is less severe.

Objectives

1. Explain how to correctly place leads from a 12-lead electrocardiographic (ECG) monitor (p 480–483).
2. Explain how to correctly place additional precordial leads for diagnosing right ventricular and posterior infarctions (p 483).
3. Explain how to determine the heart's electrical axis (p 486).
4. Discuss the step-by-step systematic approach that should be used when interpreting an ECG (p 484–486).
5. Describe how to monitor a patient by using an ECG machine during a critical care transport (p 543).
6. Explain the assessment process for a patient undergoing ECG monitoring during a critical care transport (p 544).
7. Describe how to identify a hemiblock on an ECG (p 489).
8. Explain the management of a patient with a hemiblock during critical care transport (p 494).
9. Describe how to identify a bundle branch block on an ECG (p 489–492).
10. Explain the management of a patient with a bundle branch block during critical care transport (p 489–492).
11. Describe the significance of ST- and T-wave changes and how they are identified on an ECG (p 496).
12. Describe complications that can occur with a cardiac patient during critical care transport (p 544).
13. Describe different criteria for determining the presence of left ventricular hypertrophy (LVH), right ventricular hypertrophy (RVH), and the presence of strain (p 498–499).
14. Using various criteria, identify cases of LVH and RVH on a 12-lead ECG (p 498–499).
15. Describe the clinical significance of LVH (p 498).
16. Identify criteria suggestive of right and left atrial enlargement, and describe the clinical implications of such enlargement (p 497–499).
17. Describe the ECG changes that indicate the presence of Wolff-Parkinson-White syndrome (p 500).
18. Identify ECG changes that could indicate conditions such as pericarditis, acute pulmonary embolism, and early repolarization variant (p 501).
19. Describe the potential implications of a prolonged QT interval (p 501–502).

20. Describe how to identify ventricular tachycardia on an ECG, including when it occurs in conjunction with wide complex tachycardia (p 502–504).
21. Explain the management of a patient with ventricular tachycardia, including when it occurs in conjunction with wide complex tachycardia (p 502–504).
22. Describe ECG changes associated with drug and electrolyte disturbances, hyperkalemia, hypokalemia, hypercalcemia, and hypocalcemia and the clinical implications of these conditions (p 504–507).
23. Generally describe the field of electrophysiology, including its purpose and capabilities (p 529).
24. Describe the spectrum of therapeutic options for patients with cardiac arrhythmias (p 529–530).
25. Briefly discuss the general categories of cardiovascular drugs and their actions and indications (p 531–532).
26. Understand the basic concepts underlying cardiac pacemaker technology, including the following:
    - Pacing circuits and impulses
    - Leads and electrodes
    - Single-chamber demand pacemakers and a dual-chamber pacemaker
    - NASPE/BPEG Generic (NBG) codes for describing pacemaker functions and capabilities (p 530–538).
27. Describe the general steps in pacemaker troubleshooting and the specifics of identifying and resolving problems with electromagnetic interference (p 536–537).
28. Recognize single- and dual-chamber pacing systems by their ECG characteristics (p 538–539).
29. Understand the purpose and function of the atriobiventricular pacing device (p 539–540).
30. Describe the components and function of implantable cardioverter defibrillators (ICDs) (p 540–541).
31. Understand the purpose of an atrial tachycardia ICD (p 543).
32. List the types of therapy an ICD can deliver and their indications (p 530, 540–541).
33. Discuss the general types of ICD malfunction, including the following:
    - Historical factors that may play a role or offer diagnostic clues
    - Common reasons for malfunction
    - The role of the "doughnut" magnet in managing ICD malfunction (p 532–533, 537)
34. Briefly list the special considerations related to external defibrillation when an ICD is present (p 542).

Introduction

On a routine basis, CCTPs encounter patients with cardiac arrhythmias and, when providing care, must be familiar with the various cardiac devices used to diagnose and treat such disorders. In particular, interpretation and monitoring of the 12-lead electrocardiogram (ECG)—including the understanding of the process behind the ECG changes and how they are depicted on the ECG monitor or printout—are key skills for CCTPs.

The 12-lead ECG graphically represents electrical activity in cardiac tissue. By using this information, CCTPs can interpret normal findings vs those found with changes in the function of cardiac tissue as a result of disease or injury. During the transport of a special care or critical care patient, there

are many modalities available to continuously monitor vital bodily functions. Cardiac monitoring in this setting typically includes a view of the heart's electrical rhythm in three or more leads and the serial evaluation of the 12-lead ECG. In some cases, additional precordial leads are placed for the diagnosis of right ventricular and posterior infarctions, which will be discussed later in this chapter. A key role of the critical care transport team is to continuously monitor the cardiac rhythm and serial 12-lead ECGs, responding to changes with rapid and appropriate intervention as indicated by local protocol and national guidelines, such as advanced cardiac life support (ACLS) and pediatric ALS. With that in mind, this chapter provides concise methods and patterns of interpretation to help CCTPs develop a deeper understanding of the causes and changes noted in electrical activity as a result of injury or illness.

Traditionally, patients with cardiac arrhythmias have most often been treated with medication therapy. These medications come with side effects that can reduce the patient's quality of life. However, patient adherence to the medication regimen is crucial to effectiveness. In some cases, medications are not always effective, even when patients use them correctly.

Technological developments that began with early ECG discoveries led to a cardiac subspecialty called electrophysiology. This field, in turn, has developed diagnostic and therapeutic equipment that vastly broadens the options for patients with cardiac arrhythmias—equipment that CCTPs will encounter routinely.

Implanted pacemakers and implantable cardioverter defibrillators (ICDs) offer solutions for patients with arrhythmias that might otherwise be disabling or lethal. These adjuncts also considerably raise the level of technological expertise required by the providers, including CCTPs, who care for patients with such devices. This chapter describes aspects of implantable devices and their electrical therapies that may be important during transport.

Cardiac Anatomy and Physiology

The Heart

Although CCTPs are already very familiar with cardiac anatomy and physiology, this section provides a brief review of some aspects. **Figure 13-1** shows the anatomy of the heart.

Myocardial cells require an uninterrupted supply of oxygen and nutrients. Indeed, the cardiac demand for oxygen is particularly unremitting because the heart never stops to rest (not without catastrophic consequences), so it is essential that the heart have an absolutely reliable blood supply. Oxygenated blood reaches the heart through the coronary arteries **Figure 13-2**, which branch off the aorta at the coronary ostia, just above the leaflets of the aortic valve. The numerous connections (anastomoses) between the arterioles of the various coronary arteries allow for the development of collateral circulation in case of blockage. Unfortunately, the coronary arteries are also vulnerable to narrowing in atherosclerotic heart disease. When the lumen of one of the arteries becomes so narrowed that blood flow through it is impeded, the symptoms of angina occur.

Heart Sounds

The purpose of listening to heart sounds is to identify the "lub-dub" that indicates the cardiac valves are operating properly. The major heart sounds are the two normal sounds, S_1 and S_2 **Figure 13-3**, and the two abnormal sounds, S_3 and S_4 **Figure 13-4**.

S_1 occurs near the beginning of ventricular contraction (systole), when the tricuspid and mitral valves close. The closing of these two valves should occur simultaneously as the pressure within the ventricles increases. This is the "lub" sound. Any delay in the closing of these two valves, heard as a split sound, is considered abnormal.

S_2 occurs near the end of ventricular contraction (systole), when the pulmonary and aortic valves close. As the ventricles relax, these valves close because of backward flow in the pulmonary artery and aorta. The two valves can close simultaneously or with a slight delay between them under normal physiologic circumstances. This is the "dub" sound.

S_3 is the result of the end of the rapid filling period of the ventricle during the beginning of diastole. An S_3 sound should occur 120 to 170 milliseconds after S_2, if it is heard at all. S_3 is generally heard in children and young adults. When it is heard in older adults, it often signifies heart failure. S_3 is sometimes called a Kentucky gallop, to help differentiate it from the S_4 sound, discussed next. When S_3 is present, the heartbeat sounds like dub-lub-dub (the second sound is the most pronounced, as in the word "Kentucky").

S_4, if heard, coincides with atrial contraction at the end of ventricular diastole. If heard at any other time, it usually occurs in patients who have resistance to ventricular filling, as with a weak left ventricle. S_4 is also normally heard in children and young adults. S_4 is sometimes called a Tennessee gallop, to help differentiate it from the S_3 sound. When S_4 is present, the heartbeat sounds like lub-dub-dub (the first sound is more pronounced than the latter two, as in the word "Tennessee").

Table 13-1 lists some of the most common heart sounds, where they are heard, and potential associated causes.

The Cardiac Cycle

The cardiac cycle comprises one complete phase of atrial and ventricular relaxation (diastole) followed by one atrial and ventricular contraction (systole).

During the relatively longer relaxation phase (normally 520 milliseconds), the left atrium fills passively with blood, under the influence of venous pressure. Approximately 80% of ventricular filling also occurs during this time as blood flows through the open tricuspid and mitral valves.

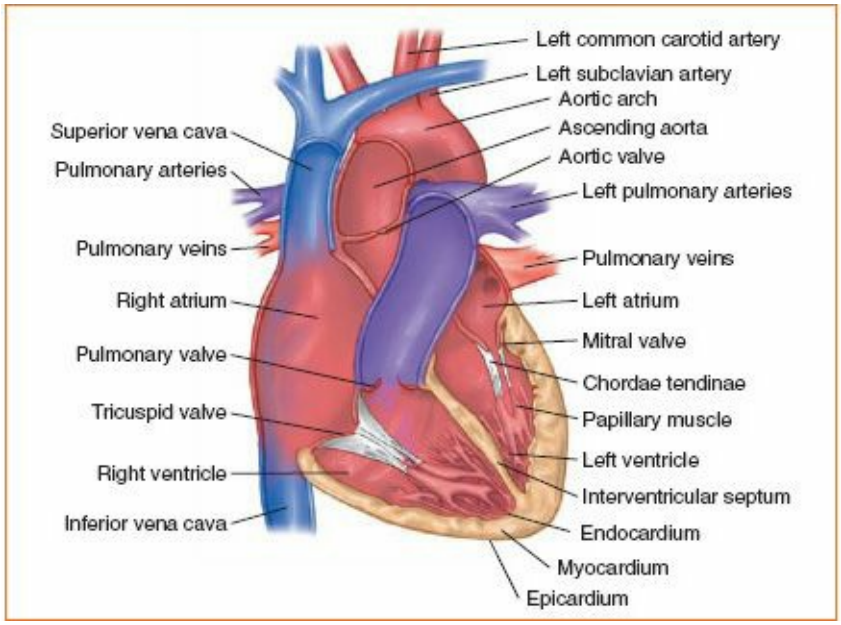

Figure 13-1 Anatomy of the heart.

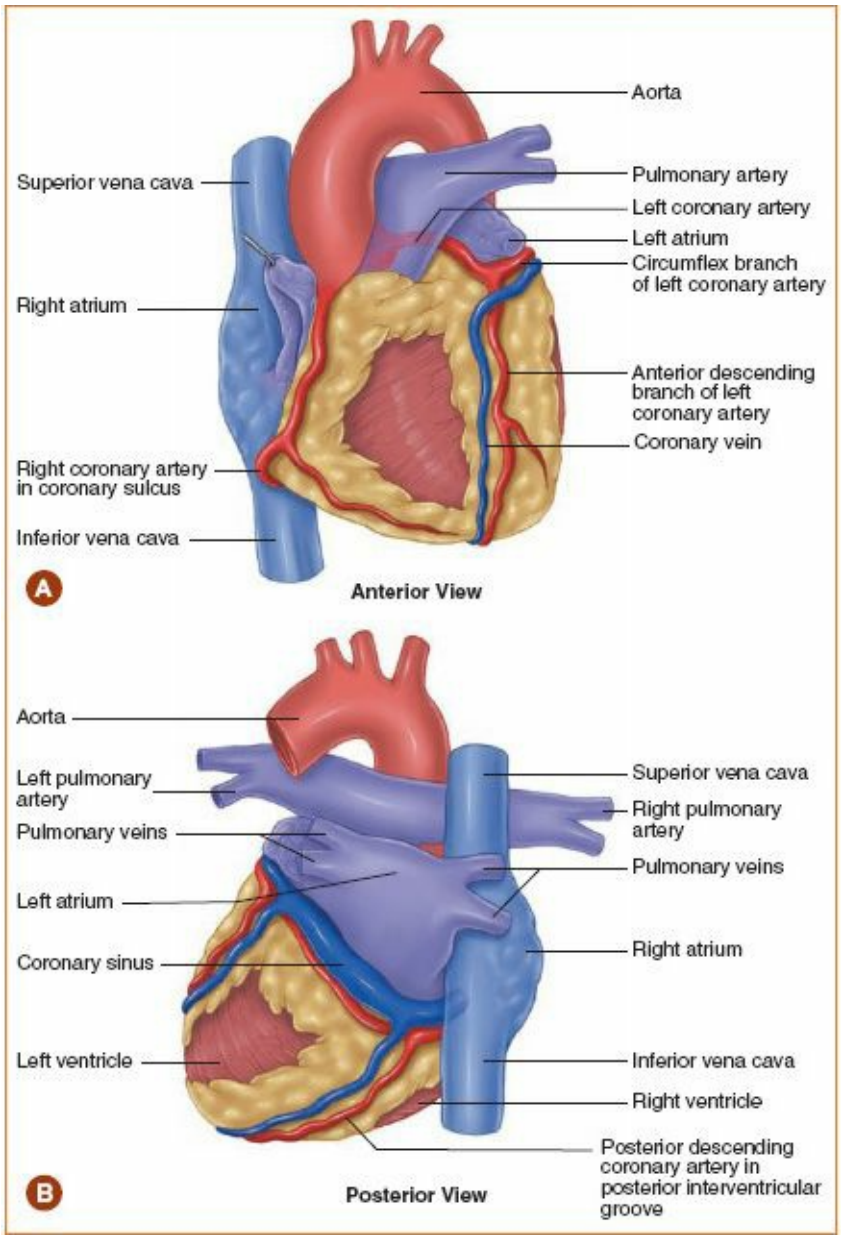

Figure 13-2 Coronary arteries. **A.** Anterior view, showing the takeoff point of the left and right main coronary arteries from the aorta. **B.** View from below and behind, showing the coronary sinus.

With atrial contraction, the contents of each atrium are squeezed into the respective ventricle to complete ventricular filling (atrial kick). Approximately 70% to 90% of the blood in the atria fills the ventricles by gravity; the remaining 10% to 30% comes from atrial contraction or atrial kick. At the beginning of ventricular contraction, the atrioventricular (AV) valves snap shut, the two ventricles contract (ventricular systole), and the semilunar valves are forced open. Blood squeezed out of the right ventricle moves forward, through the pulmonic valve, and into the pulmonary arteries. Blood from the left ventricle is pushed through the aortic valve and out into the aorta. Systole is usually accomplished in a little more than half the time it takes to fill the ventricles, about 280 milliseconds.

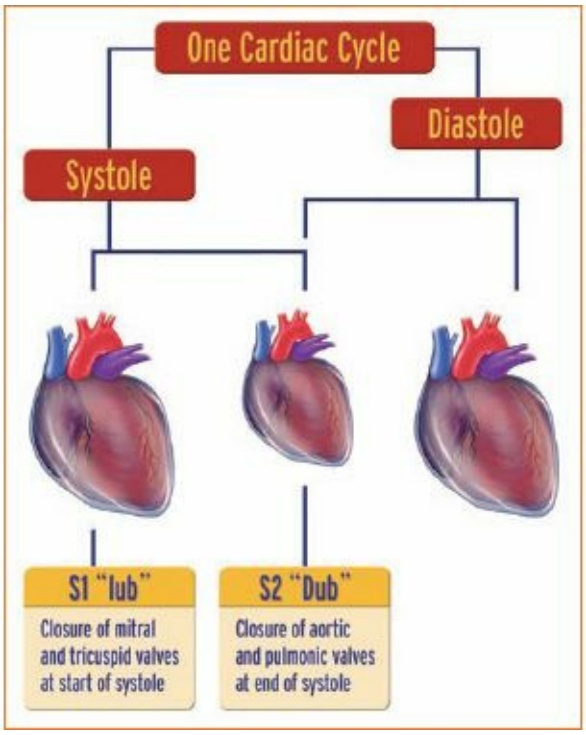

Figure 13-3 The normal S_1 and S_2 heart sounds.

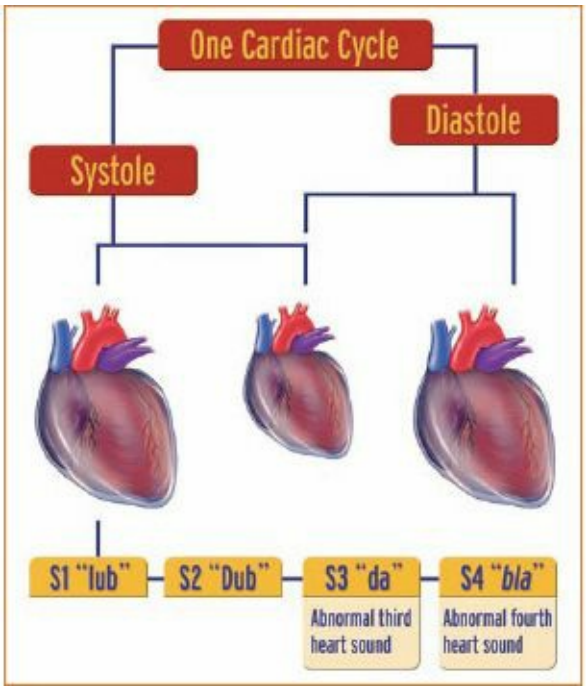

Figure 13-4 The abnormal S_3 and S_4 heart sounds.

TABLE 13-1 Heart Sounds

Heart Sound	Usual Location	Cause
S_1	Loudest in the mitral area, using the diaphragm	Normal
Split S_1	Between the apex of the heart and the sternum, usually during expiration, using the diaphragm	May be normal, nonsynchronous closing of mitral and tricuspid valves or pathologic, such as in a bundle branch block, an atrial septal defect, or

		pulmonary stenosis
S_2	Loudest in the aortic area, using the diaphragm	Normal
Split S_2	Loudest in the pulmonic area, usually on inspiration, using the diaphragm	May be normal, nonsynchronous closing of aortic and pulmonic valves or pathologic, such as in hypertension
S_3/ventricular gallop	Heard in early diastole just after the S_2; may be heard at the apex (left ventricular gallop) or at the left sternal border (right ventricular gallop); loudest on expiration with the patient in the lateral position, using the bell of the stethoscope	Always abnormal; indicates ventricular filling. May be normal in children and young adults or seen in diseases such as mitral valve regurgitation, hyperthyroidism, and congestive heart failure
S_4/atrial gallop	Heard late in diastole just before S_1, at the apex or over the suprasternal notch; heard best with the bell	May be normal (children and young adults); indicates increased resistance to ventricular filling after the atrial contraction; often seen after a myocardial infarction
Systolic murmur	Turbulent blood flow through the valves of the heart, during systole, using the diaphragm; location depends on cause	May be normal or seen with aortic or pulmonic stenosis or mitral or tricuspid regurgitation
Diastolic murmur	Turbulent blood flow through the valves of the heart, during diastole, using the diaphragm; location depends on cause	Always abnormal; seen with mitral or tricuspid stenosis, or aortic or pulmonic regurgitation
Pericardial friction rub	Scratchy, high-pitched sound heard throughout the cardiac cycle; best heard with the patient leaning forward, at the third intercostal space to the left of the sternum, using the diaphragm	Often present in pericarditis

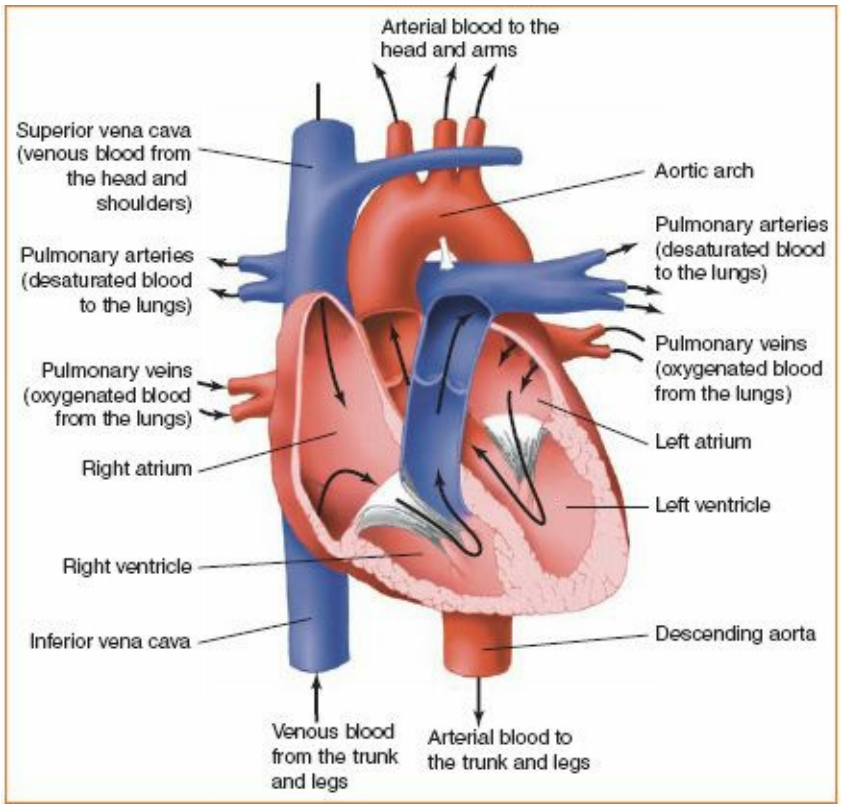

Figure 13-5 Blood flow through the heart.

Functionally, the heart is actually two pumps—a right pump and a left pump, separated by a thin wall (the interventricular septum)—that just happen, for purposes of efficiency, to be housed in one organ and to work in parallel **Figure 13-5**.

The right side of the heart is a low-pressure pump: It pumps against the relatively low resistance of the pulmonary circulation. The right atrium collects oxygen-poor venous blood from the venae cavae and the coronary sinus and pumps it into the right ventricle, which pumps the blood into the pulmonary artery for distribution to the alveoli and oxygenation.

The pulmonary veins collect the now oxygen-rich blood and return it to the left atrium, which pumps it into the left ventricle. The left side of the heart is a high-pressure pump: It drives blood out of the heart against the relatively high resistance of the systemic arteries.

At any given time, a major proportion of the body's blood flow may be shunted into one of the two circulation systems: the systemic circulation or the pulmonary circulation. If, for example, the right side of the pump fails and cannot squeeze out its contents efficiently, blood will back up behind the right atrium into the systemic veins, which then become engorged and distended. Distention of the external jugular veins signals that there is considerable back pressure from the right side of the heart throughout the systemic circulation. As pressure increases within the systemic veins, fluid starts to leak into the surrounding tissues, causing the tissues to swell. When enough fluid has leaked into the interstitial spaces, the swelling becomes visible as edema in the subcutaneous tissues (specifically, the lower extremities); it is less readily visible but equally present in the liver, walls of the intestine, and other internal tissues.

By contrast, if the left side of the pump fails, blood backs up behind the left atrium into the pulmonary circulation. As pressure builds up in the pulmonary veins, fluid is squeezed into the alveoli, producing the characteristic signs and symptoms of pulmonary edema: dyspnea, crackles, and frothy sputum.

The Blood Vessels

Figure 13-6 provides a review of the major arteries in the body.

Arterial walls are highly sensitive to stimulation from the autonomic nervous system. In response to that stimulation, the arterial diameter may change significantly as arteries contract and relax. Baroreceptors are involved in this process by sensing changes in blood pressure and, in turn, stimulating the autonomic nervous system. When baroreceptors sense increased blood pressure, they induce parasympathetic nervous system discharges that result in lowered heart rate and decreased myocardial contractility. Decreased blood pressure causes baroreceptor stimulation of the sympathetic nervous system, with a resulting increased heart rate and greater myocardial contractility. By this mechanism, the brain is able to respond to changes in blood pressure in the body. Blood pressure is influenced not only by the cardiac output and the volume present in the system, but also by the relative constriction or dilatation of arteries.

Chemoreceptors also play a role in autonomic nervous system activation in response to sensing changes resulting from respiration. When they note changes in P_{O_2} and pH or P_{CO_2}, they promote a process that not only stimulates the autonomic nervous system (thereby affecting heart rate and myocardial contractility) but also involves cell depolarization, which leads to release of dopamine and ultimately causes the respiratory centers in the brain stem to increase or decrease minute ventilation. Hypoxia or acidosis sensed by the chemoreceptors leads to sympathetic stimulation with resultant increased heart rate and contractility, whereas hyperoxia or alkalosis leads to parasympathetic stimulation with decreased heart rate and lessened contractility.

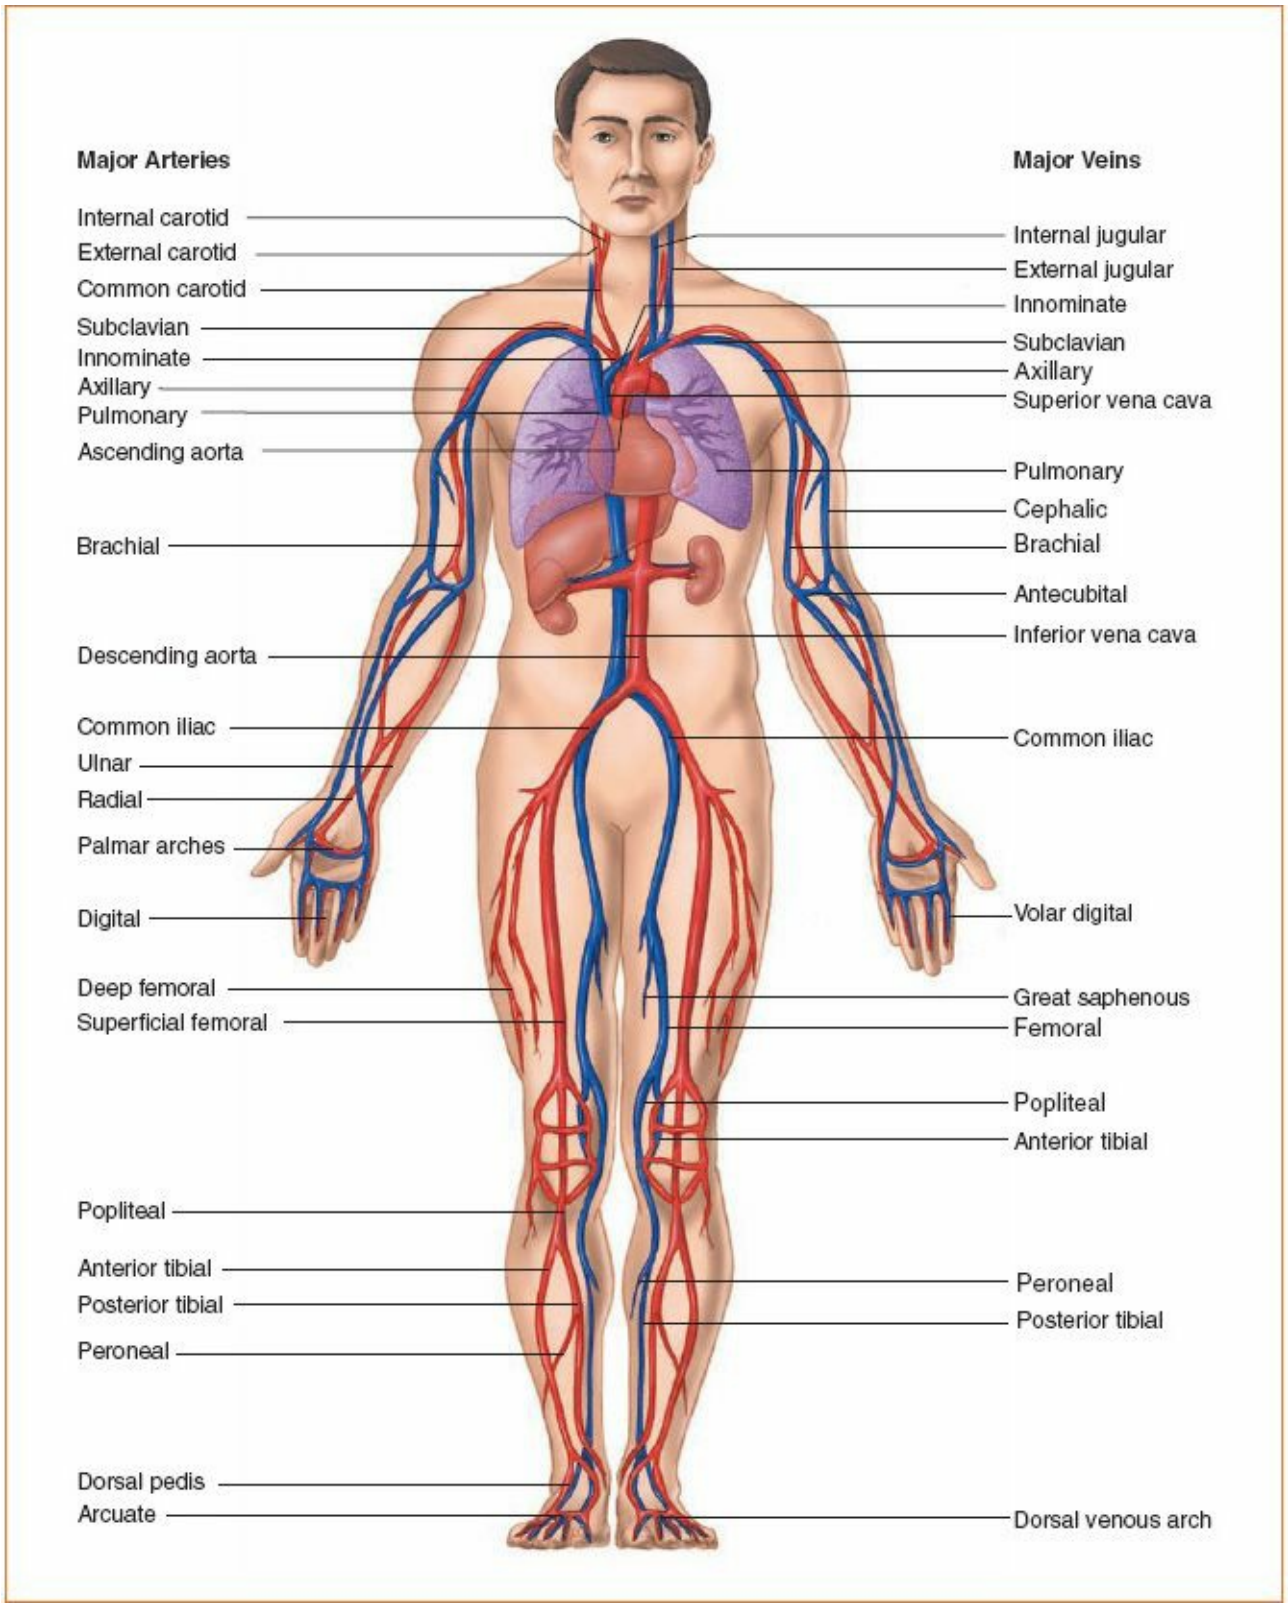

Figure 13-6 The major arteries and veins.

Functioning of the Pump

The following terms are important to understand how the heart functions as a pump:

- **Cardiac output (CO)** is the amount of blood that is pumped out by either ventricle. The left and right ventricles are approximately equal in interior size, so the two ventricles have relatively equivalent outputs. The normal CO for an average adult is 5 to 6 L/min.
- **Stroke volume (SV)** is the amount of blood pumped out by either ventricle in a single contraction (heartbeat). Normally, the SV is 60 to 100 mL, but the healthy heart has considerable spare capacity

and can easily increase the SV by at least 50%.

- **Heart rate** is the number of cardiac contractions (heartbeats) per minute—in other words, the pulse rate. The normal rate for adults is 60 to 100 beats/min.

The volume of blood that either ventricle pumps out per minute equals the volume of blood it pumps out in a single contraction times the number of contractions per minute:

$$CO = SV \times \text{Heart Rate}$$

To meet changing demands, the heart must be able to increase its output several times over in response to the body's increased demand for oxygen. The heart can increase its output by increasing the SV, increasing the heart rate, or both.

The heart has several ways of increasing SV. One characteristic of cardiac muscle is that, when it is stretched, it contracts with greater force to a limit—a property called the Frank-Starling mechanism. If an increased volume of blood is returned from the systemic veins to the right side of the heart or from the pulmonary veins to the left side of the heart, the muscle surrounding the cardiac chambers must stretch to accommodate the larger volume. The more the cardiac muscle stretches, the greater the force of its contraction, the more completely it empties, and, therefore, the greater the SV. From the CO equation, it is clear that any increase in SV, with the heart rate held constant, will cause an increase in the overall CO.

Preload (the pressure under which a ventricle fills) is influenced by the volume of blood returned by the veins to the heart. In situations of increased oxygen demand, the body returns more blood to the heart (preload increases), and CO consequently increases through the Frank-Starling mechanism. In a diseased heart, the same mechanism is used to achieve a normal resting CO (which explains why some diseased hearts become enlarged).

The heart can also vary the degree of contraction of its muscle *without* changing the stretch on the muscle; this ability is called contractility. Changes in contractility may be induced by medications that have a positive or negative **inotropic** effect. The ventricles are never completely emptied of blood with any single beat. However, if the heart squeezes into a tighter ball when it contracts, a larger percentage of the ventricular blood will be ejected, thereby increasing SV and overall CO. The nervous system regulates the contractility of the heart from beat to beat. When the body requires increased CO, nervous signals increase myocardial contractility, thereby augmenting SV.

The heart can also increase its CO, given a constant SV, by increasing the number of contractions per minute (positive **chronotropic** effect).

The Frank-Starling mechanism is an intrinsic property of heart muscle—that is, it is not under nervous system control. By contrast, contractility and changes in heart rate are regulated by the nervous system.

The Electrical Conduction System of the Heart

Heart muscle can generate its own electrical impulses without stimulation from nerves, a property called automaticity. In addition, the heart is endowed with an electrical conduction system, a specialized conduction tissue that can rapidly propagate electrical impulses to the muscular tissue of the heart. These impulses may be recorded by the provider on the ECG; therefore, all CCTPs need to understand the relationship between the activities of the body's electrical conduction system and 12-lead ECG interpretation.

Visualizing the process of impulses traveling in different directions helps in understanding what is happening in the heart. Visualizing the travel of impulses also promotes an understanding of how any changes in the structure or function of the heart can alter their travel.

The Dominant Pacemaker: The Sinoatrial Node

Theoretically, any cell within the heart's electrical conduction system can act as a pacemaker. In the normal heart, however, the dominant pacemaker is the sinoatrial (SA) node **Figure 13-7**. The SA node receives blood from the right coronary artery (RCA). If the RCA is occluded, as in a myocardial infarction (MI), the SA node will become ischemic. The subsequent death of the conduction cells will prevent the SA node from firing.

The SA node initiates the electrical discharge that passes through the **intra-atrial pathways** (or intranodal pathways); in physiology, these are sometimes called atrionodal pathways and include the anterior or Bachman bundle, middle bundle, and posterior internodal system. The SA node is the fastest pacemaker in the heart. Electrical impulses generated in this node spread across the two atria through internodal pathways in the atrial wall in about 80 milliseconds, causing the atrial tissue to depolarize as they pass. In 85% to 90% of humans, the blood supply for the SA node comes from a branch of the RCA; in 10% to 15% of humans, it comes from a branch of the left circumflex artery. The conduction of the impulse is delayed in the AV node for about 120 milliseconds so that the atria can empty into the ventricles.

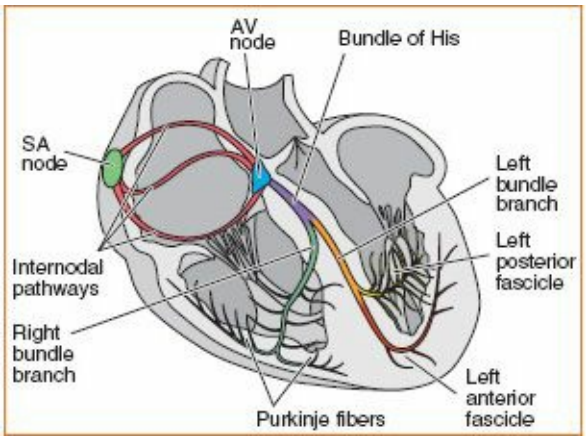

Figure 13-7 The electrical conduction system.

When the atrial rate becomes very rapid, not all atrial impulses can get through the AV junction. Normally, however, impulses pass through it into the bundle of His and then move rapidly into the right and left bundle branches located on either side of the interventricular septum. Next, they spread into the Purkinje fibers, thousands of fibrils distributed through the ventricular muscle. It takes about 80 milliseconds for an electrical impulse to spread across the ventricles, during which time the ventricles contract simultaneously. The effect on the velocity of conduction is referred to as the **dromotropic** effect.

Depolarization and Repolarization

As the electrical impulses travel along these pathways, they come into contact with each cardiac cell, which continues the process of generating electrical impulses or depolarization through the properties of automaticity and conductivity. **Depolarization**—the process by which muscle fibers are stimulated to contract—comes about through changes in the concentration of electrolytes across cell membranes. Myocardial cells, like all cells in the body, are bathed in an electrolyte solution. Chemical pumps inside the cell maintain the concentrations of ions within the cell, in the process creating an electrical gradient across the cell wall. Consequently, a resting (polarized) cell normally has a net charge of –90 mV with respect to the outside of the cell.

When the myocardial cell receives a stimulus from the conduction system, the permeability of the cell wall changes through opening of specialized channels in such a way that sodium ions (Na^+) rush into

the cell, causing the inside of the cell to become more positive. Calcium ions (Ca^{++}) also enter the cell—albeit more slowly and through a different set of specialized channels—helping maintain the depolarized state of the cell membrane and supplying calcium ions for use in contraction of the cardiac muscle tissue. This reversal of electrical charge—depolarization—starts at one spot in the cell and spreads in a wave along the cell until the cell is completely depolarized. The entire process causes a "wave of depolarization" as the electrical charges pass in all directions from one cell to another. The larger the mass of cardiac muscle, the larger this wave of depolarization will be. As each cell depolarizes, it creates a small electrical vector. In the wave of depolarization, the sum of all these small vectors creates the electrical axis, described later in more detail.

As the cell depolarizes and calcium ions enter, mechanical contraction of the cardiac cells occurs. During diastole, the coronary arteries fill and cardiac circulation occurs. As the cells contract from the base of the heart through the apex, the blood is pumped through the pulmonary and systemic circulation.

Following depolarization, each cell must recharge or repolarize by shifting intracellular electrolytes back into place to ready itself for this continual process. The cell is able to recover from depolarization through a process called **repolarization**. Repolarization starts with the closing of the sodium and calcium channels, which stops the rapid inflow of these ions. Next, special potassium channels open, allowing a rapid escape of potassium ions (K^+) from the cell. This process helps restore the inside of the cell to its negative charge; the proper electrolyte distribution is then reestablished by pumping sodium ions out of the cell and potassium ions back in. After the potassium channels close, this sodium-potassium pump helps move sodium and potassium ions back to their respective locations. For every three sodium ions this pump moves out of the cell, it moves two potassium ions into the cell, thereby maintaining the polarity of the cell membrane. To accomplish this task, the sodium-potassium pump moves ions against the natural gradient by a process called active transport, which requires the expenditure of energy.

TABLE 13-2 The Role of Electrolytes in Cardiac Function

Electrolyte	Role in Cardiac Function
Sodium (Na^+)	Flows into the cell to initiate depolarization
Potassium (K^+)	Flows out of the cell to initiate repolarization • Hypokalemia → increased myocardial irritability • Hyperkalemia → decreased automaticity/conduction
Calcium (Ca^{++})	Has a major role in the depolarization of pacemaker cells (maintains depolarization) and in myocardial contractility (involved in contraction of heart muscle tissue) • Hypocalcemia → decreased contractility and increased myocardial irritability • Hypercalcemia → increased contractility
Magnesium (Mg^{++})	Stabilizes the cell membrane; acts in concert with potassium, and opposes the actions of calcium • Hypomagnesemia → decreased conduction • Hypermagnesemia → increased myocardial irritability

Table 13-2 summarizes the roles of the various electrolytes in cardiac function.

A myocardial cell cannot respond to an electrical stimulus from the conduction system normally unless it is fully polarized. The period when the cell is depolarized or in the process of repolarizing—the so-called **refractory period**—consists of two phases. In the **absolute refractory period**, the heart muscle has been drained of energy and needs to recharge; it will not contract during this period. In the **relative refractory period**, the heart is partially charged, albeit not strongly enough to create a full contraction.

Secondary Pacemakers

The SA node normally has the most rapid intrinsic rate of firing (60 to 100 times per minute), so it will literally outpace any slower conduction tissue. If it becomes damaged or is suppressed, any component of the conduction system may act as a secondary pacemaker. The farther down the conduction system the pacemaker is, the slower its intrinsic rate of firing. Thus, the AV junction will spontaneously fire 40 to 60 times per minute, whereas the ventricular Purkinje system, which is farther removed from the SA node, will spontaneously fire only 20 to 40 times per minute.

Measuring the Electrical Conduction Activity of the Heart

The electrical conduction events in the heart can be recorded on an ECG as a series of waves and complexes **Figure 13-8**. The depolarization of the atria produces the P wave. It is followed by a brief pause as conduction is momentarily slowed through the AV node and the AV junction, which can be seen on the ECG as the **PR interval**. Collectively, the electrical impulses that pass through the right and left bundle branches and Purkinje fibers, representing depolarization of the ventricles, are depicted by the **QRS complex**. Repolarization of the atria and ventricles produces the **T wave**; however, the atrial repolarization wave is small and is buried within the QRS complex, so it is not seen. The larger ventricular T wave follows the QRS complex. The **ST segment**, or the section of the complex that is from the end of the QRS complex to the beginning of the T wave, is important in ECG interpretation and represents the period of inactivity between ventricular depolarization and repolarization. Mechanically, it represents the time that the myocardium is maintaining contraction. Finally, a U wave may be present after the T wave. There is no definitive answer as to what it represents, but it correlates with certain conditions discussed later in this chapter.

Any event that changes the structure or function of the cardiac cells typically results in change in the normal size and shape (morphologic features) of the complexes recorded on the ECG. The strategically placed ECG leads detect this electrical wave of depolarization in the selected positive lead, and the wave is recorded on the ECG as the familiar P-QRS-T waveform.

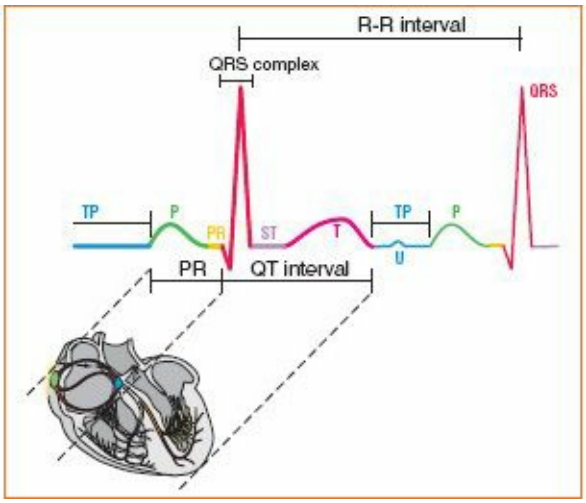

Figure 13-8 The electrocardiogram and cardiac events.

Cardiac Monitoring: 12-Lead ECG

Monitoring vs Assessment

Today's cardiac monitors and defibrillators are typically multiparameter devices that can combine continuous 3-lead ECG monitoring, 12-lead electrocardiography, semiautomatic and manual defibrillation, external pacing, capnography, pulse oximetry, blood pressure monitoring, end-tidal carbon dioxide measurements, CO measurements, and other capabilities.

Assessment of the patient's cardiac status takes place before monitoring. This assessment should include an analysis of the cardiac rhythm and 12-lead ECG to determine any underlying electrical disturbances caused by changes in the structure or function of the heart as a result of disease, ischemia, injury, or infarction.

Cardiac monitoring generally refers to the continuous observation of the patient's condition in relation to his or her cardiac rhythm. Typically, monitoring uses lead configurations for viewing from one to three leads simultaneously. If a patient's heart rhythm changes during the monitoring process, it can quickly be verified in multiple leads and the appropriate intervention can be initiated as directed by protocol.

Lead Placement

The equipment used to record the ECG may vary widely. Lead placement could also vary when using a machine that derives the 12-lead ECG from a 5- to 6-lead system. Several manufacturers currently produce this equipment, and each has its own proprietary lead set and different lead configurations. Major problems can result from using different techniques to acquire the "standard" 12-lead ECG. A "gold standard" for 12-lead ECG interpretation is the ability to perform serial evaluations for comparison; however, it is important to use consistent lead placements to ensure that all providers compare "apples to apples." Therefore, for simplicity and consistency, in this chapter the discussion on 12-lead ECG will use the "standard" lead placements and the views recorded from them.

The terms **lead**, **electrode**, and **cable** are often used interchangeably, which can be misleading; standard terminology should be used to avoid confusion. The electrode is the sensing device that connects directly to the skin and is usually a self-adhesive pad with some form of conduction media embedded in it to improve the connection of the electrode to the skin, thus improving the quality of the ECG. The lead is the designated position of the electrode (ie, limb and precordial/chest leads). The "lead" names the electrode placement. This is why the two terms are often used synonymously. The cable is the physical wire that connects the electrode to the ECG monitor.

Before connecting the electrodes to the chest, the skin should be prepared to help improve the quality of the ECG. The skin should be clean, dry, and slightly abraded by rubbing with a gauze pad. In addition to drying the skin, this step helps remove oils and improves the connection with the electrode. In a patient with excessive chest hair (or back hair with the use of additional nonstandard posterior leads), the hair should be shaved with a safety razor before connecting the electrodes. Other unusual conditions affecting the quality of the connection with the electrode to the skin should be corrected as necessary.

To get an accurate illustration and record the electrical activity of the heart, the leads must be placed so that they each provide a unique view **Figure 13-9**.

The six **limb leads** (I, II, III, aVR, aVL, and aVF [a indicates augmented; V, voltage; R, right arm; L, left arm; F, foot]) provide a view of the heart in a vertical plane, also called the frontal plane, and the six **precordial leads** (V_1 to V_6), or chest leads, show a horizontal plane. With the leads placed in standard locations, each provides a view of a particular region of the heart. For this reason, it is important to place leads in the proper location each time. The combination of limb leads and precordial leads provides a

three-dimensional view of the heart **Figure 13-10**. The six limb leads are created using only four electrodes (right arm, left arm, right leg, and left leg); the four electrodes on the body create six actual readings on the ECG.

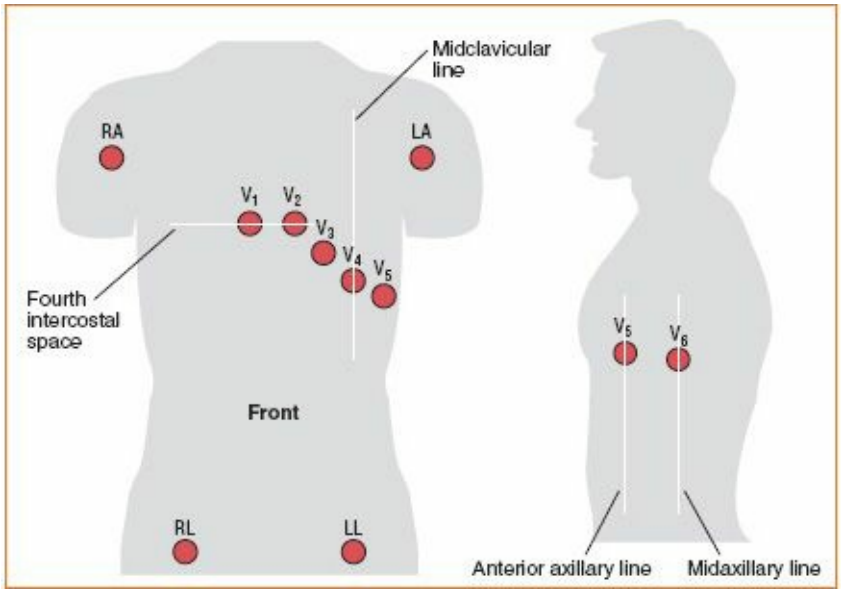

Figure 13-9 Limb lead and precordial lead placement. LA indicates left arm; LL, left leg; RA, right arm; RL, right leg.

The average of all electrical impulses generated in the heart can be detected and recorded by the ECG monitor through the combination of leads. These electrical impulses are displayed on the cardiac monitor and can be printed in a standard ECG format. To better understand the normal waveforms such as P-QRS-T and any additional electrical impulses or changes in the typical presentation, CCTPs should recall that electricity flows from negative toward positive. All ECG leads are considered positive when selected to record the electrical impulse. If the flow of electrical activity proceeds unimpeded toward a positive lead, it will be represented as a positive deflection on the ECG. If the flow of electrical activity flows away from a positive lead, it will be deflected negatively. An electrical impulse that crosses perpendicular to a positive lead is called isoelectric **Figure 13-11**.

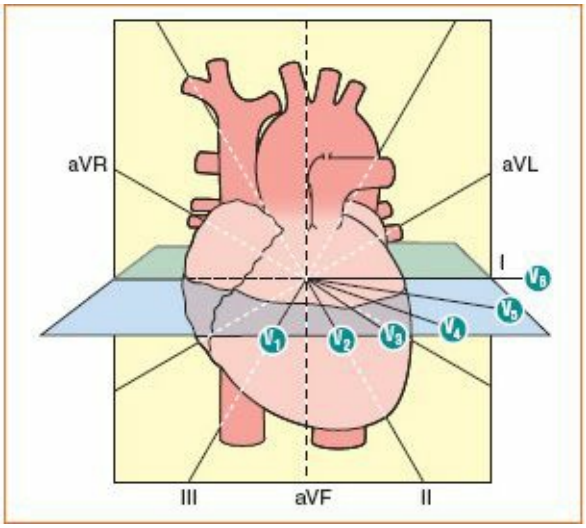

Figure 13-10 The combination of limb and precordial leads provides a three-dimensional view of the heart.

If the electrical impulse of the heart is deflected by a change in structure or function, it will be less

positive, aberrantly conducted, or deflected away from the selected electrode. Because the heart is three dimensional and the electrical impulses travel through the cardiac tissue in all directions, the leads of the cardiac monitor must be placed in the proper anatomic location to best detect these impulses. Traditionally, leads have been categorized as unipolar or bipolar, depending on how they function. The standard limb leads I, II, and III are bipolar leads because they use two leads, a positive and a negative, to measure the electrical potential as it flows from one to the other (negative to positive). The augmented leads (aVR, aVL, and aVF) and the precordial (chest) leads (V_1 through V_6) are unipolar because they use a single positive recording electrode.

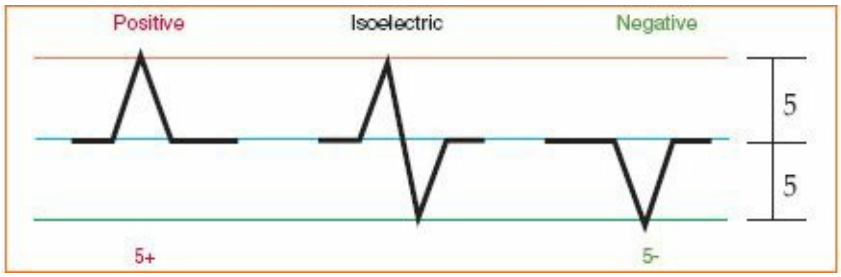

Figure 13-11 Representation of positive, isoelectric, and negative QRS deflections.

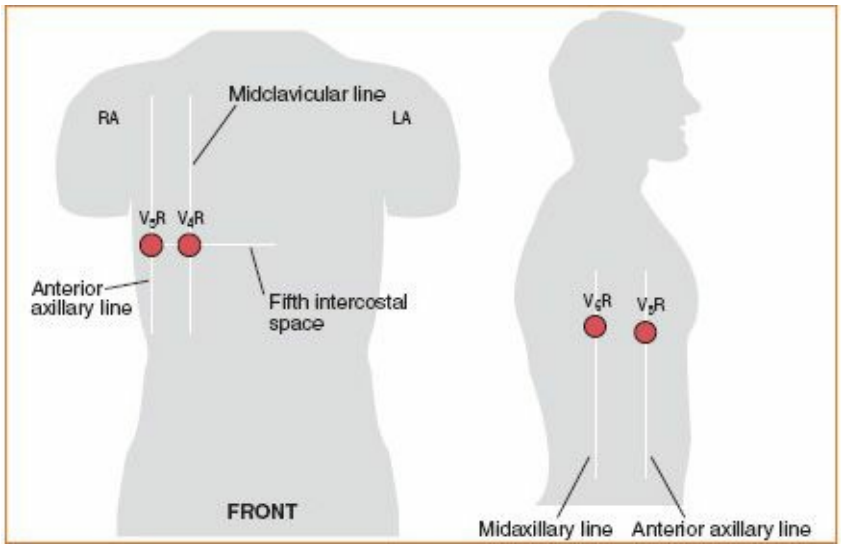

Figure 13-12 Placement of right-sided leads. LA indicates left arm; RA, right arm.

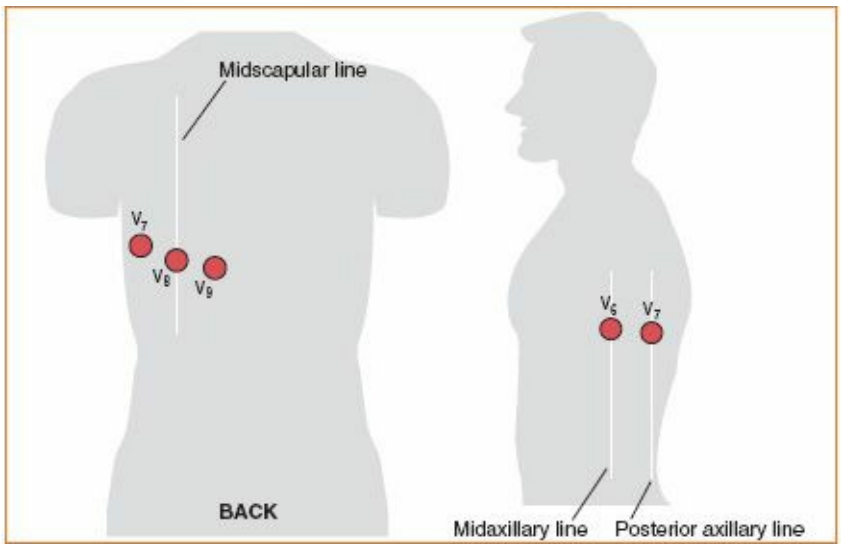

Figure 13-13 Placement of posterior leads.

As shown in Figure 13-9, the limb leads (extremity leads) include the right arm, left arm, right leg, and left leg, as marked on the lead connectors. Accurate, reproducible ECGs can be obtained by placing these limb leads on the arms or shoulders and lower abdomen as long as they are at least 10 cm from the heart, as shown in Figure 13-10. The precordial (chest) leads must be consistently placed in the proper locations:

- V_1 is placed in the fourth intercostal space to the right side (patient's right) of the sternum.
- V_2 is placed in the fourth intercostal space to the left side (patient's left) of the sternum.
- V_3 is placed between V_2 and V_4.
- V_4 is placed in the fifth intercostal space (patient's left) midclavicular line.
- V_5 is placed between V_4 and V_6.
- V_6 is placed in the fifth intercostal space (patient's left) midaxillary line.

The use of additional or nonstandard right-sided heart leads, V_4R, V_5R, and V_6R **Figure 13-12**, can provide useful information, as can the posterior heart leads V_7, V_8, and V_9 **Figure 13-13**, in suspected right ventricular and posterior MIs. The addition of these leads can increase sensitivity and specificity in the detection and location of the infarct. They are also indicated when a patient has clinical findings suggestive of acute coronary ischemia, but the results of the standard 12-lead ECG are normal or nondiagnostic.

There is specialized equipment that can be used for an ECG performed with additional right-sided leads, but this equipment is not necessary. An ECG of the additional leads can be obtained by using a standard 12-lead ECG machine. The standard principles and methods of reading the additional-lead ECG remain the same as for the 12-lead ECG, only the anatomic location that the leads are "looking" at is different. When switching standard 12-lead ECG leads to conform to the nontraditional right-sided and posterior leads, the ECG printout should be labeled to represent the leads recorded.

Before running an ECG with right-sided leads, the standard 12-lead ECG should be completed first. Then, the additional leads are attached as follows, using the precordial (chest) leads (right and left refer to the patient's right and left sides, respectively):

- V_4R is placed in the right midclavicular line, fifth intercostal space, and connected using the V_3 lead.
- V_5R is placed in the right anterior axillary line, on a straight line from V_4R, and connected using the V_2 lead.
- V_6R is placed in the right midaxillary line, on a straight line from V_5R, and connected using the V_1 lead.
- V_7 is placed in the left posterior axillary line, on a straight line from V_6, and connected using the V_4 lead.
- V_8 is placed in the left midscapular line, on a straight line from V_7, and connected using the V_5 lead.
- V_9 is placed in the left paraspinal line, on a straight line from V_8, and connected using the V_6 lead.

The bipolar lead MCL1 (modified chest lead 1) has been used as a substitute for cardiac monitoring when using a three-lead system. Modern research, however, has shown that QRS morphologic features, when recorded simultaneously with V_1 and MCL1, are different in a significant number of cases (38%), and this recording is not recommended when it is possible to obtain a true V_1 lead. Given the availability

of advanced monitoring systems in the critical care transport setting, the 12-lead ECG and multilead monitoring should be the standard of care.

Confirmation of Lead Placement

Confirming lead placement may seem like a redundant act, but in the critical care transport environment in particular, with moving a patient from one facility to another, there are innumerable opportunities for leads to become disconnected. As described later in this chapter, because each lead "looks" at a particular anatomic area of the heart, mixing up the leads will cause erroneous ECG readings, which could result in inappropriate therapeutic interventions. Placement should be confirmed before transport and several times during transport.

Recording the 12-Lead ECG

The acquisition of a 12-lead ECG is a simple procedure that takes only a few minutes. In critical care transport, it can be assumed that the patient has already had baseline ECG evaluations and that the ECG monitoring system has been connected to the patient before transport. With interfacility transports, CCTPs must ensure that the monitoring system and lead configuration at the initial facility are consistent with those that will be used during transport. A "new" 12-lead ECG should be recorded and evaluated before transport and repeated at regular intervals, when any changes in the ECG are noted, and on arrival at the receiving facility; however, obtaining additional ECGs should never delay the transport of a patient with an **ST-elevation myocardial infarction (STEMI)** to definitive care (STEMI is discussed later in this chapter). To obtain the best ECG quality, the patient should remain as still as possible while the ECG is being obtained to minimize artifact seen on the recording. The supine position is recommended; however, an adequate ECG can be obtained with the patient in a semisitting (semi-Fowler) position. (A patient's position other than supine during ECG acquisition should be noted on the ECG tracing.) The patient's condition will dictate the position of evaluation during transport. If all required electrodes for 12-lead ECG monitoring have not been applied to the skin, they should be placed before the patient is moved. The skin should be prepared as previously described to provide adequate contact with the electrodes. Following this preparatory phase, with the leads connected to the corresponding electrodes, the 12-lead ECG can be obtained.

Before obtaining a 12-lead ECG, standardization, or calibration, is necessary. With the 12-lead ECG, amplitude and duration are important factors, especially in analyzing ST segments and making other measurements. Depending on the equipment, the calibration or standardization should be set so that 1 mV is 10-mm high and 200-milliseconds wide. Some equipment can be set to half-standard calibration. This calibration is usually done when the complexes are so tall that they overlap each other on the ECG paper when recorded. Another calibration on newer machines is the paper speed, which should be set at the standard 25 mm/s, not 50 mm/s, which may have been done to help evaluate the morphologic features of ECG complexes in a tachycardic rhythm. Be sure to check your machine's calibration. Most of the newer 12-lead ECG machines can provide a printout of all 12 leads along with a rhythm strip in lead II or another designated lead.

Interpretation of the 12-Lead ECG

Interpretation of the 12-lead ECG in the critical care transport setting requires CCTPs to adjust to a unique work environment. This setting is neither fully in-patient nor prehospital but a combination of each. Patients who would typically be cared for only in the critical care unit of a hospital will be packaged, moved out of the relative safety or comfort of "the unit," and placed in a transport vehicle. Sometimes there can be multiple moves and several vehicles before the prescribed destination is reached.

Interpretation of a 12-lead ECG in this environment can pose unique challenges. Typically, time is critical, and using ECG calipers, rulers, axis wheels, and straight edges is particularly difficult in a moving vehicle.

All prospective CCTPs must have a full understanding of the standard practices and principles of 12-lead ECG interpretation and monitoring before embarking on this program. The following will provide basic ECG interpretation skills that should already be familiar to CCTPs. What will be emphasized is the understanding of the process behind the ECG changes and how they are depicted on the ECG monitor or printout. Some field-expedient methods of interpretation will be discussed to help build on the base knowledge expected of a health care provider entering this program.

Figure 13-14 provides a graphic representation of what the electrical impulses look like when transmitted to the 12-lead ECG. As shown in Figure 13-8, the configuration of the complexes varies somewhat from lead to lead; therefore, before attempting to identify any abnormalities, CCTPs must know what a typical complex looks like from each lead. In addition to knowing what each complex looks like, CCTPs must know what a normal 12-lead ECG pattern looks like. If the ECG does not fit this pattern, an abnormality is present.

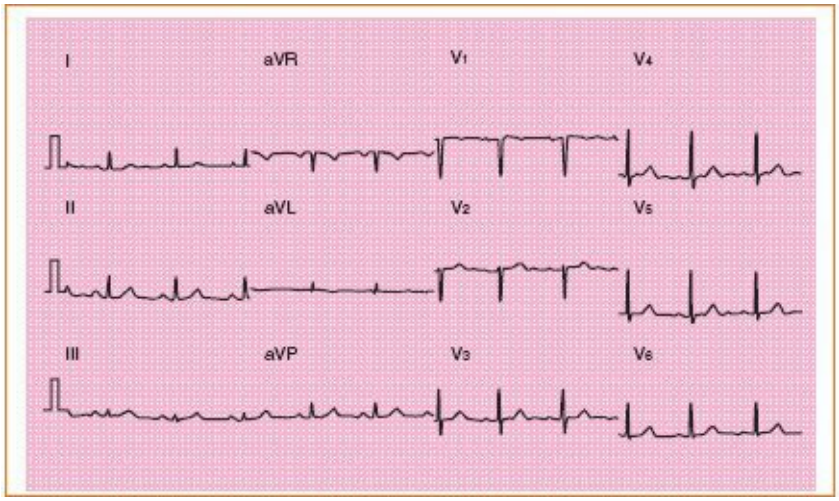

Figure 13-14 A normal 12-lead electrocardiogram.

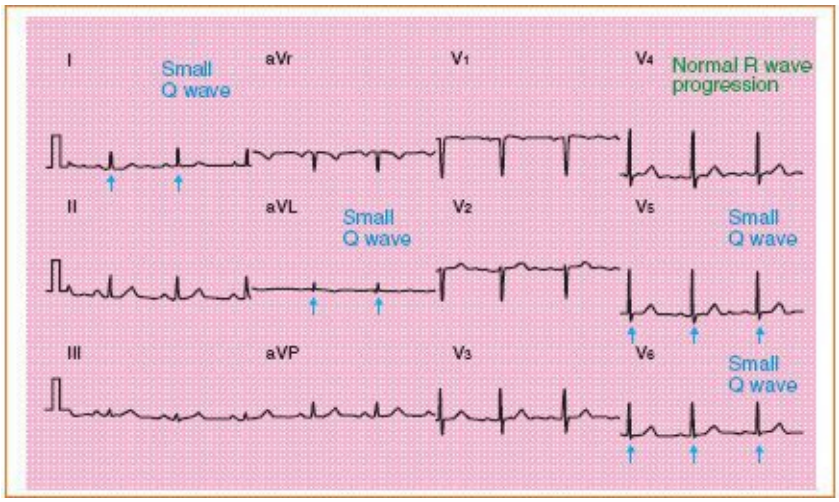

Figure 13-15 A small Q wave in leads I, aVL, V_5, and V_6 representing septal depolarization. This electrocardiogram also shows normal R-wave progression.

In the limb leads, the P wave is typically upright in leads I, II, aVL, and aVF. It is frequently biphasic in lead III and is purely negatively deflected in lead aVR. In the precordial leads, the P wave is typically

upright in leads V_5 and V_6. Lead V_1 is biphasic, and leads V_2 and V_4 are variable. These are the typical presentations for the P wave, although its appearance can vary from person to person.

The rules for measuring the PR interval remain unchanged from those for routine cardiac monitoring. The PR interval is a representation of the time from the start of atrial depolarization to the start of ventricular depolarization and also includes the delay in conduction that occurs at the AV junction. The PR interval usually lasts from 120 to 200 milliseconds (0.12 to 0.20 seconds).

The QRS complex is a representation of ventricular depolarization. The septal fascicle delivers the electrical impulse to the interventricular septum. The septum is the first part of the ventricles to depolarize. Septal depolarization is not always seen on the ECG, but when it is, a small Q wave may be seen in leads I, aVL, V_5, and V_6. **Figure 13-15** provides examples of each precordial lead and demonstrates the concept of R-wave progression.

The T wave will usually be recorded in a positive deflection in the same leads that record a positive deflection of the R wave. In other words, it is usual to find positive T waves in the same leads that have tall R waves.

As discussed in the lead placement section, each lead provides an enhanced view of a particular region of the heart. As a result, the electrical activity picked up by this lead placement is recorded as complexes from these different perspectives. Understanding that each lead represents a different enhanced view of the heart is the first step in learning to scan the 12-lead ECG by anatomic location (**Figure 13-16** and **Table 13-3**), which will become more relevant as CCTPs begin "localizing" areas of the heart to determine where ischemia, injury, and infarction have occurred. The colors in Table 13-3 will be used to represent these same leads and areas in figures later in this chapter.

It is also useful to know the intrinsic rates of cardiac cells because a problem may be located simply by the heart rate that is produced **Figure 13-17**. The higher in the conduction system in the heart, the faster the "firing rate" will be. The slower pacers lower in the conduction system will not "normally" fire as long as the higher pacers are functioning properly.

Systematic Approaches

For reading 12-lead ECGs, there are many standard methods of analysis, ranging from 5 to 12 or more steps. The method used is not as important as using one method to ensure following a consistent approach. Methods stated herein assume a basic understanding of the elements essential to the fundamentals of ECG interpretation and 12-lead ECGs.

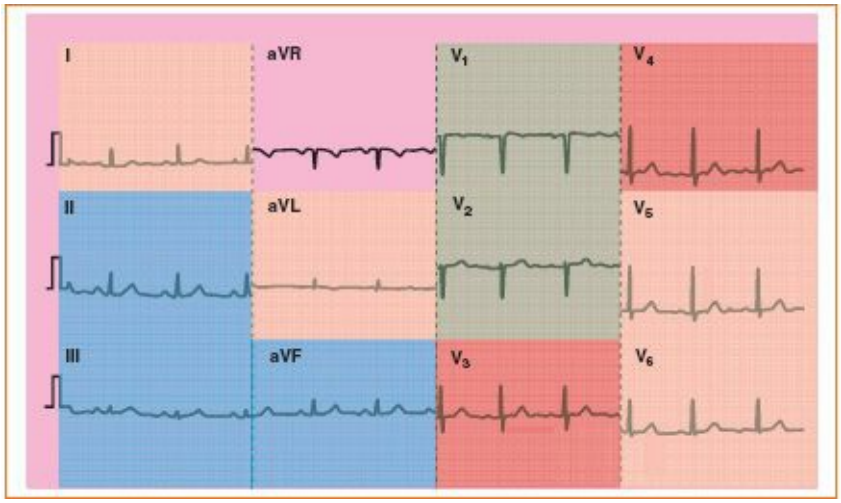

Figure 13-16 The relationship between leads and views of the heart.

TABLE 13-3 Leads Listed by the Area of the Heart That They View

Lead	Localized Area
V_1	Septum
V_2	Septum
V_3	Anterior
V_4	Anterior
II	Inferior
III	Inferior
aVF	Inferior
I	Lateral
aVL	Lateral
V_5	Lateral
V_6	Lateral
aVR	None

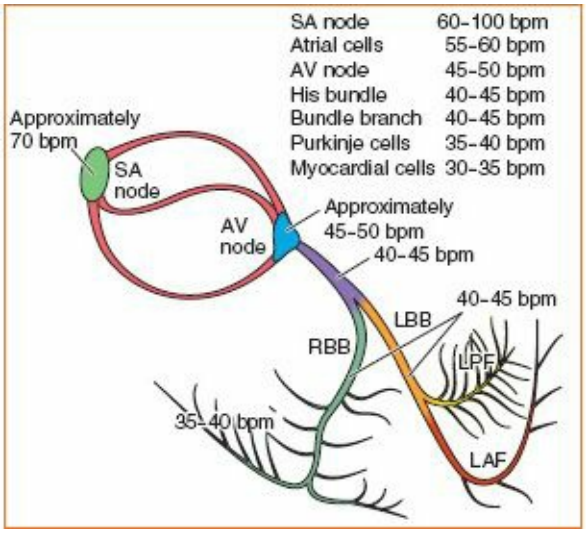

Figure 13-17 Intrinsic rates of pacing cells.

The keys to being able to quickly read an ECG are experience and, as stated, consistency. Interpretation of a 12-lead ECG is a skill that must be practiced repeatedly using a standard method of analysis. However, even among specialists examining a routine ECG tracing, there can be widely divergent conclusions. The reason this disparity is mentioned is to encourage the use of sound methods of interpretation, documentation of findings, and consideration of every piece of patient information.

During the transport of a critically ill patient, the ECG rhythm must be monitored continuously for changes that require a rapid, appropriate response as indicated by local protocol and national guidelines. In this setting, however, monitoring should not be mutually exclusive of serial evaluations of the 12-lead ECG. For systematic analysis of the 12-lead ECG, the interpretation of rhythm and arrhythmias is a fundamental building block. In rhythm and arrhythmia interpretation, there are, in general, 10 key elements

that must be assessed.

- General
  1. Is the rhythm fast or slow?
  2. Is the rhythm regular or irregular? If irregular, is it regularly irregular or irregularly irregular?
- P waves
  3. Are there any P waves?
  4. Are all the P waves the same?
  5. Does each QRS complex have a P wave?
  6. Is the PR interval constant? QRS complexes
  7. Are the P waves and QRS complexes associated with one another?
  8. Are the QRS complexes narrow or wide?
  9. Are the QRS complexes grouped or not?
  10. Are there any dropped beats?

Considering the ever-moving environment of patient transport, for CCTPs, a rapid assessment technique should be adapted to consistently review and identify changes seen on the 12-lead ECG. The approach shown in **Table 13-4** takes into consideration a variety of situations that must be identified and monitored and/or treated right away.

When examining an ECG tracing, CCTPs should make notes of findings as they are discovered to keep an accurate and a complete record of changes for serial evaluations. The ECG is only one simple test that can give information about the anatomy, pathology, and pathophysiology of the heart and also about how medications are affecting it.

The 12-lead ECG shows groupings of complexes that are recorded simultaneously by each lead. The rhythm strip, which typically appears at the bottom of the ECG, records for the entire time that the 12-lead ECG is being obtained. For comparison of cardiac electrical events, the series of complexes viewed in lead I is being recorded at the same time as the complexes in the other leads. Their appearance is different because of the angle at which the electrical vectors are viewed.

TABLE 13-4 Rapid 12-Lead ECG Assessment

Verify that aVR is negative (helps to ensure proper lead placement).
Assess rate and rhythm.
Determine the axis (leads I and aVF; also determined by the cardiac monitor's internal diagnostic hardware and printed on the 12-lead ECG).
Identify conduction abnormalities • Left bundle branch block • Hypertrophy • Aneurysm • Pericarditis • Drug or electrolyte imbalance effects • Early repolarization

Find signs of ischemia, injury, and infarction

- T-wave inversions
- ST-segment elevation
- Significant Q waves

Identify acute MI patterns

- Anterior
  - ST-segment elevation in V_1, V_2, V_3, V_4
  - ST-segment depression in leads II, III, aVF
- Inferior
  - ST-segment elevation in II, III, aVF
  - ST-segment depression in V_1, V_2, V_3, or I, aVL
- Lateral
  - ST-segment elevation in I, aVL, V_5, V_6
  - ST-segment depression in II, III, aVF
- Septal
  - ST-segment elevation in I, aVL, V_1, V_2
- Posterior
  - Tall, wide R waves and reciprocal ST-segment depression in V_1, V_2
  - T-wave inversion and ST-segment elevation in alternative posterior leads V_7, V_8, V_9
- Right ventricular
  - ST-segment elevations in V_4R, V_5R, V_6R

Consider the patient's clinical picture.

Axis Determination

As previously mentioned, each cell in the heart can produce its own electrical impulse. Each impulse varies in intensity and direction. The term vector is used to describe these electrical impulses, and the axis is the direction of the wave of depolarization as it passes through the heart. The sum of all of the electrical impulses is called the **mean electrical axis**.

As the electrical impulses or vectors travel through the heart toward the larger muscle mass of the left ventricle, the mean electrical axis should progress in a downward and leftward direction. Because the mean electrical axis is the sum of all vectors traveling in different directions, it makes sense that if there is a change in the patient's normal or preexisting axis, a change has occurred in the structure or function of the heart. For example, if there is hypertrophy in one of the ventricles, the sum of the electrical vectors would shift toward the enlarged ventricle. If there is an infarction, the area of myocardium affected will not transmit electrical impulses through it, causing a shift away from the infarction. If a section of the electrical conduction system is diseased or blocked, the impulses or vectors will shift away from the damaged area.

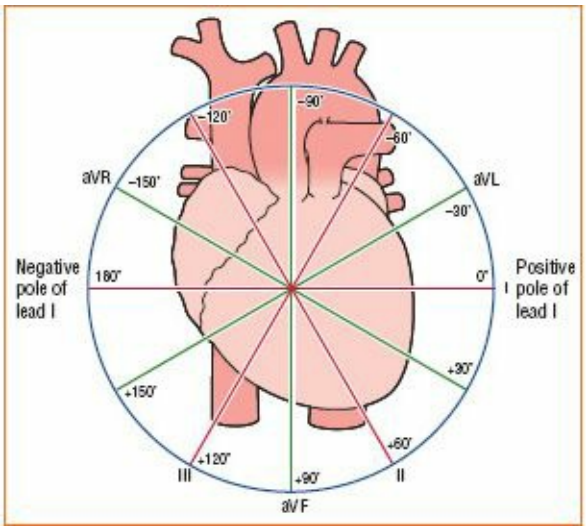

Figure 13-18 The hexaxial system.

Although the electrical axis is measured and evaluated by the internal diagnostic software of the cardiac monitor and printed on most standard 12-lead ECGs, any health care provider who "reads" ECGs must know how these determinations are made. This section shows how to determine the direction of the mean electrical axis.

The **hexaxial system** uses a circular diagram divided into 12 equal segments to describe the frontal plane that is created using the limb leads (I, II, III, aVR, aVL, and aVF) **Figure 13-18**. As mentioned, the mean electrical axis is the sum of all vectors generated in the wave of depolarization. To isolate the direction of the axis, two leads are required. To illustrate how this combination of leads will be used, the hexaxial circle is divided into four quadrants moving clockwise from 0° to +90°, +90° to 180°, 180° to –90° and –90° to 0°. A wave of depolarization directed into one of these quadrants will give the general direction of the mean electrical axis.

The QRS complex is a representation of the depolarization of both ventricles. The sum of all the vectors generated creates the mean QRS vector in a direction downward and to the patient's left. The mean QRS vector is used to determine the mean electrical axis.

The first lead examined to determine the direction of the mean QRS vector is lead I. Electrical impulses that flow toward the positive electrode create an upright deflection. An electrical impulse that flows away from the positive electrode has a negative deflection. Lead I is the positive lead located at 0°. As the wave of depolarization travels toward lead I, it is represented by a positive deflection on the ECG. If the QRS complex is negatively deflected in lead I, the wave of depolarization is shifted away from the left, which means that it is "deviated" toward the right, a right axis deviation (RAD).

The second lead examined to determine the axis is aVF. In aVF, the positive electrode is located on the left leg or lower left abdomen at least 10 cm from the heart. Electrically, this is at + 90°. If the wave of depolarization is downward, it is moving toward the positive electrode in lead aVF and will be represented by a positive deflection of the QRS on the ECG. If the QRS is positive in leads I and aVF, the mean electrical axis is downward (aVF) and toward the patient's left (lead I). This is the normal axis range **Figure 13-19**.

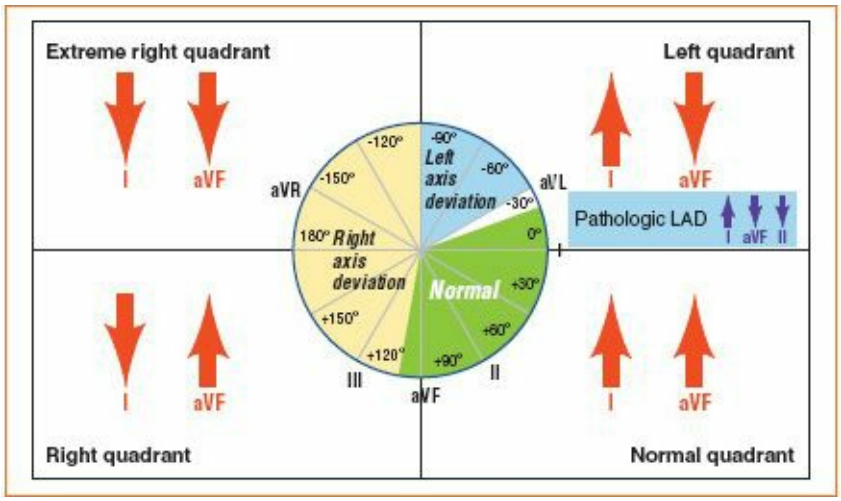

Figure 13-19 Electrocardiographic axis presentation of left axis deviation (LAD) and right axis deviation (RAD).

If the QRS complex is deflected positively in lead I, the axis is directed toward the left. A QRS complex that is negatively deflected in aVF at the same time that it is positive in lead I indicates that the axis is deflected upward and to the left, a left axis deviation (LAD).

If lead I is deflected negatively, the axis is deviated to the right. If aVF is deflected negatively at the same time, the axis is shifted upward and to the right, causing an extreme RAD. **Figure 13-20** shows sample ECG waves for practice in determining the quadrant in which the mean electrical axis is located.

Extreme RAD, –90° to 180°, is rare. It occurs when the heart is depolarizing inferiorly to superiorly. Extreme RAD can be seen in ventricular tachycardia (VT), atypical MIs, hyperkalemia, and, occasionally, right ventricular hypertrophy (RVH).

The mean QRS axis is in a "quadrant" of normal, RAD, extreme RAD, or LAD. Noting a change in electrical axis during the transport of a critically ill patient alerts CCTPs to search for the cause of the deviation. Once an abnormal axis is determined, other associated abnormalities can be found. Further evaluation can lead to an intervention. The reality in this setting is that noting the change of axis is more important than calculating the degree of axis. There are, however, some rapid assessment techniques that will help narrow down the degree of axis.

Before determining the degree of the mean electrical axis, it is important to know that there are some overlaps in the quadrants. The methods already discussed provide good approximations of the axis by isolating the quadrant in which it lies. The true pathologic measurements on the hexaxial system are shown in **Figure 13-21**.

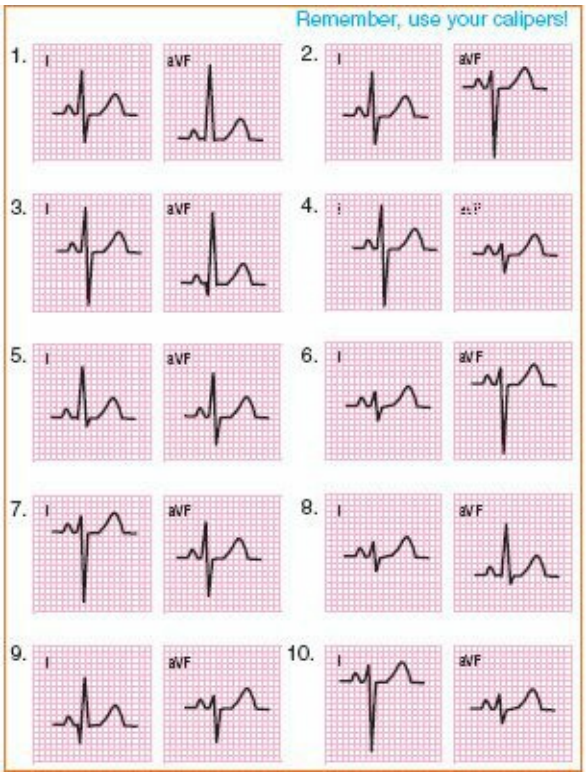

Figure 13-20 Sample electrocardiographic waves from which to determine the mean electrical axis.

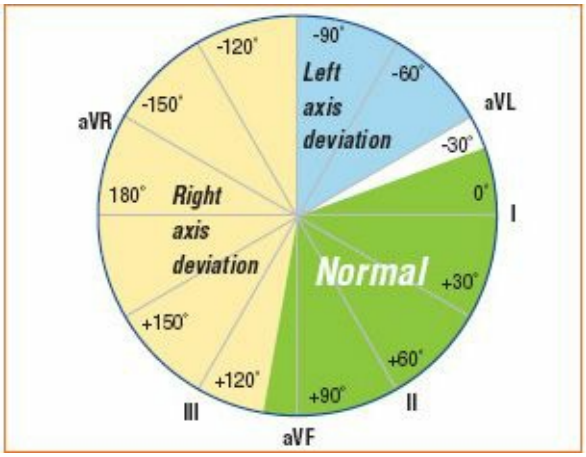

Figure 13-21 Pathologic measurements of the hexaxial system.

The normal ranges for the electrical axis extend from –20° to +100°. The 10° overlap from +90° to +100° in the right quadrant is not clinically significant. If the axis lies in either of the two right quadrants, the patient has an RAD.

In determining the left axis, it should be noted that "normal" extends to –20°. The area from –21° to –29° is considered the "physiologic" left axis and is neither pathologic nor normal. The area from –30° to –90° is the true pathologic area of the left quadrant, or LAD. The techniques already discussed should be used to isolate the axis to the left quadrant by determining if the QRS is positive in lead I and negative in aVF. If lead II is also negatively deflected, the left axis is between –30° and –90° and verifies a true pathologic LAD.

As shown in Figure 13-18, there are a number of ways to further calculate the direction and intensity of the electrical axis. An easy way to make this determination is to use the hexaxial system mentioned earlier. This system uses a circular diagram oriented in the frontal (coronal) plane. The diagram is divided into 12 equal segments around the heart, and each division of the diagram is labeled in degrees.

The divisions of the lower half of the diagram are given values ranging from 0° to 180°, and the divisions in the upper half of the diagram are each given a value of 0° to –180°. The limb leads (I, II, III, aVR, aVL, and aVF) are overlaid onto this diagram, each oriented to its electrical position on the ECG. Lead I is located at 0°, lead II at +60°, lead aVF at +90°, lead III at + 120°, aVR at –150°, and aVL at –30°. On the hexaxial diagram, each lead has a corresponding lead that is 90° away or perpendicular to the other **Figure 13-22**.

To use this system to determine the mean electrical axis, the QRS complex that has the lowest amplitude and is the most **isoelectric** in one of the limb leads is located first. Then, the corresponding perpendicular lead is found. For example, if the most isoelectric QRS complex is in lead II, located at + 60°, the corresponding perpendicular lead would be aVL, which uns between + 150° and –30°. Next, a determination is made about whether the QRS is deflected positively or negatively in the perpendicular lead. If it is positive, the mean electrical axis is + 150°. If the QRS is negatively deflected, the mean electrical axis is –30°. **Figure 13-23** shows both ends of each limb lead and their corresponding values. (The arrows show which is positive and which is negative.)

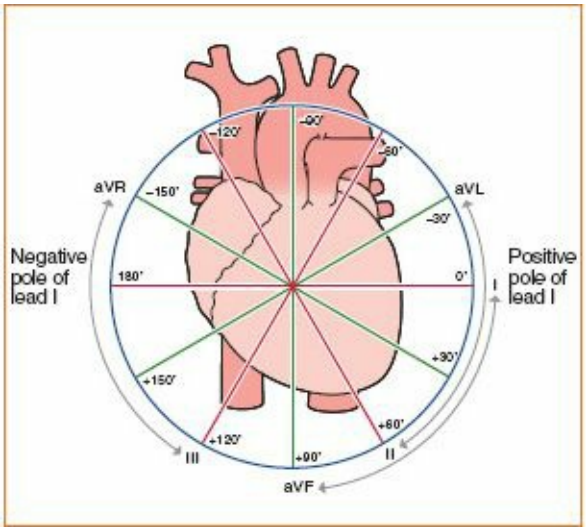

Figure 13-22 Perpendicular leads of the hexaxial system.

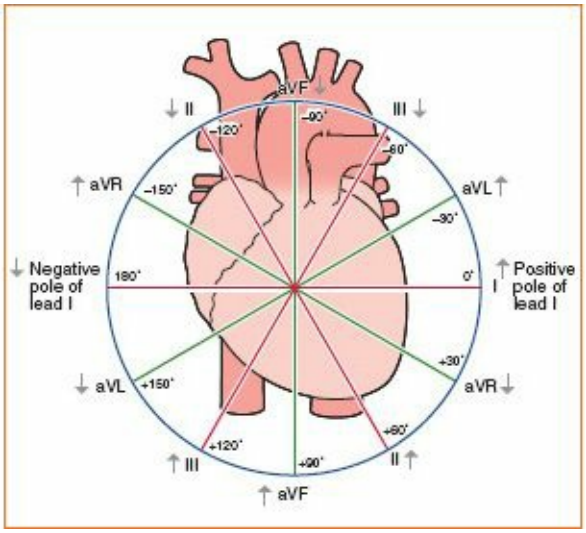

Figure 13-23 The hexaxial system with labeled limb leads, degrees, and arrows indicating the QRS deflection.

A baseline ECG on the cardiac monitor to be used during transport is required before transporting a critically ill patient. A complete assessment of the ECG should be made, noting any abnormalities,

including the mean electrical axis. An axis that deviates outside the normal range or is different from the patient's pre-existing axis usually has clinical implications. When an axis deviation is detected, CCTPs should always check for corresponding ECG changes that can provide clues to the underlying cause of the deviation.

Some common cardiac causes for axis deviation are ischemia and infarction. If the electrical conduction system is affected, the axis will be directed away from the damaged area. One of the most common areas affected is the left anterior-superior fascicle of the left bundle branch. The result is a left anterior hemiblock (LAH). If the wave of depolarization is stopped by an inferior wall MI (IWMI), the electrical impulse can be redirected upward and to the left, causing an LAD. With left ventricular hypertrophy (LVH), the enlarged ventricle can draw the electrical axis toward this larger muscle mass, resulting in LAD. Ectopic beats and rhythms can originate anywhere in the heart, directing the wave of depolarization in a right or left direction, causing an axis deviation in the affected area. An RAD is caused by events that redirect the electrical axis toward the right. A congenital cause is **dextrocardia**, which occurs when the heart develops in a right-facing position, creating a mirror image of the normal left-facing heart. Left posterior hemiblock (LPH) occurs with a conduction defect to the left posterior-inferior fascicle of the left bundle branch. Just as an enlarged left ventricle can cause the axis to shift left, an enlarged right ventricle, or RVH, can cause an RAD.

Other conditions that are not cardiac in origin can also contribute to a shift in axis. Any condition that causes the heart to be displaced from the downward leftward position can contribute to this shift. For example, a tall thin person can have a heart that is displaced (vertically) slightly more downward and away from the left, which can result in a right shift in axis. Children have larger right ventricles compared with adults, so their "normal" axis points toward the right. Chronic obstructive pulmonary disease can lead to RVH, causing an RAD. An LAD can also be caused by mechanical shifts. In obese or pregnant patients, the increased intra-abdominal pressure can push up on the diaphragm, displacing the heart into a more horizontal or left position, resulting in an LAD. **Table 13-5** summarizes possible causes of various axis deviations.

TABLE 13-5 Possible Causes of Axis Deviation

Axis Deviation	Possible Cause
Right	RVH LPH Chronic obstructive pulmonary disease Dextrocardia Ectopic beats and rhythms Normal in children
Left	LAH LVH IWMI Ectopic beats and rhythms Obesity Pregnancy

Abbreviations: IWMI, inferior wall myocardial infarction; LAH, left anterior hemiblock; LPH, left

posterior hemiblock; LVH, left ventricular hemiblock; RVH, right ventricular hypertrophy.

Bundle Branch Blocks and Hemiblocks

When a disruption of the electrical or mechanical response to the wave of depolarization occurs in the heart, bundle branch blocks (BBBs) and **hemiblocks** may occur. These events may be identified through characteristic changes on the ECG.

Right Bundle Branch Block

If there is a block in electrical conduction of the right bundle branch, CCTPs should think of how the wave of depolarization progresses. The electrical impulses that originate in the atria proceed as normal up to the block, with no change in waveforms or intervals. The impulses will continue down the left bundle branch and its fascicles as usual but are stopped in the right bundle branch **Figure 13-24**.

When a block occurs, the wave of depolarization must continue through the right ventricle by cell-to-cell conduction. Because cell-to-cell conduction progresses more slowly than conduction through the normal electrical conduction pathway, the representative complex displayed on the ECG will occur late as well, causing a prolonged QRS interval of 120 milliseconds or more. The ECG initially shows the upstroke of the R wave conducted by the left ventricle and its fascicles. Immediately behind this is the delayed right ventricle depolarization resulting in a second R wave called R′ (R prime). The combination of the normally conducted electrical impulse through the left bundle branch and the delayed conduction through the right bundle branch results in the up and down (“rabbit ear”) appearance of the QRS complex **Figure 13-25**.

The best lead to view the changes associated with a right BBB is the precordial lead, V_1, which shows the RSR′ complex. Lead V_2 can also show the RSR′. The RSR′ complex is one in which a second R wave appears in the second half of the QRS complex. The R′ representing the additional vector created by the delayed electrical impulse through the right ventricle will be positively deflected in lead V_1. In addition to the RSR′ seen in lead V_1, the delayed conduction through the right ventricle causes a “slurring” of the S wave in the lateral limb lead, lead I, and the left-sided precordial lead, V_6. Because other conditions can cause an RSR′ (eg, incomplete right BBB, some pulmonary conditions, RVH, and preexcitation syndromes such as Wolff-Parkinson-White syndrome), for an RSR′ to be diagnostic of a right BBB, the slurred S wave is required to make the diagnosis. **Figure 13-26** represents the various leads on an ECG and shows relevant areas for a right BBB diagnosis. Note: This style of illustration is used repeatedly in this chapter.

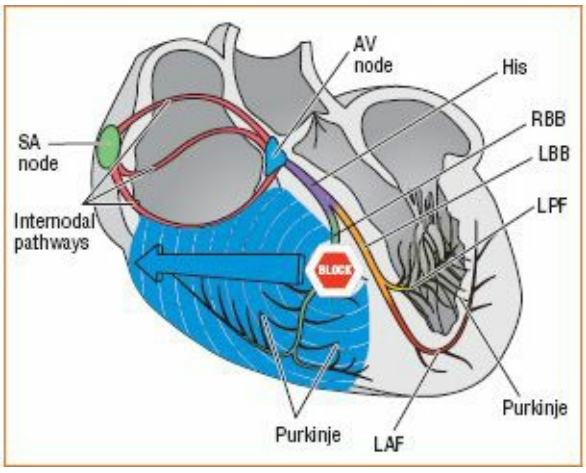

Figure 13-24 Right bundle branch (RBB) block. AV indicates atrioventricular; LAF, left anterior fascicle; LBB, left bundle branch; LPF, left posterior fascicle; SA, sinoatrial.

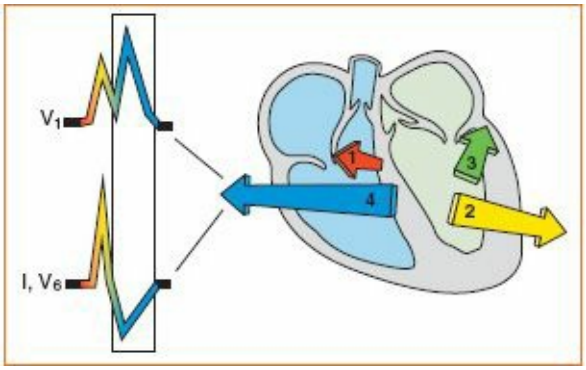

Figure 13-25 The effect of a right bundle branch block on the electrocardiogram.

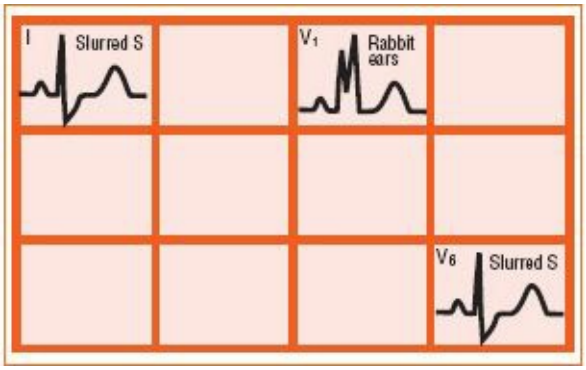

Figure 13-26 Electrocardiographic changes seen with a right bundle branch block.

Therefore, the main criteria for the diagnosis of right BBB are as follows:

1. QRS prolongation of 120 milliseconds or more
2. Slurred S wave in leads I and V_6
3. RSR′ pattern in V_1 with the R′ wave taller than the R wave

A right BBB can occur with disruption of the electrical conduction system, and it can be present in a normal healthy heart.

The QR′ Wave

Of the many potential causes of an R′ in lead V_1, the one that demands the most attention is the Qr′ or qR′ wave (when written, the larger of the two waves is represented by the uppercase letter) **Figure 13-27**.

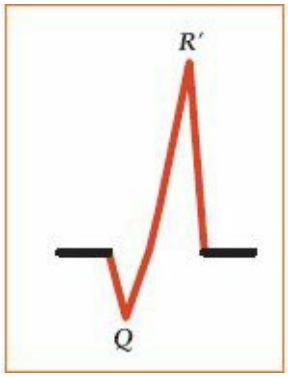

Figure 13-27 QR′ wave.

V_1 is one of the precordial leads that represents the depolarization of the anterior septum (V_2 is the other). A Q wave that occurs in lead V_1 in the presence of a right BBB is evidence of anteroseptal ischemia or infarction. If this waveform appears during transport of a patient in critical condition, early intervention may prevent ischemia from progressing to infarction.

Figure 13-28 provides an example of a right BBB. With practice, using pattern scanning of the ECG, CCTPs will see the RSR′ in the precordial leads that represent septal depolarization. Because the RSR′ alone is not sufficient to make a diagnosis of right BBB, the lateral leads, I and V_6, should be scanned.

There is no specific treatment required for isolated right BBB. The patient should, however, be seen for periodic follow-up evaluations.

Left Bundle Branch Block

A left BBB is caused by a disruption of the electrical conduction of the left bundle or both fascicles (the **left anterior fascicle** and the **left posterior fascicle**) of the left bundle. The electrical impulses that originate in the atria proceed as normal, with no change in waveforms or intervals up to the block. The electrical impulses continue to flow unimpeded down the right bundle. With the electrical conduction of the left bundle branch blocked, the wave of depolarization must then proceed by cell-to-cell transmission beginning right to left **Figure 13-29**.

The delay of electrical conduction in the left bundle branch or its fascicles results in a complex that is 120 milliseconds or longer in duration. Because normal ventricular depolarization proceeds down and to the left, the inferior and lateral leads (I, V_5, and V_6) will show the most direct results of the block. With left BBB, the complexes in these leads will not have Q waves and will typically have tall monomorphic R waves. When the conduction of electrical impulses is delayed, the normal sharp rise of the R wave is replaced with a more gradual or bowed, upward appearance. The peak of the R wave is notched, wide, or both. Reciprocal findings are present in the right-sided chest leads with wide, deep, monomorphic S waves. Repolarization is also affected in BBBs. In a left BBB, the T waves should be **discordant** or deflected opposite of the terminal deflection of the QRS complexes **Figure 13-30**.

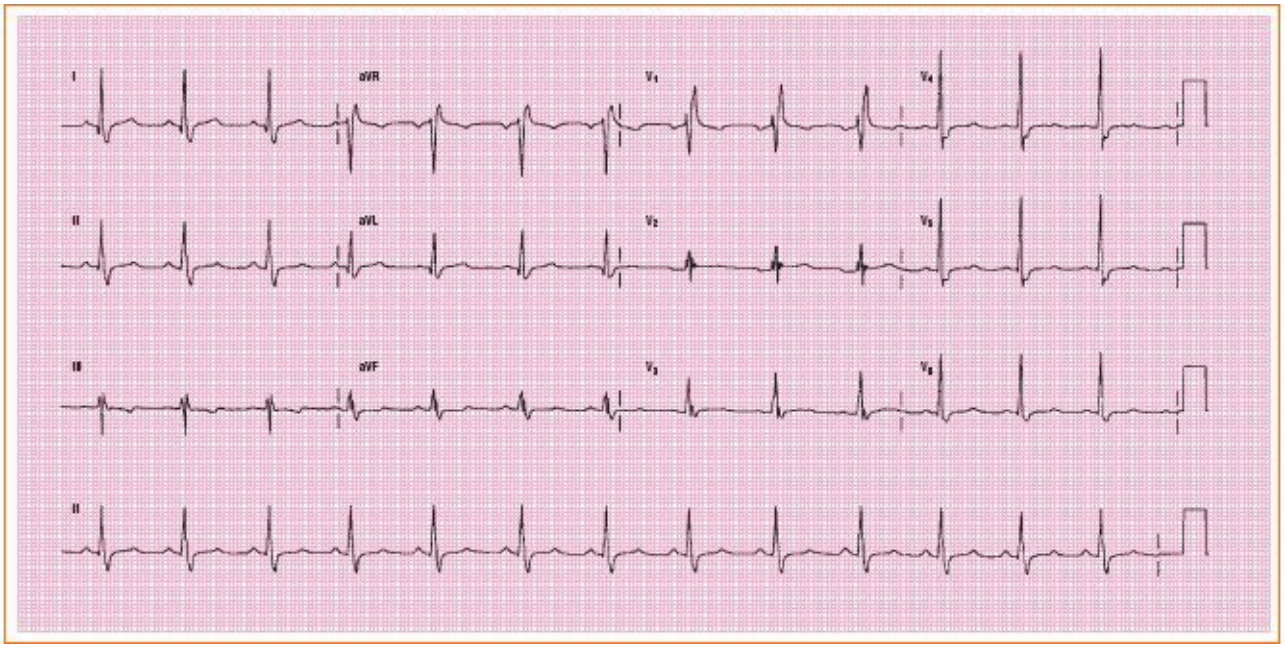

Figure 13-28 A 12-lead electrocardiogram showing a right bundle branch block.

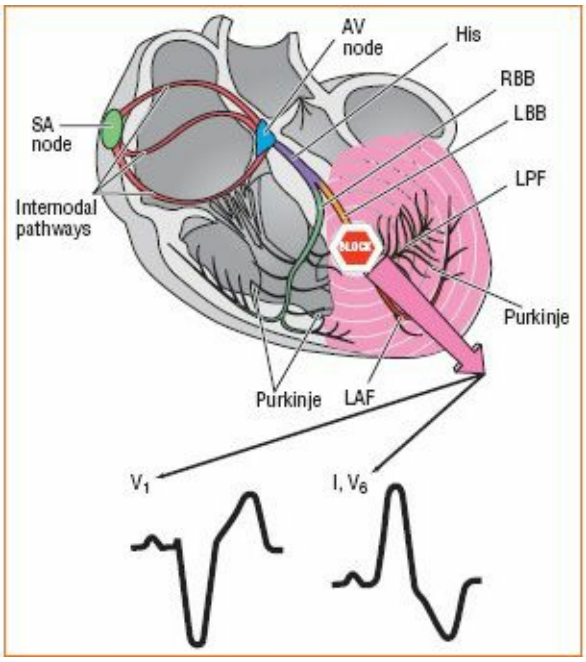

Figure 13-29 Left bundle branch (LBB) block. AV indicates atrioventricular; LAF, left anterior fascicle; LPF, left posterior fascicle; RBB, right bundle branch; SA, sinoatrial.

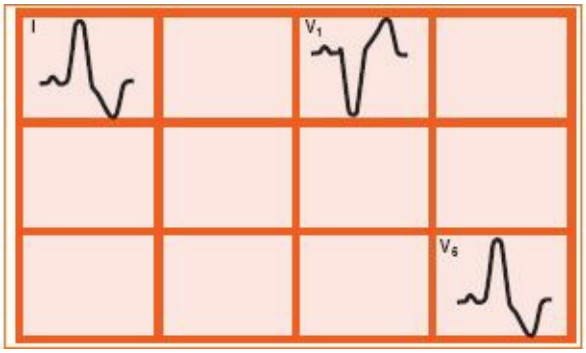

Figure 13-30 Electrocardiographic changes seen with a left bundle branch block.

The main criteria for the diagnosis of a left BBB are as follows:

1. Complex duration of 120 milliseconds or longer
2. Wide R waves in leads I and V_6, with no Q wave
3. Wide, deep S waves in lead V_1; may also have a small r wave

Lowercase letters are used to represent small waves, where as capital letters are used to represent large waves. Therefore, “r wave” represents a small r wave, whereas “R wave” represents a large R wave.

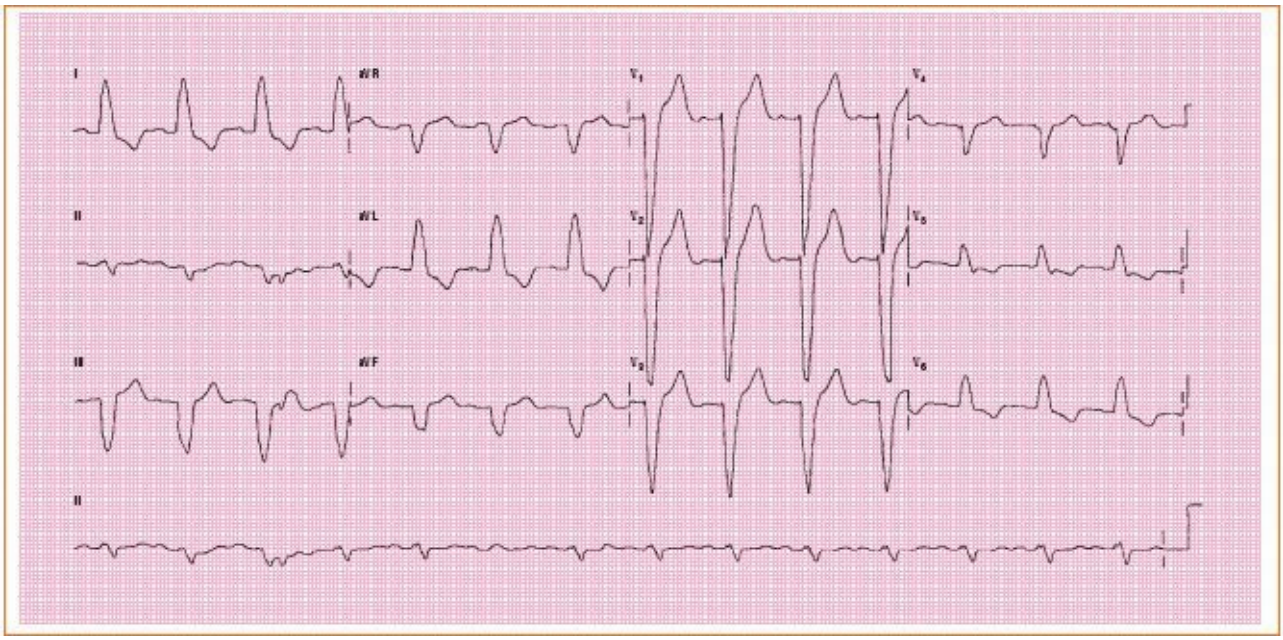

Figure 13-31 A 12-lead electrocardiogram showing a left bundle branch block.

Although a right BBB can be present in a healthy heart, a left BBB seldom occurs in a healthy heart and usually means that there is a serious problem within the conduction system or ischemia from coronary artery disease. A pacemaker rhythm can also give wide complexes, so CCTPs should be watchful for pacemaker spikes with a rhythm that has this appearance.

Figure 13-31 is an example of a left BBB. The pattern of wide complexes of 120 milliseconds or longer and discordant T waves in every lead indicates that this is a disturbance that affects the ventricular conduction system. The presence of P waves, however, provides assurance that the rhythm originates in the atria and is not in the ventricles. The QRS complexes are deflected positively in the lateral leads (I, V_5, and V_6) with corresponding wide, deep S waves in the reciprocal lead, V_1.

Patients with a left BBB require complete cardiac evaluation, and patients with a left BBB and near-syncope or syncopal episodes may require a pacemaker. Guidelines for device-based therapy of cardiac rhythm abnormalities have been established and revised by the American College of Cardiology and the American Heart Association.

Hemiblocks

A hemiblock is a block in the electrical conduction of one of the two fascicles of the left bundle branch. An LAH is the same as a left anterior fascicular block, and an LPH is the same as a left posterior fascicular block. Unlike complete BBBs, hemiblocks cause little to no widening of the QRS complexes because the resultant cell-to-cell transmission of the electrical impulses is much less.

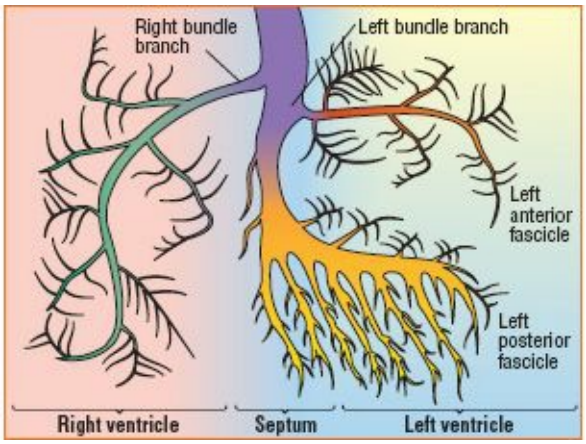

Figure 13-32 Ventricular electrical conduction system.

Each fascicle branches off of the left bundle branch, and the structures of the two are quite different **Figure 13-32**.

The left anterior fascicle forms a thin bundle of fibers that conducts electrical impulses to the anterior and lateral walls of the left ventricle. The left posterior fascicle forms a broad network of fibers that conducts electrical impulses to the inferior and posterior walls of the left ventricle. Observing the structural differences of these two fascicles makes it easy to understand why a hemiblock occurs more frequently in the left anterior fascicle. It would take a smaller area of ischemia or infarction to impede the electrical conduction to a single strand of fibers than to block the conduction to a broad network of fibers. Even though the blood supply to all areas of the heart varies somewhat from person to person, the left posterior fascicle typically receives blood from branches of the left and right coronary arteries, which means that coronary occlusions would have to occur in both sources of blood supply to have a major effect on the left posterior fascicle.

Left Anterior Hemiblock

An LAH occurs when electrical conduction to the left anterior fascicle is blocked **Figure 13-33**.

With conduction to the anterior-superior part of the left ventricle blocked, depolarization of this area is from the interventricular septum and retrograde conduction from the inferior and posterior walls. The direction of the wave of depolarization for this blocked area is now spreading upward and to the left, causing a shift in the electrical axis to the pathologic left, which makes an LAD between –30°and –90° the main criterion for the diagnosis of LAH. Additional findings on the ECG include a qR complex or a large R wave in lead I. An rS complex also may be found in lead III. These small q and r waves are the result of the interventricular septum depolarizing unopposed.

The criteria for diagnosing LAH are as follows:

1. Left axis deviation within –30° to –90°
2. qR complex or large R wave in lead I
3. rS complex in lead III (likely to also appear in lead II and aVF)

Figure 13-34 is an example of an LAH. The most obvious feature is an LAD. The QRS complex is positively deflected in lead I and negatively deflected in lead aVF. To further isolate this vector to the pathologic range or –30° to –90°, lead II should be examined. Negative deflection, as in this example, confirms the diagnosis of LAD and is presumptive of LAH. Other criteria for LAH are also met in this example. There is a qR complex in lead I, and there are rS complexes in leads II, III, and aVF. The Q waves that appear in leads I and aVL are insignificant. They are normal and represent the first vector of ventricular depolarization. For a Q wave to be significant and represent an MI, it must be more than one third the total height of the QRS complex that it appears with and must also be more than 40 milliseconds in duration.

Left Posterior Hemiblock

An LPH is exceedingly rare because of the dual blood supply to the area and the broad network of fibers that have to be blocked **Figure 13-35**. In addition to being rare, LPH is more difficult to diagnose. When the depolarization of the inferior and posterior portions of the left ventricle is delayed, the resultant wave of depolarization is directed further inferior and to the right. This rightward deflection results in an RAD. The electrical impulses conducted up to the block are unopposed and depolarize the interventricular

septum and the superior-anterior walls of the left ventricle. This is shown on the ECG as a small r wave in lead I and a small q wave in lead III.

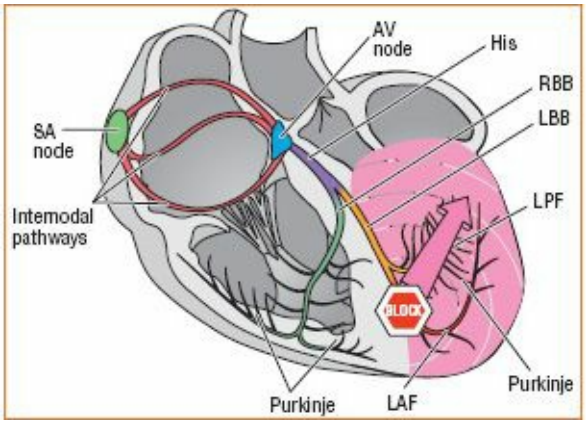

Figure 13-33 Left anterior hemiblock. AV indicates atrioventricular; LAF, left anterior fascicle; LBB, left bundle branch; LPF, left posterior fascicle; RBB, right bundle branch; SA, sinoatrial.

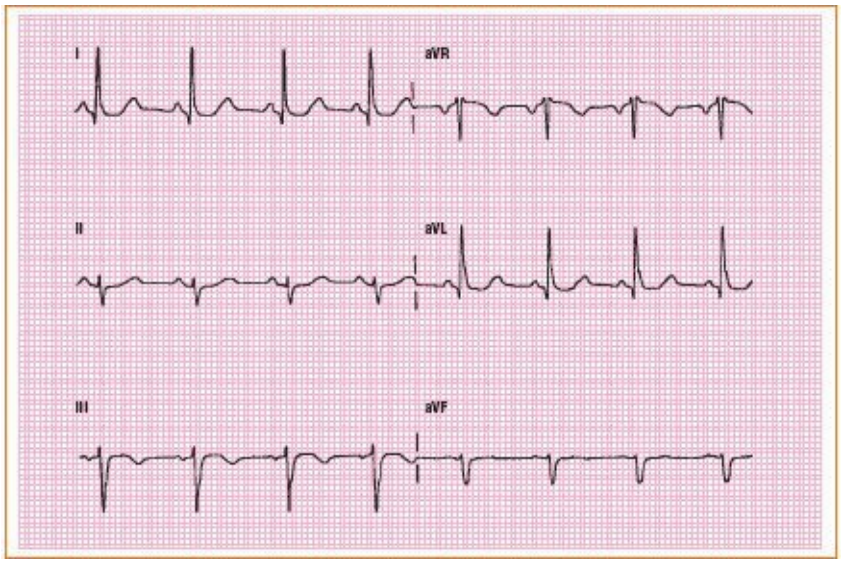

Figure 13-34 A 12-lead electrocardiogram showing a left anterior hemiblock.

The criteria for diagnosing LPH are as follows:

1. RAD of +90° to 180°
2. r wave in lead I and q wave in lead III
3. Exclusion of right atrial enlargement and/or RVH

An LPH is a diagnosis of exclusion—one reason it is more difficult to diagnose. Other causes of RAD, such as right atrial enlargement and RVH, must be ruled out. Certain chronic lung diseases that cause an overload of the right atrium can be the cause of an RAD. With these additional factors to consider in diagnosing LPH, when an RAD is found, an r wave in lead I and a q wave in lead III should be sought. With no other evidence of right atrial enlargement or RVH, LPH needs to be considered.

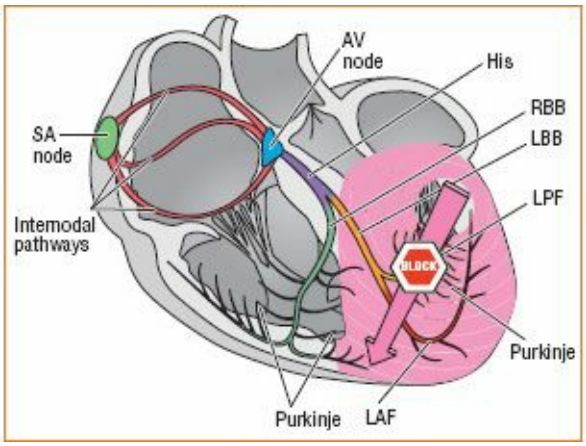

Figure 13-35 Left posterior hemiblock. AV indicates atrioventricular; LAF, left anterior fascicle; LBB, left bundle branch; LPF, left posterior fascicle; RBB, right bundle branch; SA, sinoatrial.

Figure 13-36 is an example of an LPH. The figure shows an RAD. There is also an s wave in lead I and an insignificant q wave in lead III. There is no evidence of right atrial enlargement. A pulmonary condition that makes the diagnosis of LPH impossible in many cases is pulmonary embolism. In 15% to 30% of patients with a pulmonary embolism, there is an ECG pattern of $S_1Q_3T_3$ caused by acute right ventricular strain (S_1Q_3 is also a criterion for LPH). This pattern has an s wave in lead I and a q wave and an inverted T wave in lead III. In this situation, a clinical history suggestive of pulmonary embolism is important. A thorough history and a reason for transport should be ascertained.

Bifascicular Blocks

As the name of this condition implies, two conduction pathways are blocked at the same time. A **bifascicular block** includes concurrent findings of right BBB with LAH or LPH.

When right BBB with LAH occurs as a chronic condition, it is considered stable. A new onset of bifascicular block with ischemia, however, is not stable. This presentation will show a right BBB pattern with a slurred s wave in leads I and V_6 and an up-and-down (rabbit ear) appearance of the RSR′ in V_1. The QRS duration will be 120 milliseconds or longer. In addition, with LAH, the typical pattern will include an LAD and rS waves in lead III.

A bifascicular block with a right BBB and an LPH is always considered an unstable rhythm. Owing to the amount of myocardium that has to be damaged to cause a true LPH, it commonly involves other conduction pathways of the ventricles (tight bundle branch). This block often deteriorates into a complete heart block, especially in the presence of an acute MI. Because of the extensive damage it takes to cause an LPH, it does not take much more to progress to a higher degree of block. When a bifascicular block includes a right BBB and an LPH, the typical right BBB pattern with RAD and a small q wave in lead III will be found. **Figure 13-37** illustrates two bifascicular block patterns. The right BBB is in black, the LAH is in blue, and the LPH is in green.

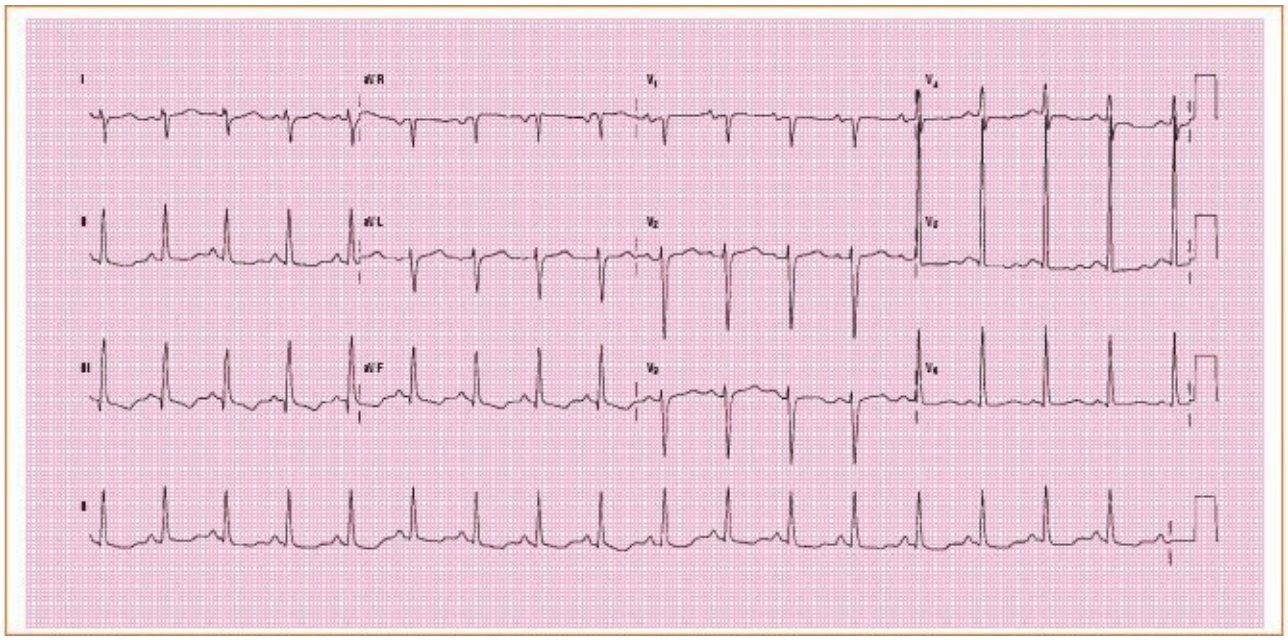

Figure 13-36 A 12-lead electrocardiogram showing a left posterior hemiblock.

Figure 13-38 provides an example of a bifascicular block that includes a right BBB with an LAH. First, the ECG should be scanned for abnormal patterns. In the example, the QRS intervals are 120 milliseconds or more. There is a slurred S wave in leads I and V_6. An RSR′ is present in lead V_2. (RSR′ can be found in the septal precordial leads V_1 and/or V_2.) These criteria so far indicate a right BBB. The evaluation is continued, and the mean electrical axis is determined. The QRS complex is positively deflected in lead I and negatively deflected in aVF, indicating an LAD. To further isolate the axis, lead II is examined. It is negatively deflected, placing the axis between –30° and –90°, the pathologic left axis. This finding provides the additional criterion to determine that an LAH is also present. Bifascicular blocks with a right BBB and an LAH are generally stable unless they occur in the presence of an acute MI. The additional ischemia and tissue death could take out the remaining left posterior fascicle, causing a complete heart block. In a critically ill cardiac patient with an existing bifascicular block consisting of a right BBB and an LAH, signs of ischemia or infarction indicate the need for an acute pacemaker placement, especially in the presence of a second- or third-degree AV block. This procedure will not likely be available in the transport setting, so medical control should be contacted and the patient should be prepared for external cardiac pacing. The receiving facility may need to be urgently prepared for pacemaker placement and should be notified of developments so that an implantable pacemaker will be available without delay on arrival.

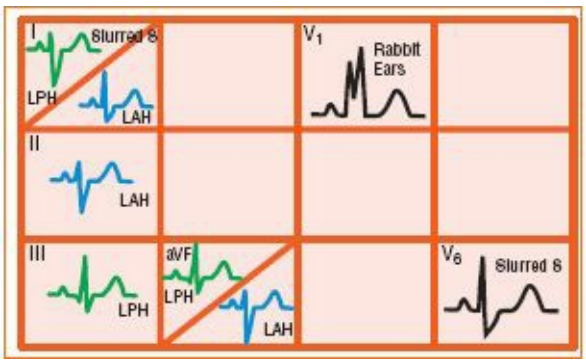

Figure 13-37 Electrocardiographic changes seen with a bifascicular block.

Figure 13-39 provides an example of a bifascicular block with a right BBB and an LPH. First, the

ECG is scanned for abnormal patterns. Slurred S waves are found in leads I and V_6. There is an RSR′ in V_1 consistent with a right BBB. The axis is determined to be in the right quadrant because the RSR is negatively deflected in lead I and positively deflected in aVF. To further isolate the axis, the most isoelectric limb lead with the smallest amplitude should be found. In this example, it is lead aVR. In the hexaxial system, the perpendicular lead (90° away) to aVR is lead III. Lead II should be assessed to determine if it is positively or negatively deflected. In this case, lead II is positive, placing the mean electrical axis at + 120° (RAD). There is also an S wave in lead I and a qS complex in lead III, consistent with an LPH. There are no exclusionary findings to contradict a diagnosis of LPH. Finally, in this example, there is also a first-degree heart block. This pattern of a right BBB with an LPH is inherently an unstable rhythm owing to the extensive myocardial damage necessary to cause the LPH in the first place. Additional ischemia or even a small infarction could extend the conduction defect to include the anterior fascicle as well.

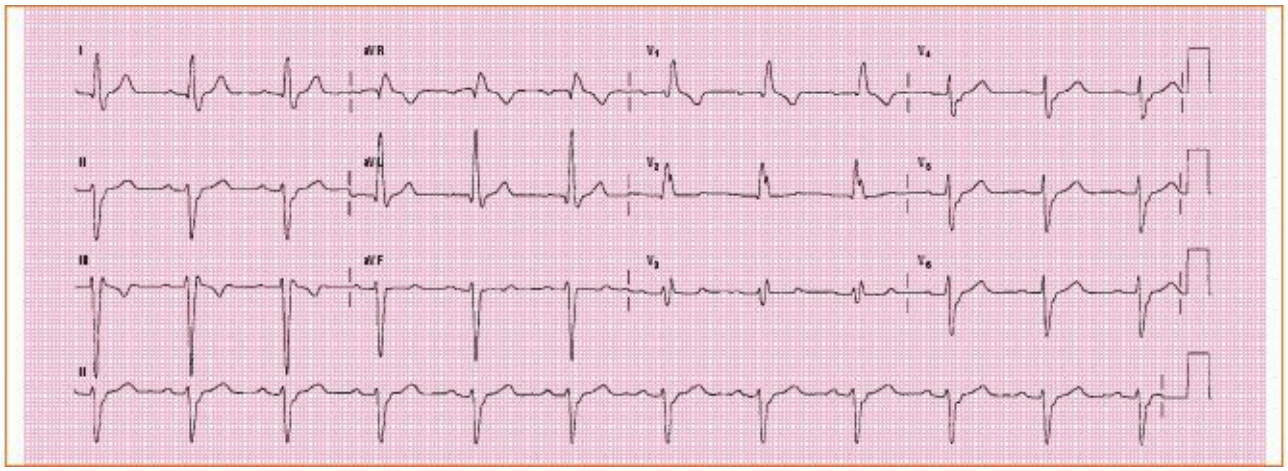

Figure 13-38 A 12-lead electrocardiogram showing a bifascicular block with a right bundle branch block and a left anterior hemiblock.

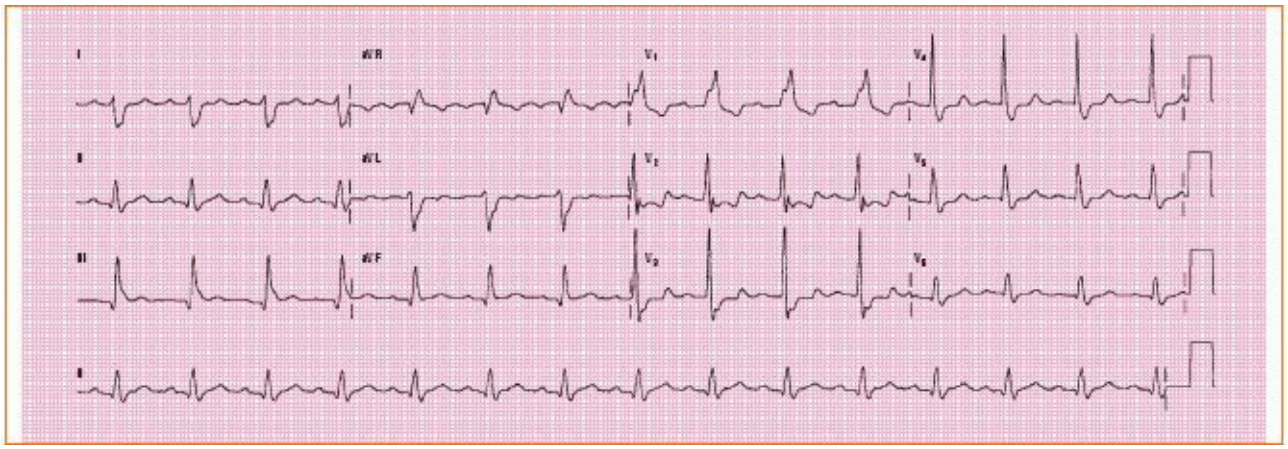

Figure 13-39 A 12-lead electrocardiogram showing a bifascicular block with a right bundle branch block and a left posterior hemiblock.

Trifascicular Block

The term **trifascicular block** is used to describe the combination of bifascicular block (right BBB with a block in the left anterior fascicle or left posterior fascicle) that occurs with a first-degree heart block (prolonged PR interval). Trifascicular block is important to diagnose because it is difficult to tell if the prolonged PR interval seen with the first-degree heart block component is the result of disease in the AV

node or to diffuse distal conduction system damage. If the block at the AV node level becomes a complete heart block, the escape rhythm that will originate is from the bundle of His. This escape rhythm will produce heart rates in the 40s and be symptomatic for fatigue, near-syncope, or complete syncopal episodes. If there is diffuse conduction system damage, the escape rhythm may be fascicular or ventricular, which may result in heart rates that are life-threateningly low.

The presence of a trifascicular block after an MI implies extensive cardiac damage. True trifascicular blocks require immediate temporary pacing followed by the placement of a permanent pacemaker.

Selected ECG Findings

The following ECG findings have been selected for review because they can appear alone or coexist with the conditions already discussed. They may help CCTPs identify the many changes in structure and function that occur with chronic conditions or during an acute cardiac event and, hopefully, help put the pieces of the clinical puzzle together and show how they reflect onto the ECG.

Hyperacute T Waves

Within the first few minutes of coronary occlusion, the T wave can become tall and narrow because of the ischemia that is present. This is called peaking and is sometimes referred to as a hyperacute T wave. This presentation is transient, beginning within minutes to a few hours before the T wave inverts (flips). The first change that might appear with hyperacute T waves is an upward slanting of the ST segment and a subtle enlargement of the T wave that is disproportionate to the QRS complex. The hyperacute T waves are localized to the area of ischemia and infarction and may be associated with depression of the J point and a prolonged QT interval. The hyperacute T waves are different from those seen in other conditions. In hyperkalemia, for example, the T wave peaking will be tall and narrow and have a "tenting" appearance. These T-wave changes will appear through all leads of the ECG. Hyperacute T waves that appear as a result of ischemia and infarction appear only in leads that view the area of ischemia and infarction.

ST-Segment Elevation

ST-segment elevation is caused by changes that affect ventricular depolarization and repolarization. Non-MI changes can also cause this condition and include left BBB, ventricular rhythms, LVH, pericarditis, and early repolarization.

As the complete ECG picture of infarction evolves, within a few hours the ST segment usually returns to baseline. A persistent ST-segment elevation may indicate the formation of a ventricular aneurysm.

In addition to myocardial injury, ST-segment elevation can be seen in a number of other conditions, such as early repolarization, and is made evident by elevation of the J point. The J point is where the ST segment "takes off" from the QRS complex, and elevation in the absence of other findings has no pathologic implications. The way to determine the difference between benign elevation of the J point and elevation caused by myocardial injury is by the distinctive configuration seen with myocardial disease. In benign J-point elevation, the T wave is clearly distinguished as a separate wave. With myocardial disease, the elevated J point bows upward and merges with the T wave **Figure 13-40**.

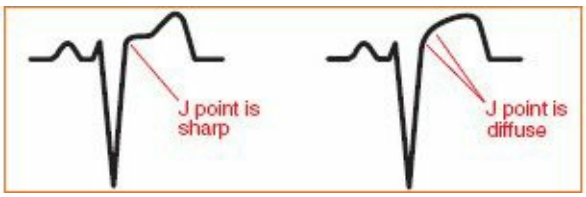

Figure 13-40 Sharp and diffuse J points.

Differential Diagnosis

ST-Segment Elevation

- Myocardial disease
- Left BBB
- Ventricular rhythms
- LVH
- Pericarditis
- Early repolarization
- Ventricular aneurysm

Hypertrophy

Hypertrophy is thickening or excessive growth; in this chapter, it refers to any chamber of the heart. Hypertrophy is an increase in muscle mass caused by an increased workload on the heart when it has to pump against resistance. Dilation is an enlargement of the chamber cavity, and both conditions can occur together. The end result is that the heart has a larger mass in the affected area. As discussed in the section on axis determination, the larger the muscle mass, the higher the concentration of electrical impulses or vectors.

Atrial Enlargement

Left atrial enlargement results in a prolonged electrical conduction time through the left atrium. With normal electrical conduction being initiated by the SA node in the right atrium, the initial impulse is transmitted without delay through this smaller chamber and is recorded on the ECG as the beginning or leading side of the P wave. As the electrical impulse is delayed through the enlarged left atrium, it gives rise to the end or trailing side of the P wave. Overall, the resulting P wave has a notched double-humped appearance **Figure 13-41**.

A P wave that is greater in duration than 120 milliseconds in limb leads I and II and has a notched appearance is known as **P mitrale**.

Right Atrial Enlargement

Right atrial enlargement is caused by cardiac and pulmonary conditions affecting the pressures in the right atrium. Causes include mitral stenosis or regurgitation, chronic obstructive pulmonary disease, and pulmonary emboli. It occurs commonly in the pulmonary condition **P pulmonale**, characterized by tall, peaked P waves found in leads II and III that have an amplitude of 2.5 mm (2.5 mV) or more. P waves can be peaked, but must be 2.5 mm or higher; if they are less than 2.5 mm, they are not typically associated with right atrial enlargement **Figure 13-42**.

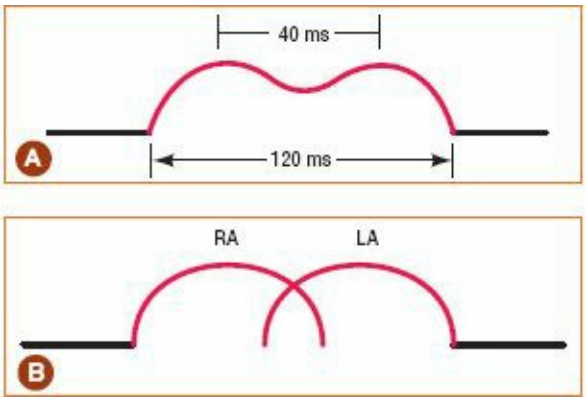

Figure 13-41 **A.** A notched P wave greater than 120 milliseconds in the limb leads shows P mitrale. **B.** The cause of a notched P wave. LA indicates left atrium; RA, right atrium.

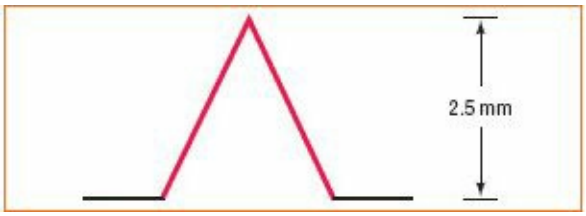

Figure 13-42 P pulmonale.

When the evidence suggests atrial enlargement, but the measurements are not enough to make the diagnosis, some different P-wave patterns might emerge. **Biphasic** P waves in lead V_1 are common. The biphasic P wave indicates nonspecific **intra-atrial conduction delay**. Often, biphasic P waves seen in IACD are related to atrial enlargement, but the wave is not significant enough to be classified as P mitrale or P pulmonale.

Comparing the P waves in leads V_1 and V_6 can be helpful. When the leading half of the P wave is taller and wider in V_1 than it is in V_6, right atrial enlargement is probable. If the trailing half of the P wave is wider and deeper than the leading upright half is in V_1, left atrial enlargement is probable. If the trailing end of the P wave is wider and deeper than one small block on the ECG (1 mm in height by 40 milliseconds in duration), left atrial enlargement is likely.

Both atria can be enlarged at the same time, referred to as biatrial enlargement. To make the determination of biatrial enlargement, any combination of the aforementioned criteria can be applied. For example, in the inferior leads II, III, and aVF, with lead II being the best view for left atrial enlargement, a notched P wave greater than 120 milliseconds in duration or a tall, peaked P wave of 2.5 mm or more in amplitude is found. Then in lead V_1, there is a biphasic P wave meeting the criteria for right or left atrial enlargement. Any combination of right atrial enlargement and left atrial enlargement equals biatrial enlargement **Figure 13-43**.

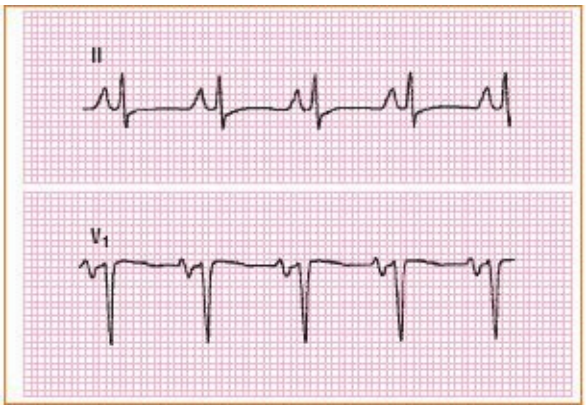

Figure 13-43 Biatrial enlargement.

Left Ventricular Hypertrophy

An enlargement or an increase in muscle mass of the left ventricle is known as LVH. LVH is the end-organ response to increased pressure or overload seen in hypertension. With increased detection and aggressive treatment of hypertension, there is a relative decrease in the ECG incidence of LVH. Patients who have evidence of LVH on the ECG have a higher risk of developing coronary artery disease, making them more susceptible to the sequelae of that disease. People who have LVH are actually more susceptible to increased mortality than people who experience an MI without an LVH.

Although a normal axis is the most common, a physiologic LAD is often present. A pathologic left or right axis can occur with LVH, but the hypertrophy is usually not the cause. In general, the increased R wave amplitude in the leads that look at the left ventricle forms the basis of an ECG diagnosis of LVH. The increased amplitude of waves seen on the ECG, in particular the precordial leads, is caused by a two-fold process. First, as the left ventricle enlarges, there is a greater concentration of vectors, increasing the wave of depolarization toward the precordial leads. Second, the increase in muscle mass typically extends anteriorly, bringing the heart physically closer to the electrodes on the chest. This positioning may be the reason for a normal axis instead of a pathologic axis deviation.

There are several ECG criteria used to determine LVH; however, for simplification, increased R wave amplitude in leads overlying the left ventricle and increased S wave amplitude in leads overlying the right ventricle are discussed. To assess for LVH, the deepest S wave in V_1 or V_2 is found, followed by the tallest amplitude of R wave in V_5 or V_6. If the sum of the deepest S wave and the tallest R wave is 35 mm or more, LVH is likely. The following criteria are very useful in making a determination of LVH. The more criteria that are met, the greater the likelihood that the patient has LVH.

1. Any precordial lead of 45 mm or more
2. An R wave in aVL of 11 mm or more
3. An R wave in lead I of 12 mm or more
4. An R wave in lead aVF of 20 mm or more

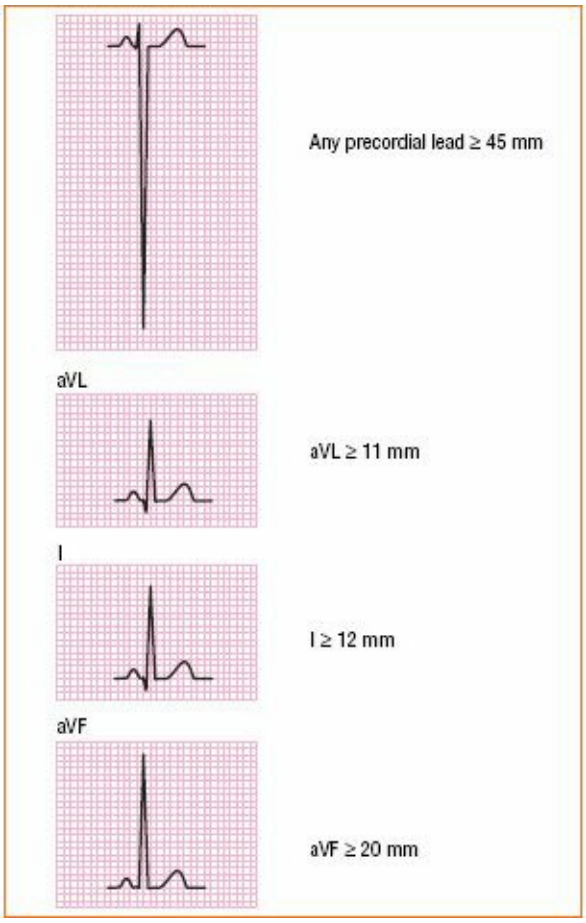

Figure 13-44 Examples of criteria for left ventricular hypertrophy.

Figure 13-44 demonstrates several criteria for the diagnosis of left ventricular hypertrophy.

The ECG in **Figure 13-45** also demonstrates several criteria for the diagnosis of LVH. The S wave is largest in V_1, which is added to the largest R wave found in V_6; the sum is 45 mm or more. Second, the R wave in aVL is well beyond the criterion of being 11 mm or more. In lead I, the R wave is clearly 12 mm or more. More than one of the criteria typically exist on the same ECG, and as many as possible should be found.

Right Ventricular Hypertrophy

The right ventricle can also become hypertrophied. This is usually caused by right ventricular overload because of a pulmonary disease such as pulmonary hypertension. The ECG is quite different in RVH than in LVH because of the electrical vectors being drawn in the anterior and rightward direction. Therefore, a right shift in axis in leads I and aVF and in precordial leads V_1 and V_2 for increased R wave deflection would be expected **Figure 13-46**.

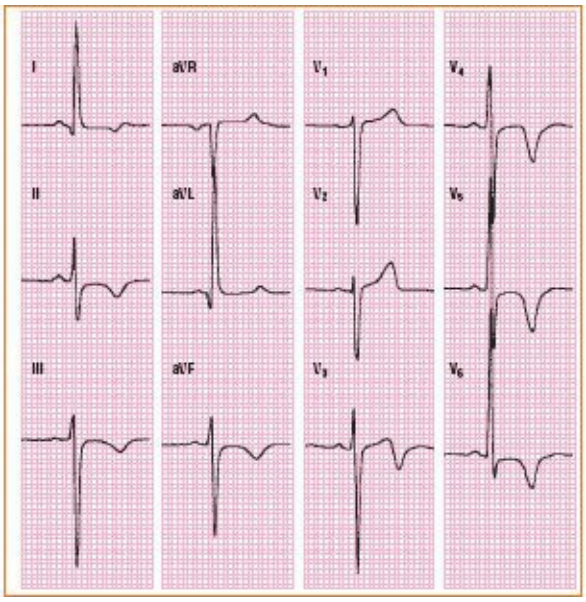

Figure 13-45 A 12-lead electrocardiogram showing several criteria for left ventricular hypertrophy.

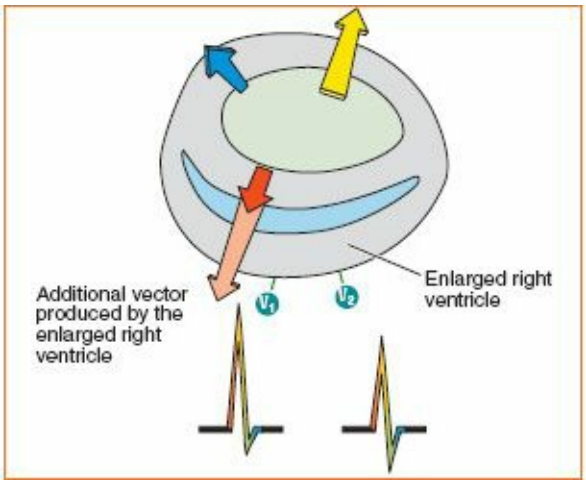

Figure 13-46 Right ventricular hypertrophy.

In RVH, the first finding is often a large R wave in lead V_1 or V_2. This should stand out because during normal conduction, there would be a larger S wave. Owing to the large R waves seen in V_1 or V_2, the normal R-wave progression pattern is altered. The shift of electrical vectors may also cause an S wave in V_6 that is larger than the R wave. The other criterion for RVH is the RAD that lies between 100° and 180°.

Strain Pattern

When severe ventricular hypertrophy occurs, the myocardium can become so thick that the coronary blood supply may be reduced. As a result, the subendocardium, or innermost layer of the heart, is most likely to become ischemic. When hypertrophy is uncomplicated by ischemia, the changes seen in QRS complexes are used to diagnose ischemia. When subendocardial ischemia is present, changes to the ST segment and T wave also appear as a **strain pattern**.

In LVH, the strain pattern in the right precordial leads, V_1 to V_3, is seen as ST-segment elevation with a concave appearance of the upward slope. The T wave is upright and asymmetric in these leads. The precordial leads V_4 to V_6 show a downward-sloping ST-segment depression with an inverted asymmetric T wave. The key to identifying the strain pattern is that it is greatest in the lead with the tallest

and deepest QRS pattern.

The ECG in **Figure 13-47** shows LVH with strain. First, the criteria are met to make the diagnosis of LVH by adding the S wave in V_2 to the R wave in V_5, and the sum is 35 mm or more. The strain pattern is demonstrated by the concave up-sloping of the ST segments in the right precordial leads V_1 and V_2 with asymmetric upright T waves. The right precordial leads V_5 and V_6 show the strain pattern as down-sloping ST segments with asymmetric inverted T waves.

Strain patterns also occur in RVH. The mean electrical axis is anterior and to the right, causing an RAD. This situation causes an increased R wave in the right precordial leads V_1 and V_2. The associated strain pattern shows a downward-sloping depressed ST segment and inverted asymmetric T waves. If the T wave is biphasic instead of inverted, the leading half will usually be negatively deflected and the trailing half will be positive in RVH.

It is important to distinguish between the strain pattern and ST-segment and T-wave changes seen in ischemia and infarction. The strain pattern is problematic, but the ST and T-wave changes can be immediately life threatening. The key is to look closely at the shapes of the patterns. The ST-segment elevations or depressions in ischemia are usually flat and not sloping. The T waves in ischemia are usually symmetric and not asymmetric. Another key used to define the two entities is the J point. In ischemia or infarction, the J point is more sharp or clearly defined. The point at which the T wave takes off from the ST segment is seen. In LVH with strain, the J point is usually more diffuse and slopes up or down depending on the lead being viewed. The clinical correlation between ECG findings and other patient information is most important.

Preexcitation Syndromes

The preexcitation syndrome that is of most interest in the critical care setting is **Wolff-Parkinson-White (WPW) syndrome**. The many situations that occur as a complication to this syndrome should be studied in depth in a cardiology or 12-lead ECG textbook. This section briefly reviews WPW syndrome.

WPW syndrome occurs when there is an accessory pathway for electrical current to bypass the AV node to enter the ventricles. It occurs in less than 3% of the population. This pathway is known as the bundle of Kent. In people with WPW syndrome, the accessory pathway does not have the same ability to slowly conduct electrical impulses as it does through the AV node, which puts the person at risk for extremely fast heart rates that cause hemodynamic instability. The accessory pathway can occur on the right side, connecting the right atrium to the right ventricle, or on the left side, connecting the left atrium to the left ventricle.

There are two basic events when premature ventricular depolarization occurs through the accessory pathway. First, the PR interval is shortened to less than 120 milliseconds. Second, the QRS complex is widened to more than 100 milliseconds. The widening is not the result of a delay in ventricular activation but rather the result of premature activation. Typically in WPW syndrome, most of the ventricular depolarization is activated through the normal conduction pathways. The electrical impulse that passes unobstructed through the bundle of Kent causes early depolarization of a section of the ventricle, resulting in a QRS complex that has a characteristic slurred upstroke called a **delta wave** **Figure 13-48**. The delta wave is not seen in all leads, so all leads should be checked.

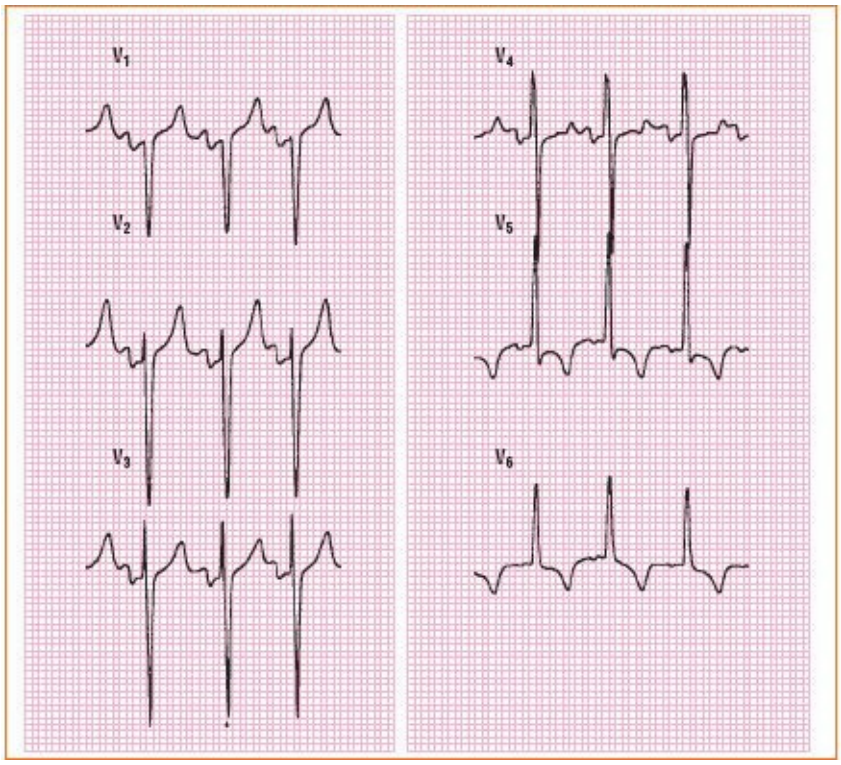

Figure 13-47 Precordial leads showing left ventricular hypertrophy with strain.

In many people with WPW syndrome, the preexcitation causes few clinical problems. It is well documented, however, that this syndrome can predispose a person to dangerous tachyarrhythmias. The two tachyarrhythmias that occur most often in WPW syndrome are **paroxysmal supraventricular tachycardia** (a supraventricular tachycardia [SVT] that starts and ends abruptly) and atrial fibrillation.

In the critical care transport setting, CCTPs should be aware of the potential for wide complex tachycardia developing that is difficult to distinguish from VT.

In WPW syndrome, when tachycardia is present, the electrical impulses can travel down the normal conduction pathway, through the AV node, and back up the accessory pathway. This condition is called orthodromic and usually results in a narrow complex tachycardia. The abnormal conduction can progress the other way as well, in which the electrical impulse travels through the accessory pathway and back up through the AV node. This condition is called antidromic and causes a wide complex tachycardia. The antidromic tachycardias can be very fast if caused by atrial fibrillation or flutter in which transmission is one to one.

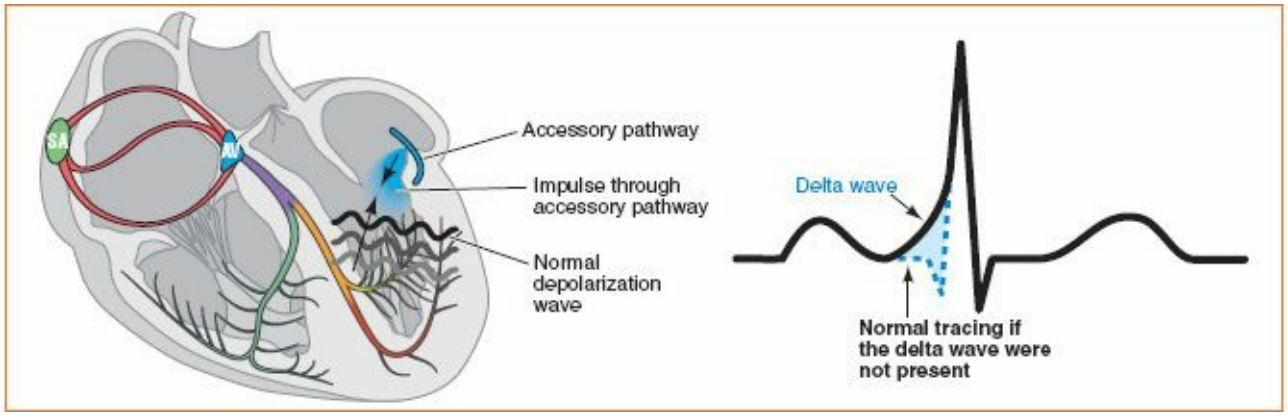

Figure 13-48 Impulse propagation through an accessory pathway and formation of the delta wave.

Transport Management

Wolff-Parkinson-White Syndrome

- Provide electrical cardioversion if the patient's condition is unstable.
- Administer procainamide, but only under the direction of a cardiologist and if the patient is in stable condition.

Treatment of WPW tachyarrhythmias may require electrical cardioversion if they are unstable. Electrical cardioversion is considered the safest treatment. Management with drug therapy produces unpredictable results. Previously, patients with WPW syndrome and atrial fibrillation with rapid ventricular response may have been treated with amiodarone (Cordarone) to stabilize the heart rate, but this treatment has fallen in disfavor because of the possibility of degrading to ventricular fibrillation.

Under the direction of a cardiologist and if the patient is in stable condition, procainamide (Procanbid, Pronestyl, Pronestyl-SR, Procan SR) may also be administered while watching for hypotension to develop and watching for widening of the QRS. Procainamide blocks the accessory pathway but increases conduction through the AV node. Because of the risk of hypotension with rapid IV administration, slow IV infusion is required. Procainamide given slowly has a prolonged onset of action and may not reach therapeutic levels for 40 to 60 minutes. Procainamide may control the atrial fibrillation rate through the accessory pathways, but because of the increased conduction through the AV node, it can also create a dangerous conventional atrial fibrillation. Careful consideration of all variables is necessary to make the right therapeutic decision. In any patient with WPW syndrome and atrial fibrillation, particularly if hemodynamic instability is occurring, cardioversion is the treatment of choice.

The use of adenosine (Adenocard) and other AV node blockers (diltiazem [Cardizem, Dilacor, Tiazac], verapamil [Calan, Covera, Isoptin, Verelan], other calcium channel blockers, and beta-blockers) in atrial fibrillation and atrial flutter should be avoided. Patients with a rapid heart rate and narrow complex tachycardias may also undergo cardioversion.

The definitive treatment for WPW syndrome is ablation of the accessory pathway.

Controversies

Although amiodarone is often thought to be safe in atrial fibrillation with WPW syndrome, it is not. In a case series of twelve patients who received amiodarone, seven experienced ventricular fibrillation. The safest treatment of WPW tachyarrhythmias is cardioversion.

Pericarditis

Pericarditis is an inflammation of the pericardium, the membrane that surrounds the heart. It can be caused by a number of disorders and conditions, such as infection, MI, autoimmune disorders, chest trauma, cancer, drugs, and other causes.

Pericarditis may cause ST-segment elevation and T-wave flattening or even inversion. These ECG findings are consistent with evolving MI, and the signs and symptoms can also mimic an MI. There are features on the ECG that can be helpful to distinguish the two. First, the ST-segment and T-wave changes in pericarditis tend to be throughout all leads of the ECG. The same changes seen with ischemia, injury, and infarction tend to occur only in the leads that are viewing the affected area of the heart. In

pericarditis, the T wave usually does not invert until the ST segment has returned to baseline. In infarction, inversion of the T wave occurs after ST-segment elevation. Finally, Q waves do not form in pericarditis.

Another finding on an ECG that is consistent with pericarditis is the appearance of low voltage in all leads because of pericardial effusion that often accompanies pericarditis. ST and T-wave changes can usually still be seen in this situation. Fluid in the pericardial sac can cause a condition called **electrical alternans** because the heart is able to move or rotate. The electrical axis can vary from beat to beat and is most easily recognized on the ECG by the varying amplitude of each complex.

Long QT Syndrome

Long QT syndrome is a congenital disorder that can be worsened by a variety of factors, including physical exertion, female sex, electrolyte disturbances (hypokalemia and hypomagnesemia), hypothermia, abnormal thyroid function, structural heart disease, bradycardia, medications, and drug overdose **Table 13-6**.

Long QT syndrome is characterized by the prolonged QT interval as seen on the ECG; under certain conditions, it has a tendency to deteriorate into ventricular tachyarrhythmias, including **torsade de pointes** (a very rapid rhythm related to VT), which can lead to syncope or sudden cardiac death. The rhythm is too fast to maintain effective CO, so the patient loses consciousness, often without warning.

TABLE 13-6 Drug Classes That May Worsen Long QT Syndrome

Antianginal
Antiarrhythmic
Antibiotics
Anticancer
Antihistamine
Anti-infectives
Antimalarial
Antinausea
Antipsychotic
Gastrointestinal stimulants
Opiate agonists
Sedatives

It is the deterioration of long QT syndrome that poses a management challenge for CCTPs. Carefully evaluating the ECG, reviewing the patient's medications, and obtaining a medical history will help provide clues to the diagnosis and will alert about the possibility of a tachyarrhythmia developing during transport. For example, CCTPs who will be transporting a cardiac patient who has recently started taking a n **antiarrhythmic** known to increase the QT interval (such as amiodarone [Cordarone]) should be prepared to treat any adverse effects.

As mentioned, long QT syndrome occurs primarily as a congenital defect but can be caused by a

variety of conditions, medications, and drug overdoses. The measurement of the QT interval depends on the heart rate (the faster the heart rate, the shorter the QT interval; the slower the heart rate, the longer the QT interval) and, therefore, must be corrected to make this adjustment. The corrected QT interval, or QTc, as printed on the 12-lead ECG, has already been corrected for heart rate by the cardiac monitor's diagnostic software.

The QT interval is measured from the start of the Q wave to the end of the T wave. Normal values for the QTc are between 300 and 440 milliseconds for men and between 300 and 450 milliseconds for women. During transport, if any patient's QTc reaches 500 milliseconds and the patient's rhythm has not deteriorated into a ventricular tachyarrhythmia such as torsade de pointes, preventive medical intervention may be indicated. This intervention includes correcting electrolyte imbalance, the use of beta-blockers (such as propranolol [Inderal]), and being prepared to treat a developing ventricular tachyarrhythmia.

Typically, long QT syndrome is asymptomatic until the patient becomes physically active or experiences emotional stress (eg, during critical care transport). Symptoms usually begin in the preteen to teenage years but can be present from right after birth to middle age. The initial clinical sign of sudden loss of consciousness is often misdiagnosed as a vasovagal event or seizure. To make the correct diagnosis, a health care provider should give close attention to a history of loss of consciousness during physical activity.

Long-term treatment for this condition is with beta-blockers. They should be started for women who have QTc-interval prolongation of greater than 460 milliseconds and for men who have a QTc-interval prolongation of greater than 440 milliseconds. Patients who cannot tolerate or do not respond well to the medication may need a pacemaker, an ICD (discussed later in this chapter), or a surgical procedure called a cervicothoracic stellectomy.

In the critical care transport setting, CCTPs should watch for the prolonged QTc and the tachyarrhythmias that may develop as a result. Torsade de pointes can occur in short bursts of 15 seconds or less or as a longer hemodynamically unstable rhythm. The treatment for torsade de pointes includes correcting the underlying cause, overdrive pacing, and the IV administration of magnesium sulfate in a dose of 1 to 2 g. Other therapies for patients in unstable condition may include electrical cardioversion and defibrillation. Basic and advanced life support measures should be used as directed by local protocol and national standards. This example is for illustration only, and all treatment should be under direct supervision of a physician or within standing protocols approved by the agency or jurisdiction.

Transport Management

Prolonged QT Syndrome

Preventive Measures

- Correct the electrolyte imbalance.
- Administer a beta-blocker (such as propranolol [Inderal]).
- Be prepared to treat a developing ventricular tachyarrhythmia.

Torsade de Pointes

- Consult with a physician or standing protocols.
- Apply BLS and ALS measures.
- Correct the underlying causes (such as hypomagnesemia and drug overdose).
- Consider initiating overdrive pacing.
- Consider administering magnesium sulfate.

- Consider initiating electrical cardioversion or defibrillation for patients in unstable condition.

Ventricular and Wide Complex Tachycardia

Wide complex tachycardia in general refers to a cardiac rhythm of more than 100 beats/min with a QRS duration of 120 milliseconds or more. This rhythm can present a diagnostic dilemma for health care providers because it can be of ventricular or supraventricular origin. Identifying the origin of the arrhythmia can lead to the correct diagnosis and proper therapeutic interventions.

The differential diagnosis for wide complex tachycardia includes the following major categories:

- VT (most common)
- SVT with aberrance
- Preexcited tachycardias
- Electrographic artifact
- Ventricular paced rhythms

Evaluation of the electrocardiogram is the cornerstone for making the correct diagnosis of wide complex tachycardia. A variety of different diagnostic criteria have been suggested to distinguish the various origins of wide complex tachycardia, and each has its own sensitivity and specificity. This section discusses some of the more common methods of making the diagnosis.

Differential Diagnosis

Wide Complex Tachycardia

- VT
- SVT with aberrance
- Preexcited tachycardias
- Electrographic artifact
- Ventricular paced rhythms

Transport Management

Wide Complex Tachycardia

Patients in a Hemodynamically Unstable Condition

- Perform synchronized cardioversion.
- Give an antiarrhythmic drug to maintain a stable rhythm.

Patients in a Hemodynamically Stable Condition

- Review the history, physical examination, and ECG findings.
- Give amiodarone (Cordarone; first choice) or procainamide (Procanbid, Pronestyl, Pronestyl-SR, Procan SR).
- Give lidocaine (Xylocaine), in case of VT of ischemic origin.
- Give adenosine (Adenocard), if SVT is suspected.
- Give an antiarrhythmic drug to maintain a stable rhythm.

New-Onset Wide Complex Tachycardia (During Transport)

- Provide basic life support (the ABCs).
- Initiate ACLS measures.
- Initiate immediate defibrillation.
- Secure the airway.
- Provide CPR.
- Perform endotracheal intubation.
- Support ventilations with a bag-mask device with supplemental oxygenation.
- Continue CPR as indicated.
- Administer epinephrine or a one-time dose of vasopressin.
- Circulate the medication by performing CPR and repeated defibrillations.
- Give amiodarone if ventricular fibrillation or pulseless VT persists.
- Alternatively, give lidocaine, magnesium sulfate, or procainamide.

The most useful ECG criterion for establishing the diagnosis of VT is the presence of AV dissociation with more ventricular than atrial events. This finding practically rules out an SVT origin. An AV dissociation can be implied during wide complex tachycardia with the presence of fusion beats (simultaneous activation of the ventricular myocardium through normal conduction and from an ectopic ventricular focus). A capture beat or Dressler beat that is seen in VT is a narrow QRS complex that results from an atrial electrical impulse (p wave) that captures the ventricular myocardium through the normal conduction system. A narrow complex beat can also be seen during wide complex tachycardia in a patient with SVT and BBB when a premature ventricular beat originates from or close to the nonconducting bundle branch and fuses with the impulse traveling down the contralateral bundle. This results in a simultaneous ventricular depolarization on both sides of the septum and is demonstrated by a narrow QRS complex.

The QRS duration can also be used to help distinguish between VT and SVT. Studies have shown that nearly 70% of VTs have a QRS duration greater than 140 milliseconds; SVTs typically never have a QRS duration greater than 140 milliseconds. To further expand this criterion, in a patient with a right BBB with a QRS duration of greater than 140 milliseconds, VT is the likely diagnosis. In a left BBB, a QRS duration of greater than 160 milliseconds indicates VT.

The electrical axis seen during wide complex tachycardia is also useful to determine the origin of the arrhythmia. If the axis is 180° to –90° (extreme RAD), the wide complex tachycardia is not likely to be an SVT because this pattern is inconsistent with any type of typical bundle branch or fascicular block. If there is electrical concordance across the precordium (all QRS complexes pointing in the same direction in ECG leads V_1 through V_6), the tachycardia is more likely a VT and is rarely consistent with an SVT.

The morphologic features of the QRS complex provide another way to help identify the different origins of wide complex tachycardia. The usefulness in distinguishing VT from SVT in a wide complex tachycardia is limited, however, because some measurements are required, making the method less accurate and more time consuming in a moving transport vehicle. The following discussion of QRS morphologic features in wide complex tachycardia is provided to help CCTPs better understand the various ECG findings with wide complex tachycardia from different origins. In a patient with a right BBB, the precordial lead V_1 should be examined. If the left R wave is taller than the R′ or if the QRS is biphasic with an Rs or qR pattern, the origin of wide complex tachycardia is likely VT. In a patient with a left BBB, again, precordial lead V_1 should be examined. If the duration of the initial r wave is greater than 30 milliseconds, the time from the beginning of the QRS to the nadir of the S wave is greater than 70

milliseconds, and the down stroke of the S wave is notched, the origin is likely to be VT. If the QRS complex in precordial lead V_6 has a monophasic QS or biphasic rS with an r to S ratio of less than 1 during a right BBB wide complex tachycardia, VT is likely. If the intrinsicoid deflection (beginning of the QRS complex to the beginning of the down slope of the R wave) in the precordial lead V_6 is greater than 80 milliseconds, VT is the likely origin of the wide complex tachycardia.

Management

The initial management of patients in wide complex tachycardia primarily depends on their hemodynamic status. Patients who have low blood pressure, pulmonary edema, severe chest pain, or other evidence of poor perfusion associated with the wide complex tachycardia should be promptly treated using synchronized cardioversion.

When a patient with wide complex tachycardia remains in hemodynamically stable condition, more time can be spent reviewing information from the history, physical examination, and ECG findings. As mentioned, the majority of cases of wide complex tachycardia are VT. Making the correct diagnosis, however, is the safest approach to management.

With a patient with wide complex tachycardia in whom the cause is uncertain and the patient's condition is hemodynamically stable, amiodarone (class III [Cordarone]) is the drug of choice because it can terminate SVT and VT. It is also useful in patients with a poor ejection fraction (the percentage of blood ejected out of the left ventricle during each contraction) because of its favorable hemodynamic profile.

Procainamide (class IA [Procanbid, Pronestyl, Pronestyl-SR, Procan SR]) can also be used with caution in patients with wide complex tachycardia in hemodynamically stable condition. There are several disadvantages to using procainamide. It can cause a sudden drop in blood pressure with rapid IV administration and is contraindicated in patients with complete heart block during wide complex tachycardia because it suppresses the nodal or ventricular pacemakers and can result in asystole. As with all drugs, its indications and contraindications should be fully understood before administering it to any patient.

Lidocaine (Xylocaine; class IB) is useful for VT of ischemic origin, but it does not terminate SVT. In a patient who is conscious and in hemodynamically stable condition, in higher doses, it can cause confusion.

If SVT is suspected, adenosine (Adenocard) is a useful and diagnostic medication. It works by blocking conduction through the AV node, which is an essential part of the tachycardia circuit in most SVTs. It can sometimes terminate atrial tachycardias and, rarely, VT. Because adenosine has a very short half-life, it rarely causes complications in patients with wide complex tachycardia. An exception is a patient with an irregular wide complex tachycardia as a result of atrial fibrillation and preexcitation over an accessory pathway. In this case, adenosine can block conduction through the AV node, allowing only conduction through the accessory pathway, and may lead to ventricular fibrillation.

Following termination of wide complex tachycardia, preventive treatment for maintaining a stable rhythm should be initiated. This treatment will help prevent recurrent episodes, minimize the patient's symptoms, and help protect the patient from sudden cardiac death. For CCTPs, intervention is generally limited to pharmacologic treatment with antiarrhythmic drugs, usually a continuation of the drug that terminated the wide complex tachycardia in the first place. Additional in-hospital treatments may include the use of an ICD and catheter ablation procedures.

Patients with or whose rhythm converts to wide complex tachycardia rhythm can pose a diagnostic dilemma, especially for a transport team in transit. At times, only minimal information about the patient's history and clinical and laboratory findings is known. If wide complex tachycardia develops during transport, a rapid evaluation must be performed and the appropriate treatment must be initiated in a

confined environment with relatively limited resources. BLS is always the first step in patient management, closely followed by ACLS practices. If the patient is in a hemodynamically unstable condition, wide complex tachycardia should be managed as if it were VT until proven otherwise, and synchronized cardioversion would be the initial therapy of choice.

Polymorphic or pulseless VT should be treated as ventricular fibrillation. If this is a witnessed condition that occurs during transport, the patient should already be connected to a cardiac monitor and have a patent IV line. The patient may also already have a secured airway. Immediate defibrillation is indicated because it is a witnessed arrest. The treatment should be in accordance with current standard American Heart Association/BLS/ACLS guidelines and include the following steps: Defibrillate at 200, 200 to 300, and then 360 J; if using a biphasic defibrillator, use three consecutive shocks at 150, 150, and then 200 J. Ensure that the airway is secured, and provide CPR as indicated. Perform endotracheal intubation if the tube is not already in place, and support ventilations with a bag-mask device with supplemental oxygenation. Continue CPR as indicated. Because the patient should already have an IV line in place, epinephrine may be initially administered, 1.0 mg IV, and repeated at 3- to 5-minute intervals as long as the arrhythmia persists. (Peripheral IV lines in a transport setting can be particularly vulnerable to becoming dislodged. If this occurs, until another line can be established, the following medications can be administered through a patent endotracheal airway: epinephrine, atropine, and lidocaine [Xylocaine].) An alternative one-time dose of vasopressin, 40 U IV, can be given in place of the initial epinephrine. After each drug is administered, circulate the medication by performing CPR and repeating defibrillations at 360 J (200 J biphasic). If ventricular fibrillation or pulseless VT persists, amiodarone (Cordarone), 300 mg IV, is indicated. This may be repeated with a second dose of 150 mg in 5 to 10 minutes. Alternatively, lidocaine (Xylocaine) in a 1.0 to 1.5 mg/kg bolus may be given and repeated every 5 minutes up to a maximum dose of 3.0 mg/kg. Magnesium sulfate, 1.0 to 2.0 mg, can be considered for its antiarrhythmic effects. Procainamide (Procanbid, Pronestyl, Pronestyl-SR, Procan SR) is also used to treat this rhythm and is administered at 20 to 50 mg/min to a total dose of 17 mg/kg. When administering an antiarrhythmic medication, it is recommended that the maximum dose be reached before moving to the next drug of choice. Continued resuscitative efforts should be directed by a physician on the transport team or in direct radio communication and consultation with a physician with telemetry capabilities.

Electrolyte and Drug Effects

Electrolytes have an essential role in the proper functioning of cells and are found in the intracellular and extracellular fluids. Important electrolytes are sodium, potassium, calcium, and magnesium. It is the exchange of electrolytes into and out of cells that generates electrical energy for cellular depolarization and repolarization. As the cells depolarize electrically, they have a mechanical response in the form of contraction, and when they repolarize, they relax and expand back to their original state. In the cardiac muscle, this process is repeated continuously for a lifetime. Proper levels of these electrolytes are essential to keep the cells functioning correctly. When changes in electrolytes occur, their effects are often seen on the ECG.

Certain drugs have an effect on the electrolyte channels of the cell membranes, changing how the electrolytes flow into and out of the cells. These drugs can alter conduction patterns that have an effect of how the ECG is represented.

This section discusses ECG effects of two of the most clinically important electrolytes, potassium and calcium, because they produce the most recognizable changes on the ECG.

Hyperkalemia

Potassium is the primary intracellular ion (the other is phosphate). An elevation of the potassium level is called **hyperkalemia**. Hyperkalemia is the most dangerous of all electrolyte abnormalities. This condition

can cause death and prevents some drugs used in resuscitation efforts from being effective. On the ECG, hyperkalemia can cause changes in the appearance of all waveforms, representing a change that has occurred within the cell, and it can cause virtually any arrhythmia. Rapid recognition and correction of this electrolyte disturbance is essential to reversing any harmful effects. The main ECG changes found in hyperkalemia are the following:

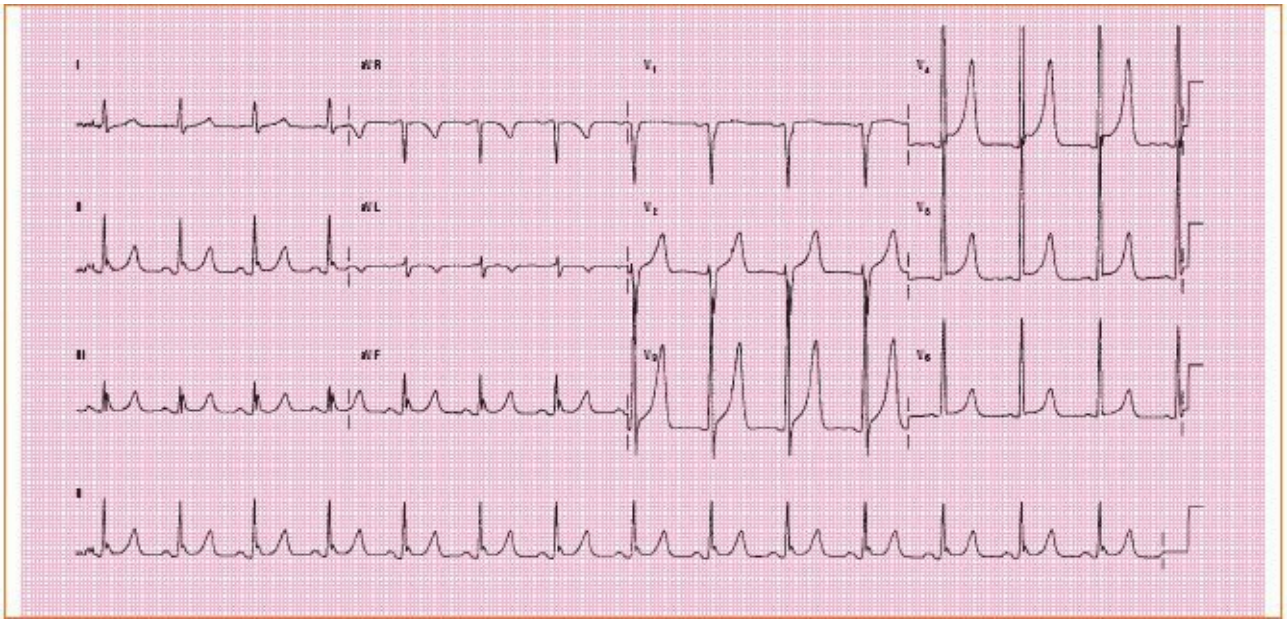

Figure 13-49 A 12-lead electrocardiogram showing T-wave changes with hyperkalemia.

1. T-wave abnormalities (tall and peaked)
2. Intraventricular conduction delays
3. P-wave abnormalities (missing or decreased amplitude)
4. ST-segment changes simulating an injury pattern
5. Cardiac arrhythmias (predominantly bradycardias)
6. Sinusoidal ECG pattern

On the ECG, T-wave abnormalities are the first to appear with hyperkalemia. These changes start to appear when the potassium level exceeds 5.5 mEq/L. The most common changes are tall, narrow, peaked T waves, but these changes are not seen in every patient with hyperkalemia. A prolonged QT interval may be present. As the potassium level increases, the height of the T wave decreases and widens; the PR, QRS, and QT intervals also widen; and the amplitude decreases.

The ECG in **Figure 13-49** represents hyperkalemia. There are tall, narrow, peaked T waves in V_2 through V_4. Tall T waves also appear in the inferior leads II, III, and aVF. When the T wave is two thirds the height of the R wave, it is considered pathologic.

A patient with known hyperkalemia or renal failure with suspected hyperkalemia should have supportive treatment with IV access and cardiac monitoring. In the presence of hypotension or marked QRS widening, three choices for medication administration include IV bicarbonate, calcium, or insulin given with 50% dextrose; any one of these or a combination of these may be given. Calcium should not be given if digoxin toxicity is suspected. Magnesium sulfate (2 g over 5 minutes) may be used alternatively with digoxin toxicity–related cardiac arrhythmias. Additional medical treatments include the use of calcium carbonate or gluconate, sodium bicarbonate, albuterol (Proventil, Ventolin, Volmax), furosemide (Lasix), and binding resins such as sodium polystyrene sulfonate (Kayexalate).

Transport Management

Hyperkalemia

- Provide supportive treatment with IV access and cardiac monitoring.
- In the presence of hypotension or marked QRS widening, give IV bicarbonate, calcium, and insulin together with 50% dextrose.
- Give magnesium sulfate for digoxin toxicity–related cardiac arrhythmias.
- Give additional medical treatments—for example, calcium carbonate or gluconate, sodium bicarbonate, albuterol (Proventil, Ventolin, Volmax), furosemide (Lasix), and binding resins such as sodium polystyrene sulfonate (Kayexalate).

Hypokalemia

A decrease in the level of potassium is called **hypokalemia**. Hypokalemia does not cause the dramatic changes on the ECG as at the other end of the spectrum with hyperkalemia. There are some mild, nonspecific changes, such as ST-segment depression, slightly decreased amplitude of the T waves, and minimal prolongation of the QRS interval. Probably the most common abnormality in hypokalemia is the presence of a prominent U wave. The U wave (shown in Figure 13-8) is usually small and follows the T wave. Hypokalemia does not typically cause arrhythmias by itself.

Differential diagnoses for U waves include the following:

1. Hypokalemia
2. Bradycardia
3. LVH
4. Central nervous system events
5. Drug use: digoxin, class I antiarrhythmics, phenothiazines

Treatment for hypokalemia is aimed at decreasing potassium losses, replenishing potassium stores, evaluating for potential toxic effects, and determining the cause to prevent additional losses.

In the transport setting, a few things can be done to decrease potassium losses. First, if possible, the use of diuretics and laxatives should be discontinued. If diuretics are required for severe heart failure, potassium-sparing diuretics should be used, diarrhea and vomiting should be treated, and H_2 blockers should be used to decrease loss from nasogastric suction.

Replacing lost potassium is done by measuring the loss and estimating the replacement. Intravenous potassium is not well tolerated because it can be highly irritating to veins and can be given only in relatively small doses (ie, 10 mEq/h). With close medical supervision, in an emergency situation, as much as 40 mEq/h can be administered through a central line.

In evaluating for the potential toxic effects of hypokalemia, monitoring for cardiac arrhythmias and prompt treatment are essential. This is one condition in which a more aggressive approach would be taken to IV potassium replacement.

Finally, intervention to prevent future losses of potassium is not a major component of interfacility care. By preventing further losses and treating significant hypokalemia, a first step in prevention has been accomplished.

Differential Diagnosis

Hypokalemia

- Bradycardia
- LVH
- Central nervous system events
- Drug use: digoxin, class I antiarrhythmics, phenothiazines

Transport Management

Hypokalemia

- Discontinue diuretics and laxatives.
- Use potassium-sparing diuretics if required for severe heart failure.
- Treat diarrhea and vomiting.
- Use H_2 blockers to decrease nasogastric suction losses.
- Measure the potassium loss, estimate the replacement, and administer through a central line.
- Monitor for cardiac arrhythmias, and treat them promptly if they occur.

Hypercalcemia

Hypercalcemia is a disorder that is most commonly caused by malignancy or primary hyperparathyroidism. Other causes of an elevated calcium level are less common and not typically considered until the most common causes are ruled out. ECG changes are minimal, with the most significant change being a shortening of the ST segment, which, in turn, shortens the QT interval. The PR interval may be prolonged; at higher levels, the QRS may lengthen and T waves may become flat or even invert. Because hypercalcemia affects conduction times, a variable degree of heart block may develop. Arrhythmias seldom occur as a result of hypercalcemia.

Treatment of hypercalcemia includes supportive management of the ABCs and increased hydration, often with the inclusion of a loop diuretic (such as furosemide [Lasix]) to increase calcium excretion and prevent overload from hydration therapy alone.

Transport Management

Hypercalcemia

- Manage the ABCs.
- Provide hydration.
- Administer a loop diuretic.

Hypocalcemia

Hypocalcemia that occurs acutely can be the result of medication or surgical effects. It causes the opposite effects of hypercalcemia. ECG changes seen include a prolongation of the ST segment that produces an apparent lengthening of the QTc interval. The cardiopulmonary effects of hypocalcemia may include wheezing, stridor, bradycardia, and pulmonary crackles (rales), and an S_3 may be heard. The

prolonged QT interval can lead to ventricular arrhythmias (such as torsade de pointes).

Signs and Symptoms

Hypocalcemia

- ECG findings: prolonged ST segment and apparent lengthening of the QTc interval
- Wheezing
- Stridor
- Bradycardia
- Pulmonary crackles (rales)
- S_3 heart sound
- Ventricular arrhythmias (such as torsade de pointes)

Transport Management

Hypocalcemia

- Initiate IV access.
- Administer oxygen.
- Monitor vital signs and the ECG.
- Provide an infusion of calcium gluconate.
- Consider administration of magnesium to help prevent torsade de pointes.

Treatment during interfacility transfer mainly includes supportive measures, including IV fluids, oxygen, and monitoring of vital signs and the ECG. An infusion with calcium gluconate can be given over a period of 5 to 10 minutes. Magnesium may be considered when there is a prolonged QTc interval to help prevent torsade de pointes.

Conditions That Mimic Myocardial infarction

Multiple conditions may mimic the clinical and ECG findings that occur with ischemia, injury, and infarction. The following is a synopsis of these conditions:

- Pericarditis: ST-segment elevation, T-wave inversion (possible)
- Left BBB: ST-segment elevation, QS complexes
- LVH: ST-segment elevation
- Ventricular rhythms: ST-segment elevation, QS complexes
- Early repolarization: ST-segment elevation, tall T waves

Drug Effects on the ECG

There are countless medications on the market that are specifically designed to alter the function of the heart. The most notorious of these is digoxin (Lanoxicaps, Lanoxin), a digitalis preparation. According to the American Association of Poison Control Centers, there is a higher incidence of adverse effects with calcium channel blockers and beta-blockers, but the mortality rate is higher with digoxin toxicity.

Understanding the actions of digoxin and treating its adverse effects are essential to decreasing the mortality when toxicity occurs. A more in-depth discussion of digoxin toxicity is provided later in this section.

Cardiac medications can increase the rate and force of contraction or slow and protect the heart from increased demands. Virtually any function of the heart can be altered by design. There are other classes of pharmaceuticals that are not cardiac medications but have expected or unexpected cardiac side effects. It is beyond the scope of any text to address the effects of the countless illicit drugs that are available on the street or even online. The point to this discussion is that there are endless possibilities of drug effects that will alter what is ultimately seen on the ECG. **Table 13-7** provides a brief overview of the cardiac effects from a few of these classes of drugs.

Digoxin Toxicity

Digoxin (Lanoxicaps, Lanoxin) is a cardiac glycoside that produces positive inotropic and negative chronotropic activity in the heart. It is primarily indicated to treat chronic heart failure and to control the ventricular rate in atrial tachyarrhythmias (such as atrial fibrillation). The inotropic effects are a result of inhibiting the sodium-potassium adenosine triphosphatase pump. This action causes a rise in intracellular calcium and sodium and a decrease in intracellular potassium. The movement of these intracellular electrolytes results in an increased force of myocardial muscle contraction, thus causing the positive inotropic effect.

TABLE 13-7 Common Toxic Drug Effects

Drug	Possible Toxic Effects
Class I antiarrhythmics	Lengthened QRS and QTc intervals Possible AV blocks Slowed or completely blocked SA node Arrhythmias
Calcium channel blockers	Blocked AV node primarily, but extent of block varies significantly among different drugs in this class
Beta-blockers	Slowed automaticity of the SA node and the Purkinje system Blocked AV node
Amiodarone (Cordarone)	Slowed conduction everywhere: the SA node, atrium, AV node, Purkinje system, and ventricles
Phenothiazines and tricyclic antidepressants	Widened QRS and QTc interval T-wave abnormalities Arrhythmias common in overdoses

Abbreviations: AV, atrioventricular; SA, sinoatrial.
Source: Garcia T, Holtz N. Figure 16-3. In: *12-Lead ECG: The Art of Interpretation.* Sudbury, MA: Jones and Bartlett Publishers; 2001:507.

Therapeutic concentrations of digoxin (1.0-2.0 ng/mL) cause the desired positive inotropic effect and decreased electrical conduction between the SA and AV nodes. Therapeutic levels of digoxin also decrease automaticity and increase the diastolic resting membrane potential.

The margin between toxic and therapeutic doses is small, and many factors can affect this level. One of the most common causes of digoxin toxicity is drug-to-drug interaction(s). In the critical care transport setting, there may be a patient who has been taking digoxin and experiencing the desired effects, but who then experiences a cardiac, medical, or other disease state and is given another medication (or more likely, multiple medications) that can affect the digoxin level. Any drug interaction or disease state (eg, hypothyroidism or renal impairment) that can interfere with the absorption or elimination of digoxin can cause an increased serum concentration.

The electrolytes potassium and calcium must be evaluated in conjunction with suspected digoxin toxicity. If the patient is given diuretic therapy, hypokalemia can develop and increased automaticity results. Hyperkalemia exacerbates the digoxin-induced conduction delays. Also, hypercalcemia increases ventricular automaticity and can increase the effects of digoxin; therefore, the administration of calcium in a patient with digoxin toxicity can lead to more harmful effects.

At toxic levels, the excessive increase of intracellular calcium elevates the resting potential and predisposes the heart to arrhythmias. Virtually any arrhythmia can occur in digoxin toxicity, and none are specific to this condition. CCTPs need to be alert to any manifestation of increased automaticity in the face of impaired electrical conduction.

The clinical manifestations of acute digoxin intoxication may not appear for several hours. When they do, they typically include gastrointestinal symptoms of nausea, vomiting, or abdominal pain. Neurologic symptoms may include lethargy, confusion, and weakness. Symptoms associated with chronic digoxin intoxication may be difficult to discern from many other medical conditions.

Signs and Symptoms

Digoxin Intoxication

- Nausea
- Vomiting
- Anorexia
- Abdominal pain
- Weight loss
- Delirium
- Confusion
- Dizziness
- Disorientation
- Drowsiness
- Headache
- Hallucinations
- Amblyopia (partial or complete loss of vision in one eye)
- Photophobia (painful sensitivity to light)
- Scotoma (area of diminished vision within the visual field)
- Chromatopsia (visual disturbance in which objects appear abnormally colored)
- Xanthopsia (yellowish visual discoloration)

Transport Management

Digoxin Intoxication

- Manage the ABCs.
- Stabilize the patient's hemodynamics.
- Administer activated charcoal to clear the gastrointestinal tract of those who recently ingested digoxin.
- Administer atropine to treat AV, junctional, or ventricular ectopy; produce first-degree AV block; slow ventricular response to atrial fibrillation; or experience accelerated AV or junctional rhythms.
- Administer digoxin-specific antibodies (Fab fragments).

The most common ECG changes in digoxin toxicity include AV, junctional, or ventricular ectopic beats; first-degree AV block; slow ventricular response in atrial fibrillation; and an accelerated AV or junctional rhythm. More severe arrhythmias may be seen and include severe bradycardia, high-degree heart blocks, and malignant ventricular rhythms. In reviewing this list of potential rhythms, it is clear that there is no signal arrhythmia that points directly to digoxin toxicity. As mentioned, CCTPs should review the patient's medications before transport. In a patient known to be taking digoxin, when an arrhythmia occurs, especially in the presence of other clinical findings, digoxin toxicity should be considered as the underlying cause. In general, CCTPs should be aware that any accelerated rhythm with conduction delays should raise the level of suspicion of digoxin toxicity.

Any patient taking digoxin in whom an altered level of consciousness or gastrointestinal symptoms develop with or without ECG changes needs further evaluation for toxicity. Because CCTPs typically are working with data collected before transport, new electrolyte values and drug assays are usually not available en route to the receiving facility. The one value that can be obtained before transport that has some prognostic value and can provide clues to the diagnosis of digoxin toxicity (in the presence of other clinical findings that develop during transport) is the potassium level. In a patient with digoxin toxicity, a potassium level greater than 5.5 mEq/L (normal serum potassium level, 3.5-5.0 mEq/L) with normal renal function is associated with higher mortality. Toxicity can occur in a patient with normal therapeutic levels if a drug–drug interaction interferes with absorption or elimination of digoxin or in the presence of increased automaticity and impaired conduction.

If a CCTP suspects digoxin toxicity during transport, based on ECG changes along with associated signs and symptoms, the initial concern is to manage the ABCs and stabilize the patient's hemodynamics. Clearing the gastrointestinal tract of recently ingested digoxin can be beneficial; in the field, this can be accomplished with the administration of activated charcoal. This measure not only helps prevent further absorption of the drug, but also may increase its excretion from the body. Atrioventricular, junctional, or ventricular ectopy; first-degree AV block; slow ventricular response to atrial fibrillation; and accelerated AV or junctional rhythms will typically respond to administration of atropine.

In the treatment of severe digoxin toxicity, the standard of care is the administration of digoxin-specific antibodies (Fab fragments or digoxin-immune Fab [Digibind]). Fab fragments neutralize free digoxin, decrease potassium levels, and increase renal excretion.

Laboratory tests for electrolyte levels, glomerular filtration rate, creatinine level, and urea level should be obtained as soon as possible. Further treatment includes the administration of insulin and glucose to treat the associated hyperkalemia and to provide the proposed cardioprotective effects. (Insulin may have a cardioprotective effect in digoxin toxicity.) The use of calcium chloride to stabilize the myocardium is controversial. If Fab fragments are used in the treatment of digoxin toxicity, the use of sodium polystyrene sulfonate (Kayexalate) to treat hyperkalemia is *not* recommended because it will overcorrect the serum potassium level. Fab fragments have also virtually eliminated the need for a

pacemaker or cardioversion in digoxin toxicity. Early recognition and aggressive treatment of digoxin toxicity is lifesaving.

Coronary Artery Disease and Angina

Coronary artery disease (CAD) is the most common form of heart disease and is a leading cause of death in US adults. The coronary arteries supply oxygen and nutrients to the myocardium. If one of these blood vessels becomes blocked, the muscle it supplies will be deprived of oxygen (ischemia). If this oxygen supply is not quickly restored, the ischemic area of heart muscle will eventually die (undergo infarction).

Atherosclerosis is of particular concern because it affects the inner lining of the aorta and the cerebral and coronary blood vessels, leading to the narrowing of these vessels and the reduction of blood flow through them. The atherosclerotic process begins, probably in childhood, when small amounts of fatty material are deposited along the inner wall (intima) of arteries, usually at points of turbulent blood flow (such as where the arteries bifurcate or where the arterial wall has been damaged). As the streak of fat enlarges, it becomes a mass of fatty tissue, an atheroma, which gradually calcifies and hardens into a plaque. The atheromatous plaque infiltrates the arterial wall and decreases its elasticity. At the same time, it narrows the arterial lumen and interferes with blood flow through the lumen. The narrowed, roughened area of the arterial intima provides a locus for the formation of a fixed blood clot, or thrombus, which may then obstruct the artery altogether (when in a coronary artery it is known as coronary thrombosis). In addition, calcium may precipitate from the bloodstream into the arterial walls, causing arteriosclerosis, which greatly reduces the elasticity of the arteries.

Risk factors for atherosclerosis and CAD include hypertension, cigarette smoking, diabetes, high serum cholesterol levels, lack of exercise, obesity, family history of heart disease or stroke, and male sex.

Peripheral Vascular Disorders

Although atherosclerosis is rarely the primary cause of medical emergencies, it is a major contributor to other conditions that may become medical emergencies. For example, arterial bruits (turbulence or "swishing" sounds heard with a stethoscope placed over the carotid arteries) signal the presence of atherosclerosis and contraindicate the use of carotid sinus massage. Atherosclerosis can also contribute to claudication, a severe pain in the calf muscle caused by narrowing of the arteries in this muscle and leading to a painful limp. Finally, atherosclerosis may be associated with phlebitis—inflammation, swelling, and pain along the veins that can lead to the formation of blood clots and thrombophlebitis, which is venous inflammation associated with a thrombus (blood clot). If dislodged, these thrombi become emboli that could travel to the heart and through its right side, lodging in the pulmonary arterial tree and causing a pulmonary embolism.

An estimated 5 to 20 million Americans are affected by significant peripheral vascular disorders annually. The most dangerous complication of these disorders is pulmonary embolism, which causes approximately 200,000 deaths each year. Risk factors for peripheral vascular disorders include age, oral contraceptive use, smoking, recent surgery, recreational IV drug use, trauma, and extended immobilization. The identification of these risk factors has a significant role in diagnosing peripheral vascular occlusions. Signs of peripheral vascular occlusion may include pain, redness, swelling, warmth, and tenderness in the extremity; however, these signs are present in only about half of all cases. The presence of claudication indicates a significant narrowing of the peripheral arteries associated with peripheral vascular disorders. Arterial bruits are another sign of vascular narrowing that can contribute to ischemia and stroke.

Unfortunately, there is not much a critical care transport team can do for peripheral vascular disease. If a blockage or potential embolus is suspected, IV heparin should be administrated initially as a bolus and followed by a drip. If ultrasound or Doppler is available on the transport vehicle, frequent assessment of the affected limb should be done. In addition to anticoagulant therapy, efforts should be

made to maximize blood flow to the extremity by using warm compresses. Keeping the leg in the position of comfort and minimizing movement are also helpful.

Signs and Symptoms

Peripheral Vascular Disorders

- Pain, redness, swelling, warmth, and tenderness in the extremity
- Claudication
- Arterial bruits

Transport Management

Peripheral Vascular Disorders (Suspected Blockage or Embolus)

- Give IV heparin, initially as a bolus and followed by a drip.
- Monitor the affected limb with ultrasound or Doppler, if available.
- Maximize blood flow to the extremity by using warm compresses.
- Keep the affected limb in the position of comfort.
- Minimize movement of the affected limb.
- Apply a cardiac monitor, record a baseline ECG before transport, and perform frequent 12-lead ECG monitoring.

All critical care transport patients should undergo cardiac monitoring, but any patient being transported a long distance with a blood clot that has the potential to become a pulmonary embolus should be given a baseline ECG before transport and must undergo frequent 12-lead ECG monitoring. ST-segment depression in the limb leads and the precordial leads accompanied by an increase in RAD may indicate a pulmonary embolus.

Acute Coronary Syndrome

The American Heart Association and the American College of Cardiology have published guidelines for the management of patients with STEMI. In the guidelines, the term **acute coronary syndrome (ACS)** is used to describe conditions that cause an episode of ischemic discomfort (chest pain) as the result of disruption of plaque within a coronary artery.

Plaques occur as the natural evolution of atherosclerosis. The plaques that are prone to disruption are usually nonobstructive but have a large amount of macrophages and other inflammatory cells associated with them. After the plaques are disrupted from within a coronary artery, these substances promote a chain reaction of platelet activation, adhesion, aggregation, thrombin formation, and, ultimately, thrombus formation. The end product is a complete occlusion of the coronary artery or one of its branches. If there is not enough collateral circulation from branches of adjacent coronary arteries, myocardial necrosis begins within 15 minutes and spreads from the endocardium toward the epicardium.

The term ACS is used to describe any group of clinical symptoms consistent with acute myocardial ischemia. ACS represents a sudden deterioration of the condition of a coronary blood vessel. Acute myocardial ischemia typically presents as chest pain as a result of insufficient blood supply to the heart muscle, which itself is a result of CAD. The life-threatening ACS disorders are responsible for much of

the emergency medical care and hospitalization in the United States.

The broad term acute coronary syndrome includes unstable angina, MI without ST-segment elevation (NSTEMI), and MI with ST-segment elevation (STEMI). Patients with STEMI have a high probability (greater than 90%) of coronary thrombus occlusion. In comparison, patients with stable angina have only about a 1% probability of having a coronary thrombus. Of patients with unstable angina or NSTEMI, 35% to 75% may have a coronary thrombus. These numbers are not good predictors to identify the patients in whom MIs with Q waves eventually develop: Not every STEMI develops Q waves, and Q waves may develop in NSTEMI.

All patients experiencing a possible cardiac event should have a 12-lead ECG performed. Use of the 12-lead ECG enables the responder to categorize two groups of patients who have experienced ACS: patients with ST-segment elevation and patients without ST-segment elevation. Most patients whose ECG displays ST-segment elevation ultimately will have a STEMI. Patients who have ischemic discomfort (chest pain) without an ST-segment elevation are having unstable angina or an NSTEMI that usually leads to a non–Q-wave MI; these conditions are collectively known as UA/NSTEMI (unstable angina/NSTEMI). Patients with non–ST-segment elevation are ultimately diagnosed with unstable angina or not (depending on whether cardiac enzymes or biomarkers indicated evidence of cardiac necrosis). Patients who experience angina may also have ST-segment depression. Finally, some patients experiencing angina or MI may have no changes indicated by the ECG.

Early recognition of the signs and symptoms of a STEMI are essential to initiate treatment or to ensure transporting the patient to a facility where the appropriate care can be provided. Signs and symptoms are discussed later in this chapter in the section on MI and include chest and arm pain, lower jaw pain, shortness of breath, and diaphoresis. The majority of deaths as a result of STEMI occur within the first 1 to 2 hours after the onset of symptoms and are usually caused by ventricular fibrillation. This is why rapid intervention with the most appropriate reperfusion therapy must be started as soon as a diagnosis of STEMI has been confirmed.

A 12-lead ECG should be performed within 10 minutes of contacting a patient with chest discomfort or other signs and symptoms suggestive of STEMI. If this initial ECG is not diagnostic of STEMI but the patient remains symptomatic and there is a high degree of suspicion about STEMI, serial 12-lead ECGs should be performed at 5- to 10-minute intervals while maintaining continuous cardiac (ST-segment) monitoring. Newer 12-lead ECG machines are equipped with multiparameter monitoring capabilities that can assess ST-segment deviation every 30 seconds. With IWMI, right-sided chest leads should be evaluated for ST-segment elevation suggestive of right ventricular infarction (RVI). The 12-lead ECG in the critical care transport setting is central to the therapeutic decision pathway because it provides evidence of ST-segment elevation in patients who will benefit from reperfusion therapy.

In a patient with STEMI, the more leads that show ST-segment elevation on a 12-lead ECG, the higher the mortality rate. In other words, if the occlusion occurred high enough in a coronary artery that has affected a large area of the heart, multiple patterns of ischemia will appear. Other important predictors of mortality are STEMI occurring in conjunction with left BBB and in a predominantly anterior location. The current guidelines for the ECG diagnosis of acute MI require at least 1 mm (0.1 mV) of ST-segment elevation in the limb leads and at least 2 mm of elevation in the precordial leads. These elevations must be present in leads that are physically next to each other or anatomically contiguous. (Each small block measured vertically on the ECG paper equals 1 mm.)

When no ST-segment elevation is present or the ECG is normal or shows nonspecific changes, there is no evidence to suggest any benefit of fibrinolytic therapy; in fact, in such cases, fibrinolytic therapy has been shown to be harmful. If clinical signs and symptoms continue, the 12-lead ECG should be repeated every 5 to 10 minutes and monitored continuously for any ST-segment changes until serologic testing for cardiac enzymes or biomarkers can be done.

All patients with ACS should receive antithrombin and antiplatelet therapy regardless of the presence or absence of ST-segment elevation. Patients with persistent ST-segment elevation are candidates for prompt reperfusion therapy, pharmacologic or catheter based, to restore blood flow in the occluded artery. Patients without ST-segment elevation should receive anti-ischemic therapy and be considered for catheter-based therapy when indicated. Medications such as heparin or glycoprotein IIb/IIIa inhibitors can be continued in the field, but revascularization will occur in the hospital.

Another situation that warrants fibrinolytic therapy is marked ST-segment depression in leads V_1 through V_4 with tall R waves in the right precordial leads with upright T waves suggestive of a true posterior wall MI (PWMI). In this case, placement of additional electrodes in the posterior position to form leads V_7, V_8, and V_9 is recommended. Primary percutaneous coronary intervention may be appropriate in patients with true PWMIs.

Lethal ventricular arrhythmias may develop in patients with STEMI, so continuous ECG monitoring is required. Because many patients with STEMI are transferred to a higher level of care for therapeutic interventions, CCTPs are in a unique position to be monitoring patients during transport and to be able to respond quickly and appropriately as these events occur.

Most patients diagnosed with ACS are experiencing an MI in progress or severe ischemia, which can quickly become an infarction. The patients are best treated at a facility where the location of the blockage can be identified by cardiac catheterization and subsequently alleviated by stenting. Unfortunately, most hospitals do not have this capability.

The role of the critical care transport team is to transport the patient from a basic hospital to a cardiac hospital with the least possible decline in the patient's condition and to prevent further loss of heart muscle. Priorities are as follows:

1. Prevent further damage to the heart muscle
2. Reduce afterload
3. Prevent the clot from getting larger
4. Reduce myocardial oxygen demand
5. Maximize oxygen delivery
6. Reduce or eliminate pain and anxiety
7. Consider tissue plasminogen activators (TPAs) to dissolve the clot or clots

If the blood pressure is elevated, the patient should receive a nitroglycerin (Nitro-Bid IV, Tridil) drip to control blood pressure. Chest pain is managed with morphine, hydromorphone (Dilaudid), or fentanyl citrate. If there is any indication of pulmonary edema, continuous positive airway pressure (CPAP) should be started or the patient should be intubated and a ventilator with positive end-expiratory pressure (PEEP) should be used if pulmonary edema is severe. Lasix should be administered per protocol.

The patient will usually be receiving an anticoagulant heparin drip and, in some cases, an IV drip of an antiplatelet medication, such as eptifibatide (Integrilin) may also be added. These drips must be administered via an infusion pump. The patient should be monitored en route for signs of serious bleeding. Minor bleeding, especially around the mouth, is common and is not a reason to discontinue or alter the drip rates.

The patient should be given sufficient oxygen to maintain an oxygen saturation of greater than 95%. Patients who need a ventilator should be monitored with waveform capnography, and a carbon dioxide level between 35 and 45 mm Hg should be maintained.

When transport times will be long or the degree of blockage is severe to the point of being life

threatening, a TPA may be required. TPAs actually dissolve clots; however, they dissolve clots throughout the body. Before administering TPA, all of the following exclusion criteria must be met. The patient cannot have or have received the following:

1. Recent major surgery
2. Recent intracranial or spinal surgery
3. Active internal bleeding
4. A history of stroke within the last 6 months
5. Intracranial neoplasm or arteriovenous malformation
6. Severe uncontrolled hypertension
7. Pregnancy
8. Anticoagulants (such as warfarin [Coumadin])

The most common TPA for an active MI or ACS is reteplase (Retavase). Reteplase is administered in two separate doses. The first dose is 10 U administered in a 2-minute period. The second dose is also 10 U administered in 2 minutes. Reteplase is not to be administered as a rapid bolus or through a heparin line. It is not uncommon to administer heparin simultaneously with reteplase. Heparin is started after the first dose of reteplase as an initial IV bolus at 60 U/kg (maximum dose, 4,000 U) followed by a drip of 12 U/kg/h (maximum dose, 1,000 U).

Transport Management

Acute Coronary Syndrome (Interfacility Transport)

- Start a nitroglycerin (Nitro-Bid IV, Tridil) drip if the patient's blood pressure is elevated.
- Give morphine, hydromorphone (Dilaudid), or fentanyl citrate to manage chest pain.
- If there is any indication of pulmonary edema, begin CPAP or intubate the patient.
- If pulmonary edema is severe, the patient needs a ventilator with PEEP.
- Give furosemide (Lasix) per protocol.
- Monitor the heparin (anticoagulant) and eptifibatide (Integrilin; antiplatelet) drips.
- Monitor the patient for signs of bleeding and headache with altered level of consciousness.
- Give sufficient oxygen to maintain an oxygen saturation of greater than 95%.
- If the patient needs a ventilator, monitor with waveform capnography, and maintain the carbon dioxide level between 35 and 45 mm Hg.
- If the transport time will be long or the degree of blockage is severe to the point of being life threatening, administer TPAs.
- Monitor the cardiac rhythm.
- If severe bleeding occurs after administration of a TPA, turn off the heparin, manage hypotension with fluids or dopamine (Intropin), and divert to the closest hospital for further treatment.

The patient's cardiac rhythm must be monitored following the administration of reteplase because reperfusion arrhythmias are likely to follow. When cardiac tissue becomes severely ischemic, potassium leaves the intracellular space. With reperfusion, the potassium rapidly returns to the intracellular spaces, creating rhythm disturbances. Usually these disturbances are short-lived, but serious rhythm disturbances,

including cardiac arrest, have occurred. Patients must be monitored for signs of bleeding (eg, rigid abdomen with hypotension) and a headache with an altered level of consciousness. If severe bleeding occurs, the heparin drip must be turned off, hypotension must be managed with fluids or dopamine (Intropin), and the transport must be diverted to the closest hospital for treatment, possibly including a blood transfusion.

Angina Pectoris

The principal symptom of CAD is angina pectoris. Angina occurs when the supply of oxygen to the myocardium is insufficient to meet the demand. As a result, the cardiac muscle becomes ischemic, and a switch to anaerobic metabolism leads to the accumulation of lactic acid and carbon dioxide. A person who experiences angina at rest, when oxygen needs are minimal, has more severe CAD than a person who experiences angina only with vigorous exercise.

When obtaining the medical history from a patient with chest pain, it is important to distinguish between stable angina and unstable angina. Stable angina follows a recurrent pattern: A person with stable angina experiences pain after a certain, predictable amount of exertion, such as climbing one flight of stairs or walking for three blocks. The pain also has a predictable location, intensity, and duration.

Chronic, stable angina is the result of an atherosclerotic lesion causing an inadequate myocardial oxygen supply during exertion. Patients with chronic, stable angina often take nitroglycerin or some other form of nitrate for relief of anginal pain. In the critical care transport environment, nitroglycerin should be given intravenously, especially for long transports. IV nitroglycerin (Nitro-Bid IV, Tridil) is better able to control blood vessel diameter than other forms of nitroglycerin. When IV nitroglycerin is given, all other forms of nitroglycerin should be discontinued. If a patient who is being transported is not taking nitroglycerin and chest pain suddenly develops, a sublingual nitroglycerin tablet or nitroglycerin paste may be used initially to reduce afterload while IV nitroglycerin is being set up.

Unstable angina is much more serious than stable angina and indicates a greater degree of obstruction of the coronary arteries. It is caused by a thrombus or a rupture of a plaque. It is characterized by noticeable changes in the frequency, severity, and duration of pain and often occurs without predictable stress. The patient may report that the anginal attacks have grown more frequent and severe during the past several days or weeks, that they awaken him or her from sleep, or that they occur when otherwise at rest. Nitroglycerin is often not effective with this type of angina. Such attacks are often warning signs of an impending MI.

Finally, silent ischemia is the presence of angina without clinical manifestations and is only detected when ST-segment elevation is noted.

Myocardial Infarction

An MI can occur as a result of the cardiac muscle being deprived of coronary blood flow long enough for myocardial tissue death to ensue. Narrowed vessels (eg, from atherosclerotic disease), coronary artery occlusion (eg, by a thrombus), spasm of a coronary artery, or reduction of overall blood flow (eg, from shock, arrhythmias, or pulmonary embolism) are causes of an MI.

The location and size of an MI depend on which coronary artery is blocked and where along its course the blockage occurred. The majority of infarcts involve the left ventricle. When the anterior, lateral, or septal walls of the left ventricle are infarcted, the source is usually occlusion of the left coronary artery or one of its branches. Usually, IWMIs are the result of an RCA occlusion. When the ischemic process affects only the inner layer of muscle, the infarct is referred to as subendocardial. An infarct that extends through the entire wall of the ventricle is a transmural MI. The infarcted tissue is invariably surrounded by a ring of ischemic tissue—an area that is relatively deprived of oxygen but is still viable. That ischemic tissue tends to be electrically unstable and is often the source of cardiac

arrhythmias.

Acute MI is the leading cause of death in the United States, accounting for more than 500,000 deaths per year; of those deaths, 60% to 70% occur outside the hospital, during the first 2 to 3 hours after the onset of symptoms. Patients at risk for sudden cardiac death include patients with the following:

- Prior sudden cardiac arrest
- Prior MI
- Heart failure, class II to IV
- Ejection fraction of less than 40%
- Family history of cardiac arrest
- Prolonged QT interval

Of all deaths of acute MI, 90% are due to arrhythmias, usually ventricular fibrillation, which typically occur during the early hours of the infarct. Arrhythmias can be prevented or treated, so most deaths from acute MI are preventable.

Infarct Recognition and Localization

Many cardiac patients are transported from one facility to another to receive specialized procedures that are not available from the sending hospital. The physical and emotional stressors of the transport can place an additional burden on a patient in already critical condition. CCTPs must always remain acutely aware of the patient's cardiac status with rapid identification of new findings—including MI—and evolving and changing events.

There are three initial components to the diagnosis of an MI: history and physical examination, testing for cardiac enzymes, and interpretation of ECG changes associated with an MI. An MI evolves from a normal state to ischemia, injury, and, ultimately, infarction because of an event that occludes vessels and limits the oxygen-enriched blood reaching the cells. Ischemia and injury are reversible conditions that must be identified and treated to help prevent death of cardiac muscle.

As soon as a chief complaint of a cardiac nature has been noted, treatment of the patient needs to start; obtaining a focused history and performing a physical examination can wait. However, for purposes of discussion, this section proceeds through the history and physical examination.

Cardiac Enzymes

Serum tests for cardiac enzymes are not typically done during transport but are discussed here for review. Test results are frequently available in the patient's chart and may help put into perspective the patient's cardiac status. Although the ECG does not directly represent levels of cardiac enzymes that are released as cells are damaged, ECG changes are seen as an aftermath of cell damage because of the change in cell function. As myocardial cells die during an infarction, they leak their internal contents into the bloodstream. Troponins T and I are contractile proteins of the myofibril that are specific for detecting myocardial cell injury. Troponins T and I are the forms most commonly tested. The levels rise during the first 2 to 6 hours after injury. They peak from 12 to 16 hours. The cardiac troponin I level can remain elevated for 5 to 10 days, and the cardiac troponin T level can stay elevated for 5 to 14 days.

Creatine kinase (creatine phosphokinase) is an enzyme found in heart (MB fraction) and skeletal (MM fraction) muscle and in the brain (BB fraction). Creatine kinase increases in more than 90% of MIs. Because it is also found in skeletal muscle and the brain, it can be elevated during trauma and physical exertion, in postoperative patients, in patients with seizures, and in those with other conditions in which cells can be damaged. In an MI, the creatine kinase level begins to rise in 4 to 6 hours. It peaks in 24 hours and returns to normal in 3 to 4 days. The creatine kinase isoenzyme MB fraction is specific to cardiac muscle. The MB fraction rises and returns to normal sooner than the total creatine kinase level. It

rises in 3 to 4 hours and returns to normal in 2 days.

Myoglobin is an oxygen-transport protein. Damage to skeletal or cardiac muscle causes it to be released into the circulation. After an MI, the myoglobin level rises in the first 2 hours. It peaks in 6 to 8 hours and returns to normal in 20 to 36 hours. An increased myoglobin level can also be found in skeletal muscle injury and renal failure.

Because several of these markers can be found with other medical conditions, they must be used in conjunction with other clinical and laboratory findings when a cardiac event is suspected.

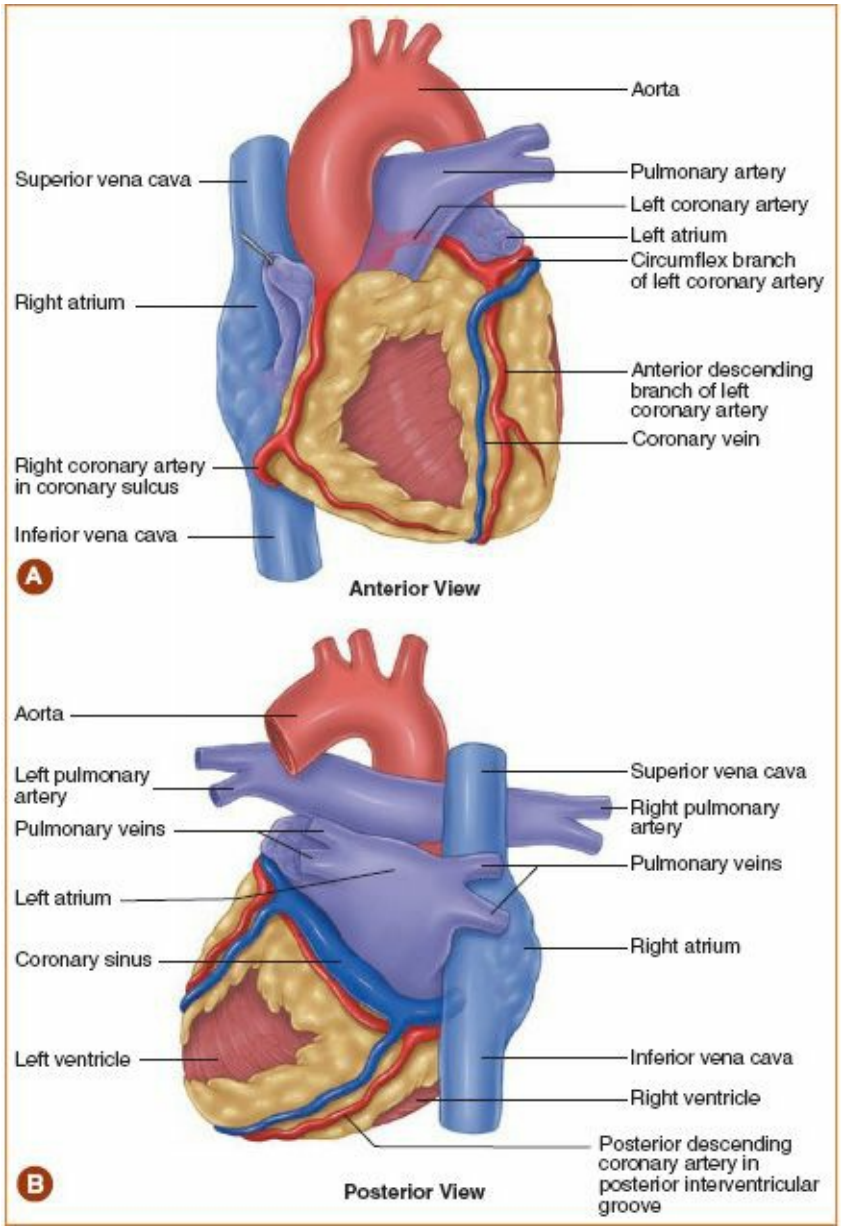

Figure 13-50 Coronary arteries. **A.** Anterior view, showing the takeoff point of left and right coronary arteries from the aorta. **B.** View from below and behind, showing the coronary sinus.

Blood Supply

Before proceeding further, a review of how blood circulates throughout the heart is given to aid understanding of the ECG changes seen in an MI. The heart is a muscle and requires an oxygen-enriched blood supply to survive. The blood supply to the heart is delivered through two main coronary arteries and their branches **Figure 13-50** during diastole. Areas that are supplied by more than one source are said to have collateral circulation. The right and left coronary arteries originate at the base of the aorta just above the aortic valve. The major branches of the RCA are the marginal, posterior (descending)

interventricular, and SA nodal branch. The RCA supplies the right atrium, right ventricle, and portions of the left atrium and left ventricle. The sinus node branch supplies the sinus node, and the AV nodal branch supplies blood to the AV node.

The major branches of the left coronary artery are the anterior interventricular, also known as the left anterior descending, and left circumflex branches. The left coronary artery supplies both ventricles, the interventricular septum, and the left atrium. The left anterior descending artery supplies the right and left bundle branches.

The deoxygenated blood is returned to the venous circulation through the coronary sinus. By understanding the coronary blood flow and the areas of the heart represented by the ECG, CCTPs can use ECG changes to identify which branch of the blood supply is affected. Note: There are slight variances in coronary artery distribution from patient to patient.

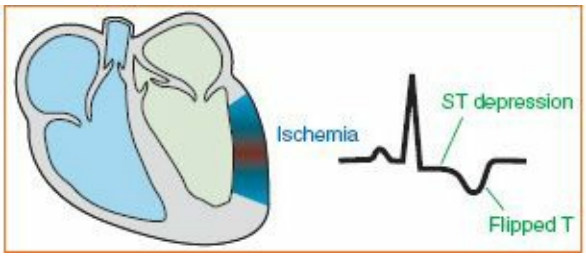

Figure 13-51 Ischemia.

Ischemia, Injury, and Infarction

Decreased blood flow to the heart can result from a chronic condition called coronary vascular disease or an acute injury in which a coronary artery or one of its branches is occluded by an embolus. The heart begins in a normal state in which it is receiving an adequate blood supply. Increased oxygen demand caused by an increased workload or a decrease in supply caused by coronary vascular disease or a blocked artery can lead to ischemia, injury, and, ultimately, infarction. Ischemia and injury are reversible, and when evidence of either is present, rapid intervention can often prevent infarction.

When ischemia develops, the tissue becomes more electrically negative compared with the unaffected surrounding tissue. This change causes a pattern of ST-segment depression. The T wave is also inverted (flipped) because of repolarization occurring along abnormal pathways **Figure 13-51**.

There are other causes of T-wave inversion, and they include ventricular hypertrophy with strain, BBB, and cerebral hemorrhage. To help distinguish ischemia from one of the other causes of T-wave inversion, the shape of the T wave may be helpful. With myocardial ischemia, the T wave inverts symmetrically. With other causes, the T-wave inversion is often asymmetric or “slurred.”

As ischemia continues uninterrupted, injury develops. The area that is injured does not repolarize completely, causing it to become more electrically positive than the unaffected area surrounding it. This change causes the ST segment to become elevated. The T wave remains inverted because it continues to repolarize through abnormal pathways. As the injury progresses, the elevation of the ST segment can increase

As ischemia and injury continue uninterrupted, infarction can occur. The infarcted tissue no longer generates or transmits electrical impulses. The area becomes “electrically neutral.” Because this tissue can no longer generate or transmit electrical impulses, no direct wave is recorded on the ECG. Electrical impulses are deflected away from the area of infarct and are represented by Q waves. Another way of looking at Q-wave formation is as a result of electrical impulses being generated by the other wall of the ventricle and passing unopposed away from the positive electrode. Because ischemia and injury continue to be present until the infarct process is completed, ST-segment elevation and inverted T waves are still

present **Figure 13-53**.

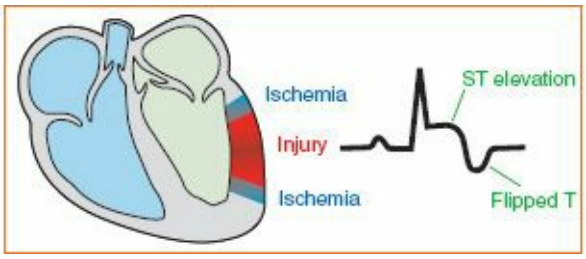

Figure 13-52 Ischemia and injury.

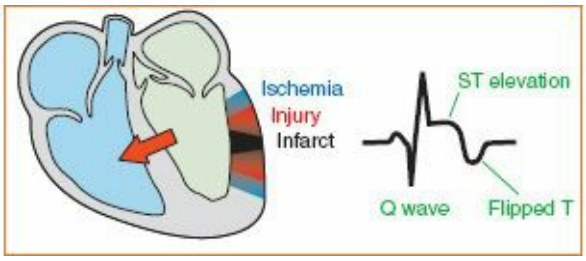

Figure 13-53 Ischemia, injury, and infarction.

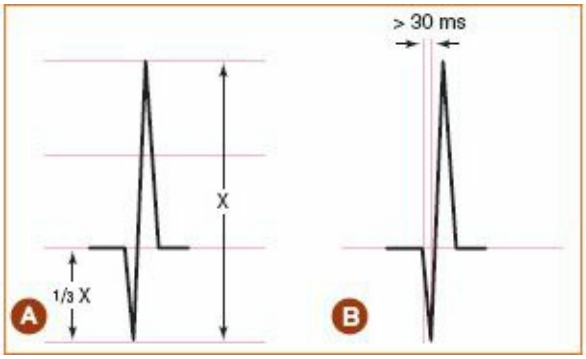

Figure 13-54 Q-wave significance. **A.** If the Q wave is more than one third the total height of the QRS, it is a pathological Q. **B.** If the Q wave is more than 30 milliseconds wide, it is a pathological Q.

Sometimes small Q waves are seen in the left lateral leads (I, aVL, V_5, and V_6) and occasionally in the inferior leads (especially II and III) of normal hearts. The normal small Q waves occur as a result of early left-to-right depolarization of the interventricular septum. For Q waves to be significant, indicating pathology, they must be more than one third the total height of the QRS they appear with and wider than 30 milliseconds in duration **Figure 13-54**.

An MI can occur with or without Q waves. Q waves can develop as discussed, especially when larger areas of myocardium are affected. With a smaller infarct, the cell-to-cell conduction of electrical impulses can hide the smaller resulting Q wave. Because ischemia and injury are always present in the setting of MI, ST-segment and T-wave abnormalities will still be present. When a patient has a history, signs and symptoms, and ECG changes suggestive of a cardiac event, a full workup is indicated. In this case, evaluation of cardiac enzymes can be the key to making the correct diagnosis.

Generally, STEMIs are associated with a higher incidence of congestive heart failure (CHF) and death because of the larger area of heart tissue damaged. In NSTEMIs, there is a higher incidence of long-term mortality because of life-threatening arrhythmias that develop out of the area of infarction.

Quick recognition of ischemia, injury, and infarction, followed by rapid intervention, can reduce the area of infarction and decrease the incidence of subsequent cardiac events that lead to death.

As mentioned earlier in this section, electrical activity in infarcted myocardial tissue becomes electrically neutral. As a result, the electrical current will be directed away from the area of infarction. The electrode that lies over the area of infarction will record a deep negative deflection, a Q wave. The electrical current that is directed away from the area of infarction causes **reciprocal changes** in leads located 180° from the site of infarction. Reciprocal leads must be 180° from the lead in question and lie in the same plane. Limb leads and precordial leads cannot be reciprocal. Limb leads lie in the frontal or vertical plane, and precordial leads lie in the horizontal plane. This apparent increase in electrical force moving toward the opposite lead will be recorded as tall, positive R waves. This applies not only to Q waves, but also to ST-segment and T-wave changes. For example, a Q wave, an ST-segment elevation, and a T-wave inversion recorded in leads II, III, and aVF will be recorded as a tall R wave, ST-segment depression, and an upright T wave in the reciprocal leads I and aVL **Figure 13-55 Table 13-8**.

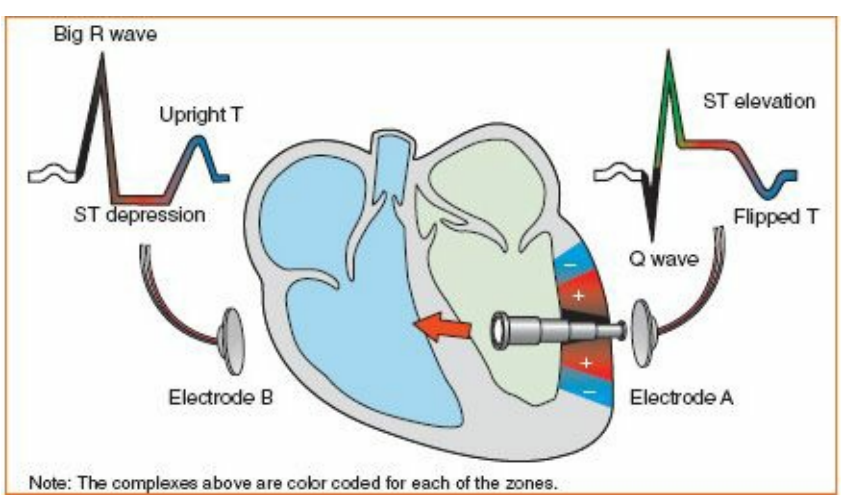

Figure 13-55 Reciprocal changes.

Localizing the Infarction

The area of myocardium that infarcts depends on which coronary arteries are occluded and the extent of collateral blood flow. It is important to localize where an infarction has occurred because the prognostic and therapeutic implications are determined largely by the area of the heart that has died. The review of coronary blood supply shows that each of the arteries perfuses more than one area in the heart. So, if one coronary artery becomes blocked, more than one region of the heart can become ischemic and proceed to injury and, ultimately, infarction. ECG findings, therefore, do not always fall neatly into one anatomic area of infarction. Acute MIs often involve more than one region of the heart; therefore, an inferior MI is often an inferoposterior MI, an anterior MI can become anteroseptal or anterolateral, lateral MIs are often posterolateral, and so forth **Figure 13-56**. Q waves from old infarctions can be present with findings of a new MI and can contribute to making the correct diagnosis from the ECG more challenging. In the critical care transport setting, the patient by definition is in serious condition and will likely have evidence of one or more underlying conditions. This makes it even more important to review an "old" ECG from the patient's chart, acquire a new 12-lead ECG before transport, and make serial evaluations along the way. To be sure an ECG change has occurred, CCTPs must know what was there before coming into contact with the patient.

With all this in mind, in general, infarctions can be grouped into several general anatomic categories **Table 13-9**.

Acute Anterior Myocardial Infarction

An anterior wall MI seldom occurs alone. It involves the anterior surface of the left ventricle and is

usually caused by occlusion of the left anterior descending artery **Figure 13-57**. Leads V_3 and V_4 are considered the anterior leads **Figure 13-58**. In an anterior MI, the normal pattern of R-wave progression may not occur. This situation is called **poor R-wave progression**. Even without significant Q-wave formation, poor R-wave progression may signify an anterior MI. Poor R-wave progression can also be seen in RVH and chronic lung disease and with improper lead placement. Alone, it is not specific for the diagnosis of anterior MI.

TABLE 13-8 Reciprocal Leads and Their Corresponding Locations

Location	Facing Leads	Reciprocal Leads
Anterior	V_3, V_4	None
Inferior	II, III, aVF	I, aVL
Lateral	I, aVL, V_5, V_6	II, III, aVF
Septum	V_1, V_2	None
Posterior	None	V1, V2

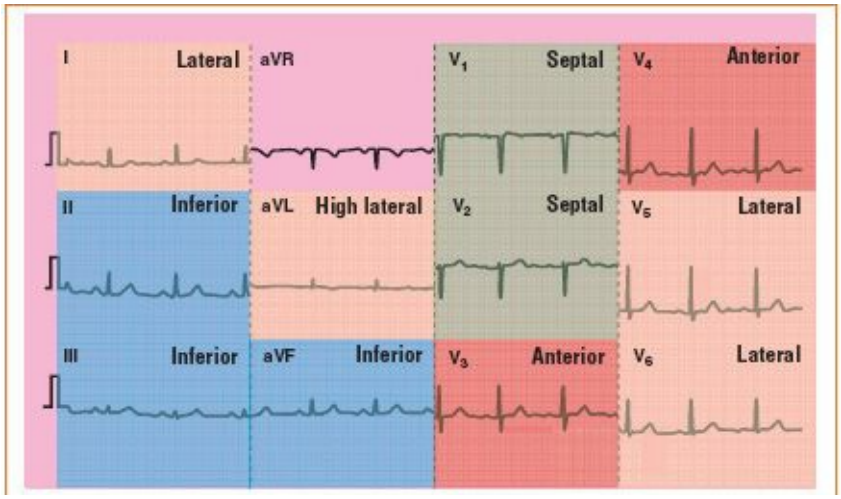

Figure 13-56 Correlation between areas of the heart and leads on the electrocardiogram.

TABLE 13-9 Coronary Artery Relationships to Area Perfused

Area of the Heart	Main Arteries That Perfuse the Area
Inferior	RCA (90%), LCx (10%)
Inferior right ventricle	Proximal RCA
Inferoposterior	RCA (90%), LCx (10%)
Isolated right ventricle	LCx
Isolated posterior	RCA (90%), LCx (10%)
Anterior	Left anterior descending
Anteroseptal	Left anterior descending

Anteroseptal-lateral	Proximal left anterior descending
Anterolateral, inferolateral, or posterolateral	LCx

Abbreviations: LCx, left circumflex artery; RCA, right coronary artery.

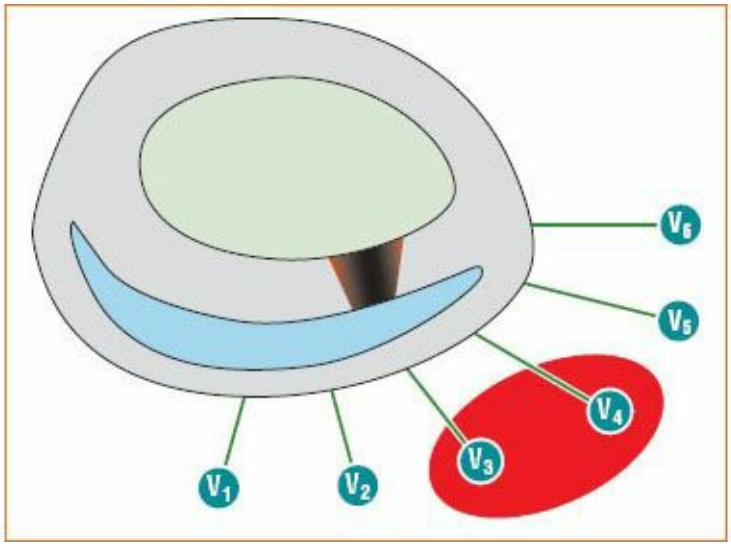

Figure 13-57 Anterior wall myocardial infarction.

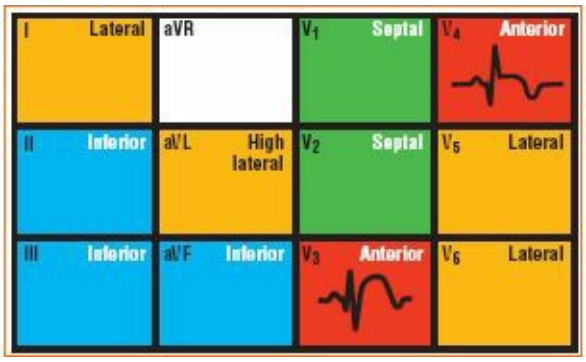

Figure 13-58 Anterior leads.

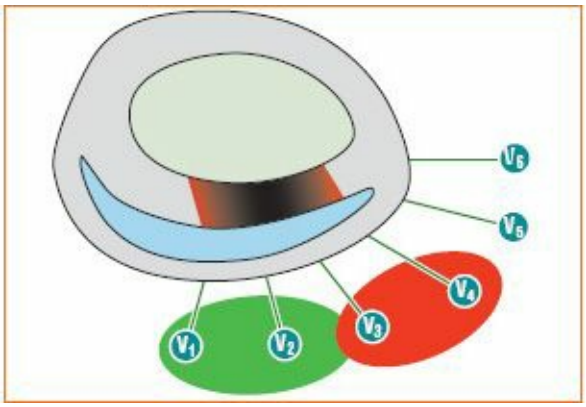

Figure 13-59 Anteroseptal myocardial infarction.

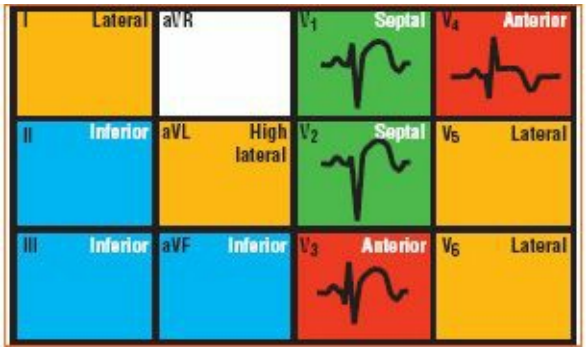

Figure 13-60 Anteroseptal leads.

Acute Anteroseptal Myocardial Infarction

An anteroseptal MI is common with an occlusion of the left anterior descending artery. As with all anterior MIs, this presentation is often associated with hemodynamic compromise and cardiogenic shock. The leads that best view this pattern of MI are the septal leads V_1 and V_2 and the anterior leads V_3 and V_4 **Figure 13-59** and **Figure 13-60**.

The ECG in **Figure 13-61** represents an acute anteroseptal MI. In the anterior and septal leads, V_1 through V_4, there is marked elevation and flattening of the ST segment, which is typical of this pattern of infarction. Further evaluation of the ECG shows some minimal elevation of the ST segment in lead aVL. All three areas are perfused by the left anterior descending artery. ST-segment depression is found in the reciprocal leads, II, III, and aVF.

Acute Anteroseptal Myocardial Infarction With Lateral Wall Extension

If the proximal left anterior descending artery is occluded, an acute anteroseptal MI with lateral wall extension may result. Changes can be seen in all precordial leads (specifically V_5 and V_6 for the lateral extension) and in leads I and aVL. With the loss of electrical impulses in the anterior infarcted tissue, there is not always significant Q-wave formation. Reciprocal changes can be found in leads II, III, and aVF **Figure 13-62** and **Figure 13-63**.

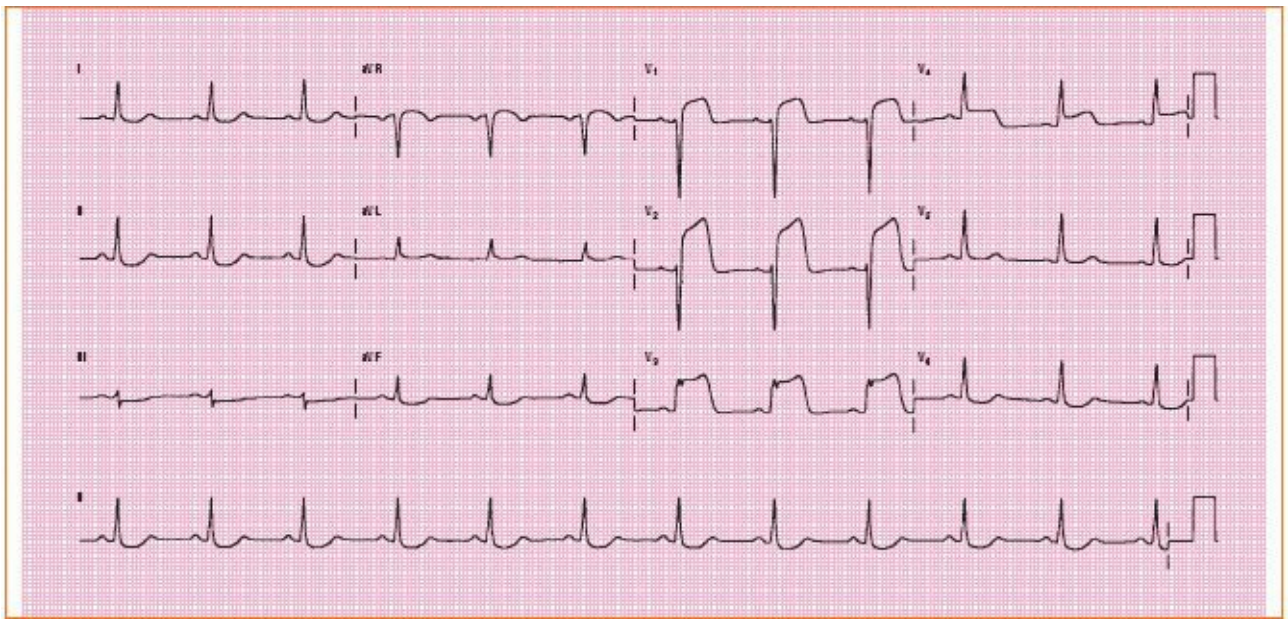

Figure 13-61 A 12-lead electrocardiogram showing an acute anteroseptal myocardial infarction.

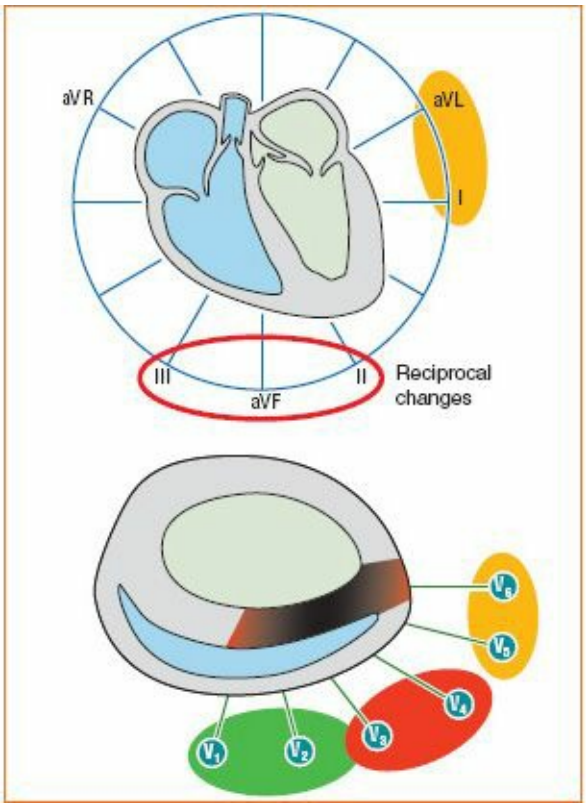

Figure 13-62 Acute anteroseptal myocardial infarction with lateral wall extension.

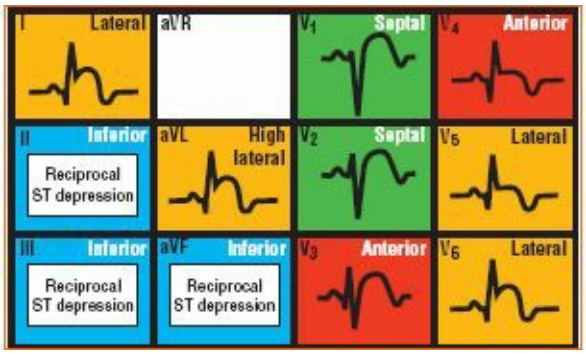

Figure 13-63 Electrocardiographic changes seen in an anteroseptal myocardial infarction with lateral wall extension.

The ECG in **Figure 13-64** represents an acute anteroseptal MI with lateral wall extension. There is ST-segment elevation in leads V_2 through V_6 that extends to leads I and aVL. Reciprocal changes are seen in leads III and aVF. In addition to the signs of ischemia and injury, there are Q waves forming in V_3 to V_6 and in leads I and aVL. In this ECG, the ST segments are very elevated and the T waves are tall and peaked, often referred to as hyperacute T-wave changes, indicating an early acute MI. The hyperacute T-wave changes occur only during the first 15 to 30 minutes of an acute MI. When they occur out of the hospital, they are seldom seen because responders usually arrive after the period when these changes can be seen. If these changes are found during transport, CCTPs are in a unique position to initiate care, even if it is only early notification of the receiving facility to decrease the door-to-treatment time. Early revascularization has a good outcome because the period of ischemia has been relatively short and less permanent damage has been done.

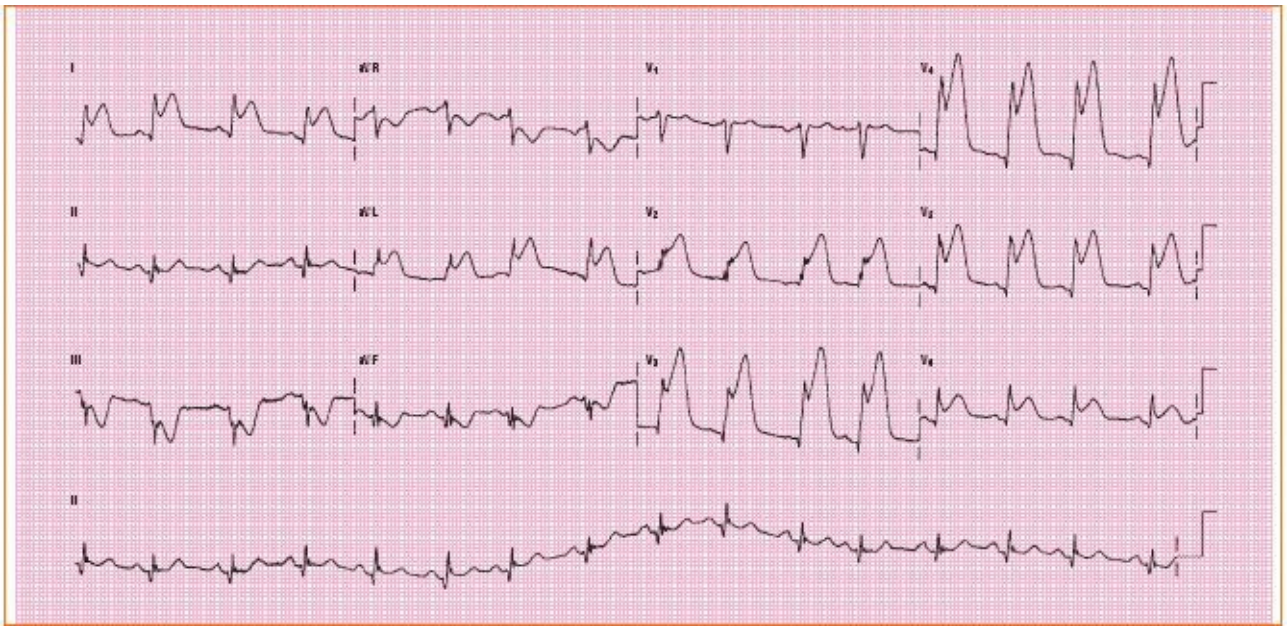

Figure 13-64 A 12-lead electrocardiogram showing an acute anteroseptal myocardial infarction with lateral wall extension.

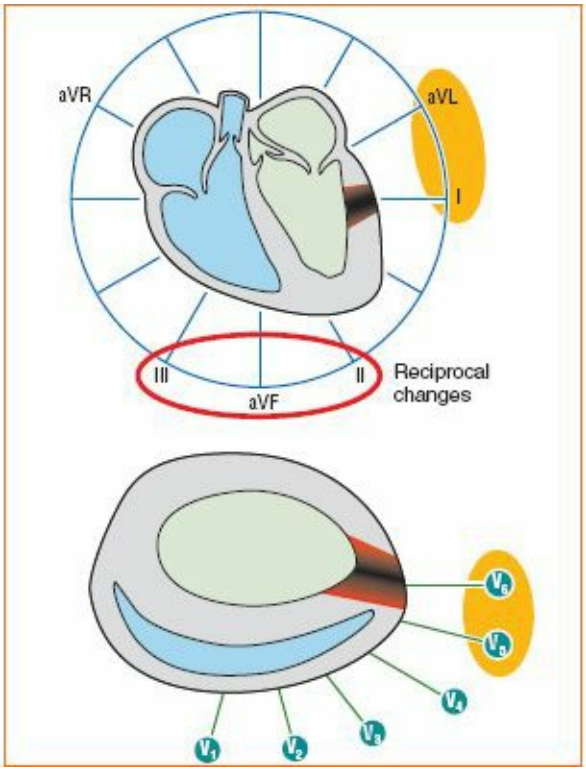

Figure 13-65 Lateral wall myocardial infarction.

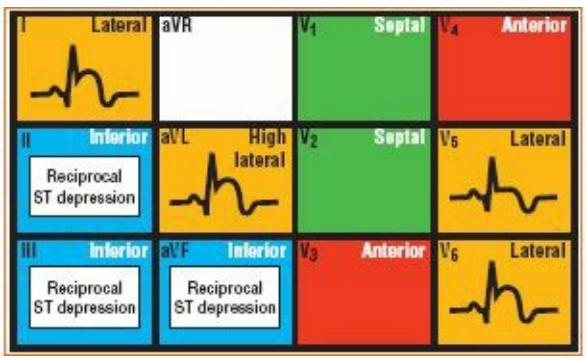

Figure 13-66 Electrocardiographic changes seen with lateral wall myocardial infarction.

Acute Lateral Wall Myocardial Infarction

An acute lateral wall MI involves the left lateral wall of the heart. It can occur alone or with other patterns of infarction. It is often the result of occlusion of the left circumflex artery. ECG changes often occur in the lateral leads, I, aVL, V_5, and V_6. Reciprocal changes may be seen in the inferior leads, II, III, and aVF **Figure 13-65** and **Figure 13-66**.

The ECG in **Figure 13-67** represents an acute lateral wall MI. There is ST-segment elevation in the lateral leads I and aVL and reciprocal changes in the inferior leads II, III, and aVF. Further evaluation shows T-wave inversions in the lateral precordial leads V_5 and V_6. Because the inverted T waves are symmetric, they are related to the acute lateral wall MI and not associated with LVH with strain. An LVH pattern shows an asymmetric inverted T wave.

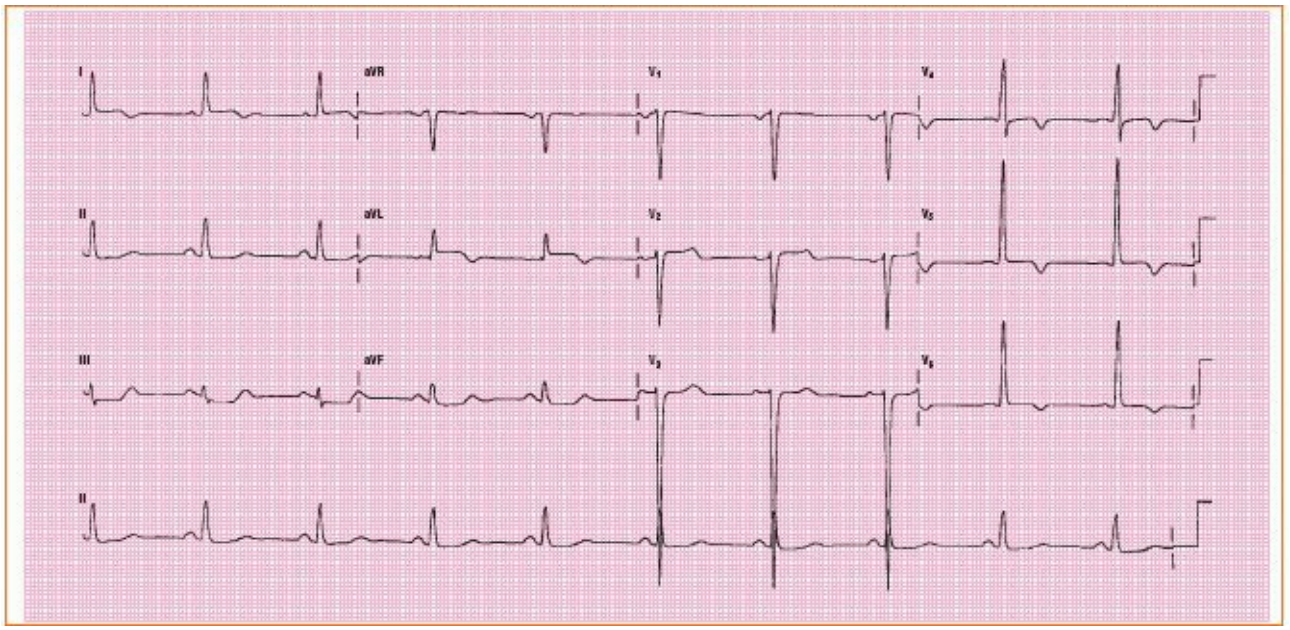

Figure 13-67 A 12-lead electrocardiogram showing an acute lateral wall myocardial infarction.

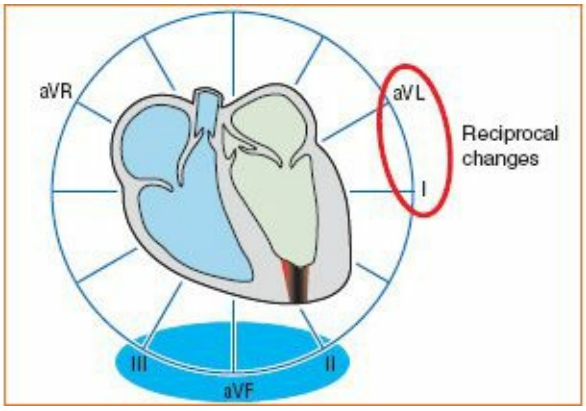

Figure 13-68 An inferior wall myocardial infarction.

Acute Inferior Wall Myocardial Infarction

An IWMI involves the diaphragmatic surface of the heart. It is caused by occlusion of the right coronary artery in 90% of patients and by occlusion in its descending branch or the left circumflex artery in 10% of patients. The characteristic ECG changes of infarction can be seen in the inferior leads II, III, and aVF.

Reciprocal changes are seen as ST-segment depression in leads I and aVL unless the high lateral wall is included in the infarction. An IWMI is commonly seen with patterns reflecting the lateral wall, the posterior wall, and RVIs. Q waves persist for the lifetime of the patient in most cases but not necessarily in inferior infarctions. Nearly 50% of inferior infarctions lose the criteria for significant Q waves within 6 months. Small Q waves in the inferior leads may suggest an old inferior infarction. Small inferior Q waves may be present in healthy hearts, so it is important to use the patient's clinical history in decision making **Figure 13-68** and **Figure 13-69**.

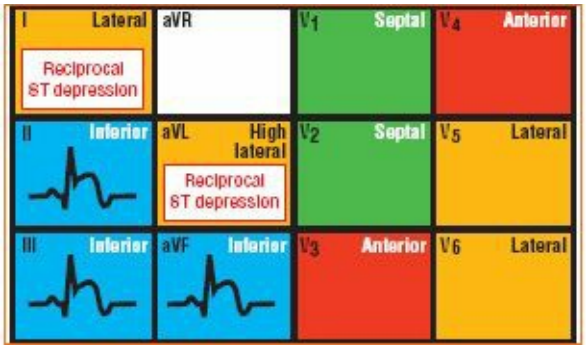

Figure 13-69 Electrocardiographic changes seen with inferior wall myocardial infarction.

The ECG in **Figure 13-70** represents an acute IWMI. Pathologic Q waves appear in leads II and aVF. There are no acute ST-segment or T-wave changes present consistent with an acute infarction. There are also no reciprocal changes found in leads I or aVL. Without signs of acute infarction, pathologic Q waves are considered age indeterminate because without a good patient history, there is no other way to know how old they are. There are also two premature ventricular ectopic beats present that are not necessarily related to the other findings.

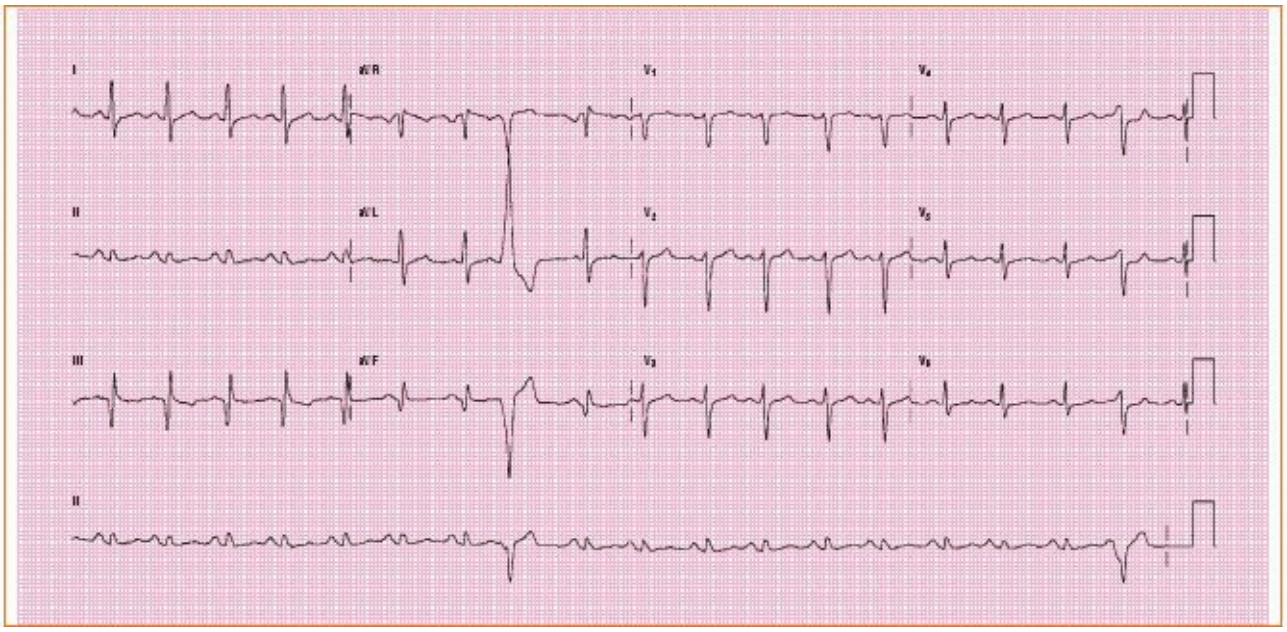

Figure 13-70 A 12-lead electrocardiogram showing an acute inferior wall myocardial infarction.

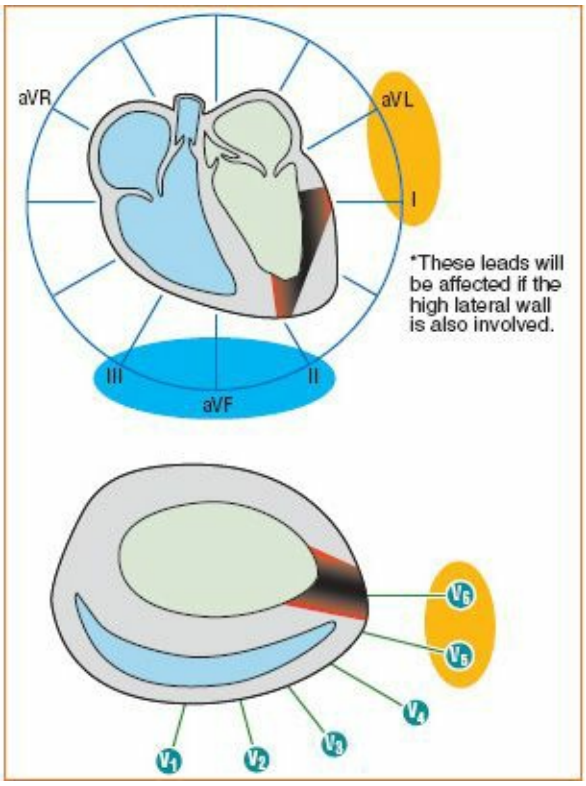

Figure 13-71 Inferolateral leads.

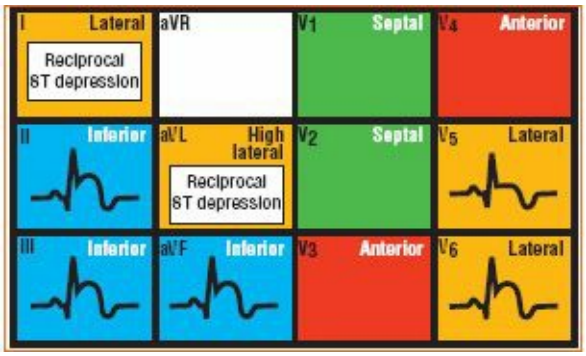

Figure 13-72 Electrocardiographic changes seen with acute inferolateral myocardial infarction.

Acute Inferolateral Myocardial Infarction

ECG changes found in the acute inferolateral MIs are seen in inferior leads II, III, and aVF and in lateral leads I, aVL, V_5, and V_6. ST-segment changes may occur and will be found in leads V_2 to V_4 if the infarct extends anteriorly. When anterior extension is present, classic ST-segment and T-wave changes will always be seen in the lateral precordial leads V_5 and V_6 **Figure 13-71** and **Figure 13-72**.

The ECG in **Figure 13-73** represents an acute inferolateral MI. The ECG shows ST-segment elevation in leads II, III, and aVF. Reciprocal findings can be found as ST-segment depression in leads I and aVF. There is also ST-segment elevation in leads V_3 through V_6. The lateral lead, aVL, shows a markedly downward-sloping ST-segment depression. This is often the first ECG change noted in an acute inferolateral MI, even before ST-segment elevation in the inferior leads.

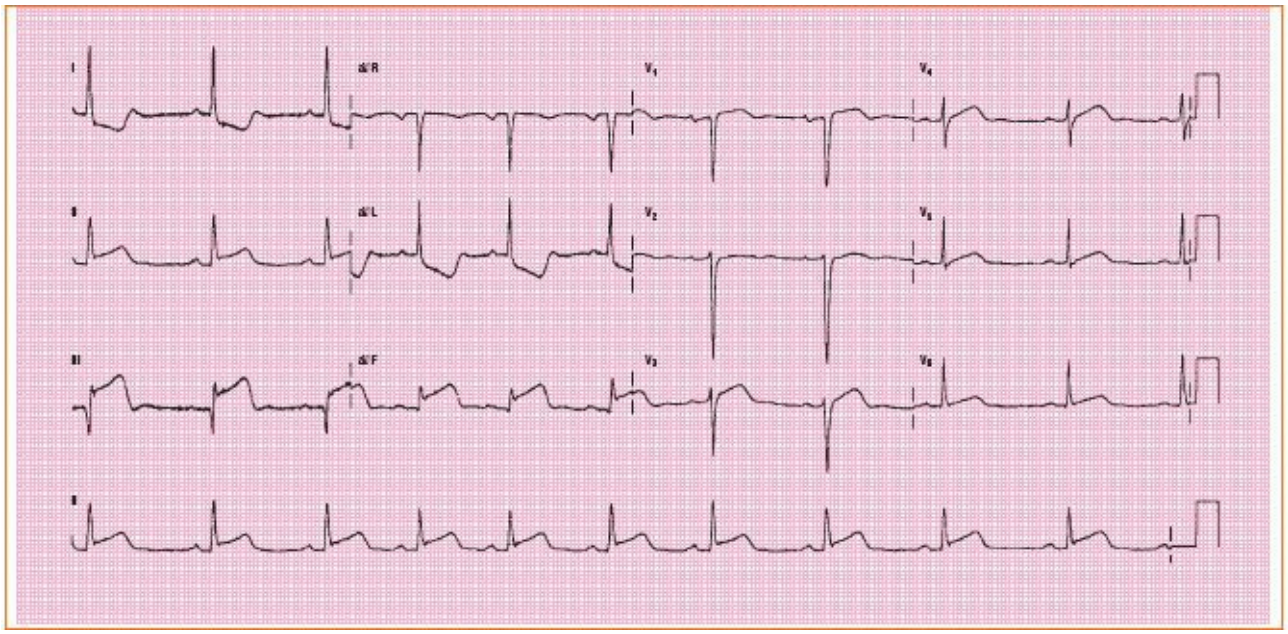

Figure 13-73 A 12-lead electrocardiogram showing an acute inferolateral myocardial infarction.

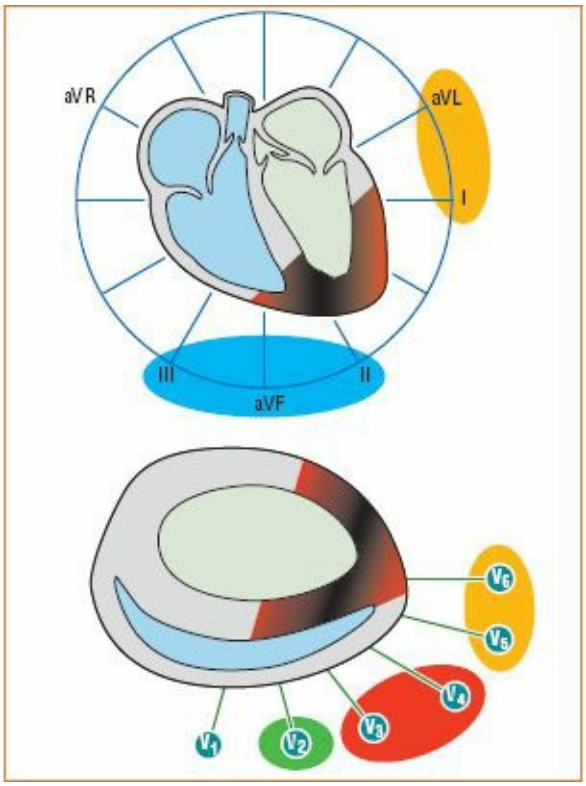

Figure 13-74 Acute apical myocardial infarction leads.

Acute Apical Myocardial Infarction

An apical MI is an extension of an inferolateral MI. It covers a large area of the inferior part of the heart and extends further anteriorly and laterally. The acute apical MI occurs in a patient with RCA dominance. Direct ECG changes can be found in inferior leads II, III, and aVF; lateral leads I and aVL; and precordial leads V_2 through V_6. Because of the diffuse ECG changes, an acute apical MI can be confused with pericarditis **Figure 13-74** and **Figure 13-75**.

The ECG in **Figure 13-76** represents an acute apical MI. Because of the large area affected, ECG changes are diffuse and can be found as ST-segment elevation in limb leads I, II, III, and aVF and

precordial leads V_2 to V_6. This widespread pattern of ECG changes must be distinguished from other conditions such as pericarditis. In pericarditis, there are no Q waves or reciprocal changes, and the T-wave inversion usually does not occur until the ST segment returns to baseline. In an infarction, the ST segment is elevated and the T wave is inverted at the same time. A very rare condition that also demonstrates diffuse ECG changes is aortic dissection, which occludes the coronary ostea (origin of the coronary arteries) on the aorta just distal to the aortic valve. This, among other things, causes a global infarction of the heart because it occludes the source of both main coronary arteries. To rule out some of the more serious differential diagnoses, complete medical histories and clinical evaluations are needed; and radiographic testing, echo-cardiograms, and more sophisticated tests such as cardiac catheterizations must be done.

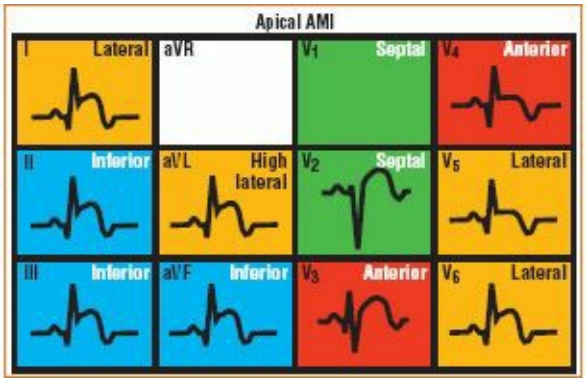

Figure 13-75 Electrocardiographic changes seen with an acute apical myocardial infarction.

Acute Right Ventricular Myocardial Infarction

This section predominantly deals with the criteria for identifying an RVI. Further study on RVI is suggested for a better understanding of the pathophysiology, clinical diagnosis, and management.

An RVI is strongly associated with IWMIs in 30% to 50% of the cases **Figure 13-77** because they are both most often perfused by the RCA and its branches. An occlusion of the RCA would likely affect both regions of the heart at the same time. In a small percentage of cases, the left circumflex artery can supply regions of the inferior wall and right ventricle; therefore, in these cases, an occlusion in the left circumflex artery could cause the same pattern of infarction. An additional 10% of anterior wall MIs are accompanied by RVIs. Because of the high coexistence of RVI with IWMI, a high index of suspicion and checking for other criteria are important.

The ST segment is greater in lead III than in lead II **Figure 13-78**. Because of the RVI, the electrical impulse flows unopposed from the interventricular septum and is directed anteriorly, inferiorly, and to the right. Because this impulse flow causes the vector to be moving toward the lead III electrode, it is recorded with greater amplitude than in lead II.

With ST-segment elevation in (septal) lead V_1 and (inferior) leads II, III, and aVF, RVI should be suspected. Because the electrical impulses are not being transmitted through infarcted tissue, they continue to travel unopposed in all other directions. The alteration in the wave of depolarization generally causes ST-segment elevation in V_1 and ST-segment depression in V_2. Depending on the extent of the MI in the involved heart tissue, ST-segment elevation can sometimes extend through V_5 or V_6.

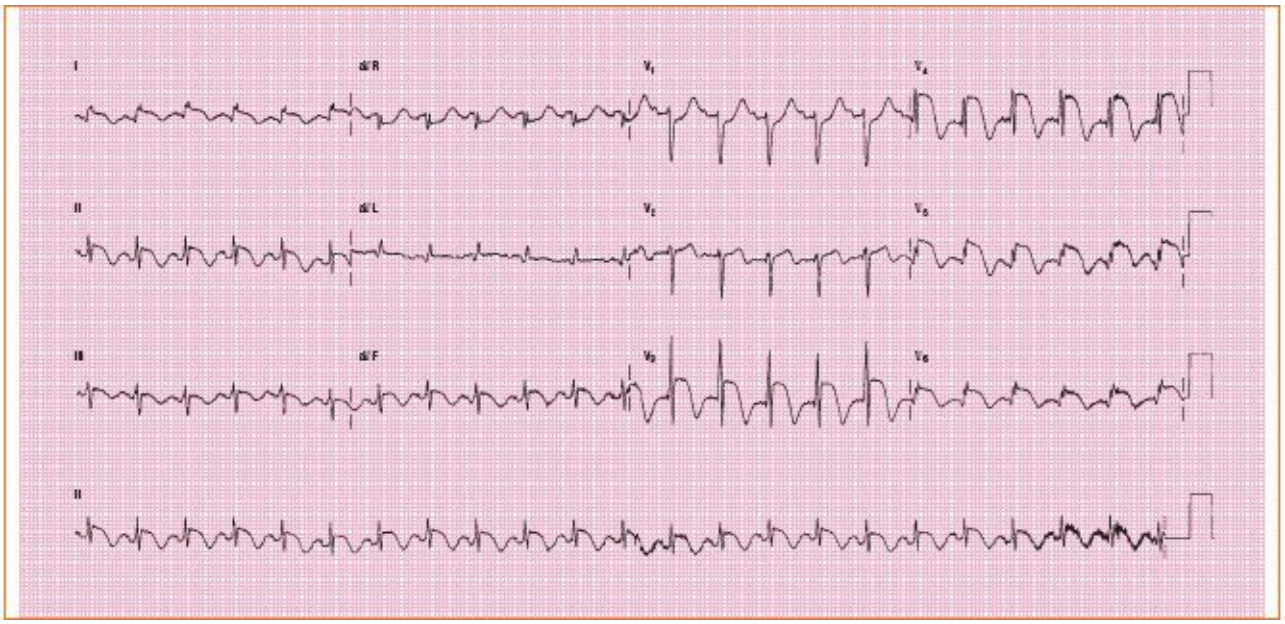

Figure 13-76 A 12-lead electrocardiogram showing an acute apical myocardial infarction.

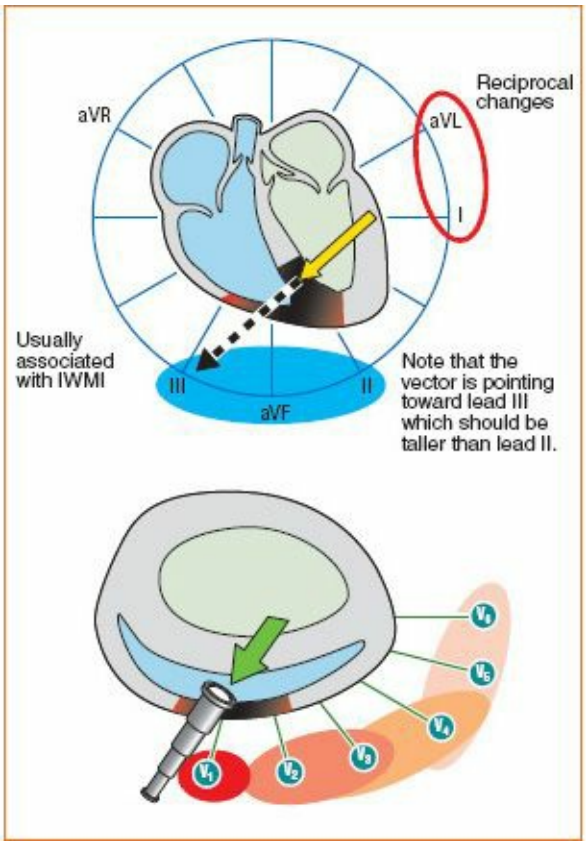

Figure 13-77 A right ventricular infarction.

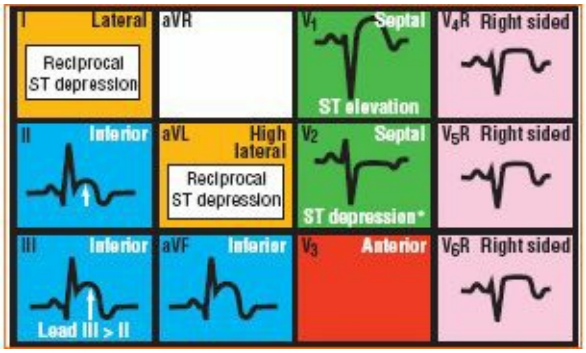

Figure 13-78 Electrocardiographic changes seen with a right ventricular infarction. Note ST elevation in lead V_1, but depending on how much of the RV is affected, it can extend up to V_6! In addition, the amount of ST depression has to be less than half of the ST elevation in aVF!

As mentioned, ST-segment elevation will occur in V_1, but it will usually be depressed in V_2. This difference is because the electrical impulse altered by the MI will cause the vector to travel more directly toward V_1 and past V_2.

An ST-segment depression in V_2 that is less than half the height of the ST-segment elevation in aVF indicates the infarct is localized to the inferior right ventricular region. An ST-segment depression in V_2 that is more than half the height of the ST-segment elevation in aVF indicates that the infarct is larger and includes the inferior wall, right ventricle, and posterior wall.

The use of nonstandard or additional leads on the right side of the chest is important for localizing an infarction. An ST-segment elevation of 1 mm or more in the right-sided chest leads, V_4R to V_6R, is the most specific indication for RVI. Evidence of IWMI (ST-segment elevation and T-wave inversion in leads II, II, and aVF) and also 1 mm or more ST-segment elevation in V_4R are diagnostic of an inferior RVI. If right-sided chest leads are being obtained, a complete set, including V_4R through V_6R, should be for a more complete view of the right ventricle. As this section on RVI suggests, in the presence of IWMI, right ventricular leads should always be recorded as well.

The criteria for RVI are as follows:

1. IWMI
2. ST-segment elevation greater in lead III than in lead II
3. ST-segment elevation in V_1 that could extend through V_5 or V_6
4. ST-segment depression in V_2 (unless the ST-segment elevation extends through V_5 or V_6)
5. ST-segment depression in V_2 not more than half the ST-segment elevation in aVF
6. 1 mm or more of ST-segment elevation in right-sided leads (V_4R to V_6R)

The ECG in **Figure 13-79** represents an RVI. The first notable changes on the standard 12-lead ECG are the classic findings of an IWMI and ST-segment elevation in leads II, III, and aVF with reciprocal findings of ST-segment depression in leads I and aVL. An RVI is suspected because of the IWMI; lead III shows an ST-segment elevation greater than in lead II. Additional criteria for RVI are met with ST-segment elevation in V_1 and ST-segment depression in V_2 that is less than half the ST-segment elevation in aVF.

With the criteria met for RVI in the standard 12-lead ECG, the additional right-sided chest leads V_4R to V_6R are indicated. The ST-segment elevation in lead V_4R completes the diagnostic criteria for RVI. (Note: This example shows only V_4R.)

Acute Posterior Wall Myocardial Infarction

A PWMI is caused by an occlusion of the RCA. The RCA bifurcates into the posterior descending artery and right posterolateral artery in 80% to 85% of the population. The posterior descending artery comes off of the left circumflex artery in the remaining 15% to 20% of the population. The posterior descending artery is sometimes called the posterior interventricular artery, and it supplies the inferior wall, ventricular septum, and posteromedial papillary muscle. The right posterolateral artery divides into

branches that supply the posterior surface of the left ventricle.

There are no leads that specifically look at the posterior surface of the heart on a standard 12-lead ECG. By using standard 12-lead ECG technology, the diagnosis is made by looking for reciprocal changes in leads V_1 and V_2. These changes include ST-segment depression, upright T waves, and tall R waves. Normally, the QRS complex in lead V_1 has a small R wave and a deep S wave. **Figure 13-80** shows the characteristic reciprocal changes of a PWMI as seen in leads V_1 and V_2. The addition of posterior leads can record a direct representation of electrical impulses through the posterior wall.

An R wave with greater amplitude than the corresponding S wave is highly suggestive of a PWMI. In RVH, there is also the presence of an R wave greater than the corresponding S wave in lead V_1. The difference is that RVH also requires the presence of an RAD, which is not present in a PWMI.

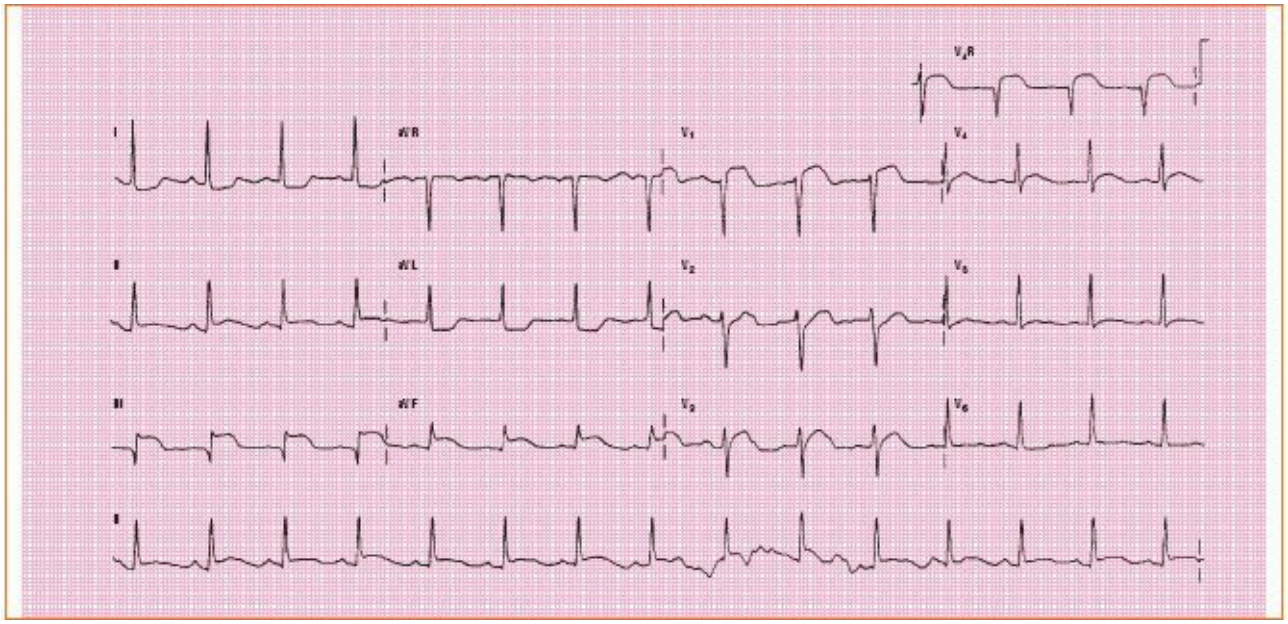

Figure 13-79 A 12-lead electrocardiogram showing a right ventricular infarction.

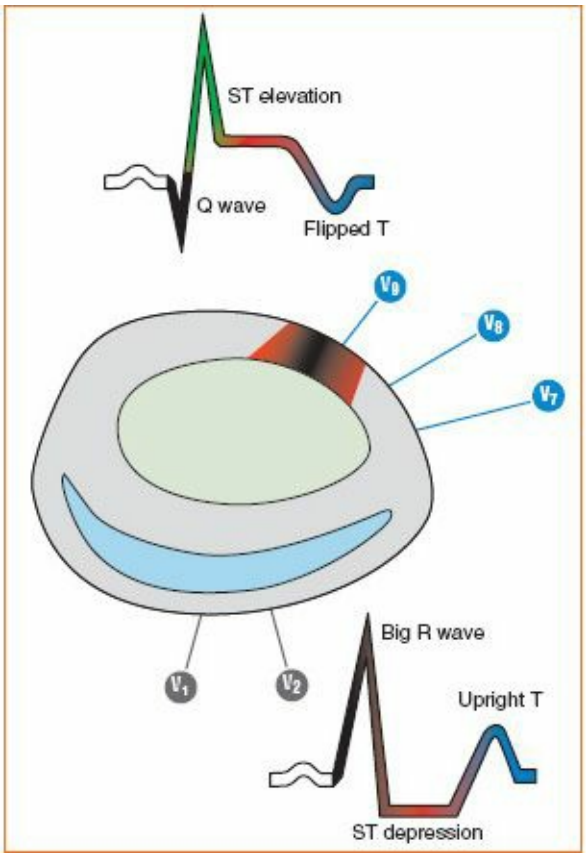

Figure 13-80 A posterior wall myocardial infarction.

Because the posterior descending artery branch of the right coronary artery also perfuses regions of the inferior wall, posterior and inferior wall MIs often occur together.

As discussed earlier, there are nonstandard or additional leads that can be used to provide a direct view of the posterior wall of the heart. When there is reciprocal evidence of a PWMI, a high index of suspicion should be maintained, and posterior leads (V_7, V_8, and V_9) should be recorded for comparison. A standard 12-lead ECG should be recorded first. Then, the additional posterior electrodes are added, the precordial leads are attached as described, and the posterior leads record and are "labeled" to avoid confusion. In the posterior leads, the electrical impulses have to travel through the larger muscle mass of the back, increasing electrical resistance. The complexes are typically positive but tend to have a lower amplitude.

Figure 13-81 and **Figure 13-82** permit comparison of the reciprocal changes of PWMI seen in leads V_1 and V_2 with those in posterior leads V_7, V_8, and V_9.

The ECG in **Figure 13-83** represents a PWMI with reciprocal changes seen on a standard 12-lead ECG. This ECG shows tall R waves in leads V_1 and V_2. There is also ST-segment depression with an upright T wave. These changes are all suggestive of a PWMI.

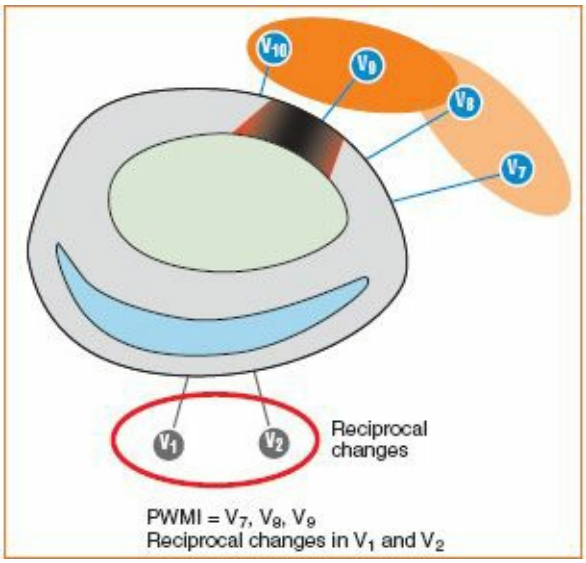

Figure 13-81 A posterior wall myocardial infarction.

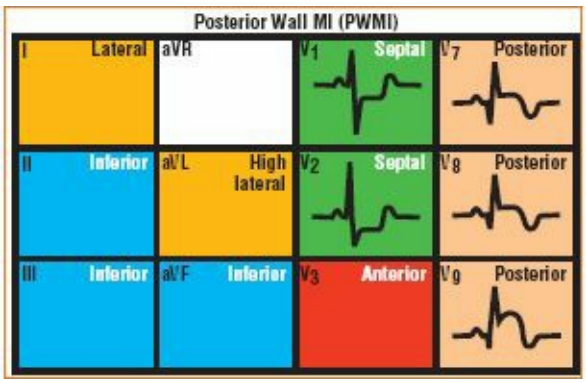

Figure 13-82 Electrocardiographic changes seen with a posterior wall myocardial infarction.

As mentioned, in the majority of the population, the coronary blood supply to the posterior wall is also shared by the inferior wall and right ventricle. This being so, patterns of infarction with changes

associated with inferoposterior and inferior-right ventricular-posterior are often seen.

Cardiomyopathy

Cardiomyopathy is a general term for diseases in which the myocardium becomes thin, flabby, dilated, or enlarged, ultimately progressing to heart failure, acute MI, or death. One variant, hypertrophic cardiomyopathy, is an autosomaldominant hereditary disease. The main feature of hypertrophic cardiomyopathy is an excessive thickening of the heart muscle (hypertrophy means to thicken or grow excessively). In addition, microscopic examination of the heart muscle shows that it is abnormal. Patients may have shortness of breath, chest pains, palpitations, or syncope; sudden cardiac death is also possible. In some patients, beta-blockers are effective treatment. Other patients require surgery or an ICD designed to deliver a shock to the heart when an arrhythmia occurs.

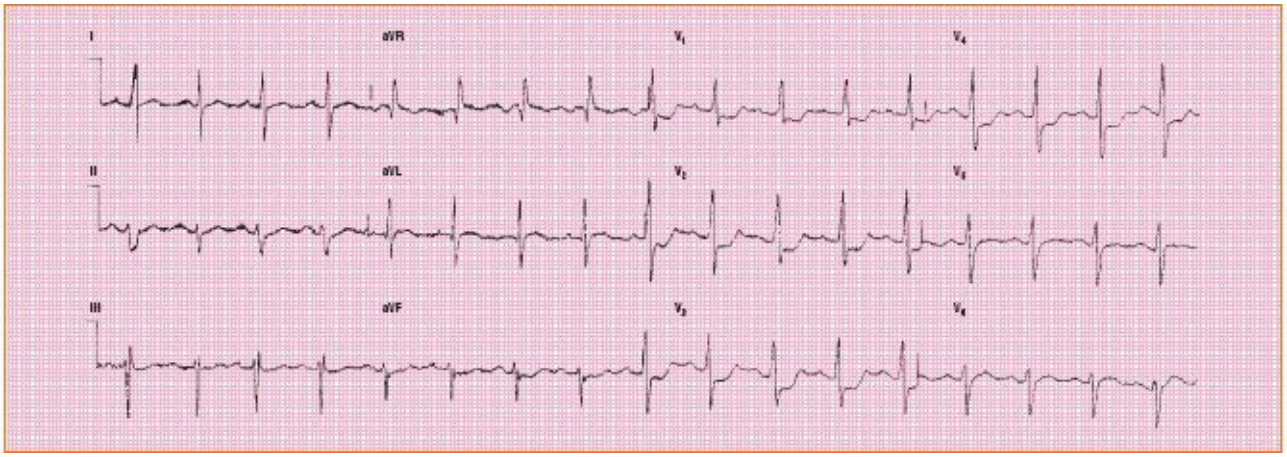

Figure 13-83 A 12-lead electrocardiogram showing a posterior wall myocardial infarction.

Signs and Symptoms

Cardiomyopathy

- Shortness of breath
- Chest pains
- Palpitations
- Syncope
- Sudden cardiac death

Congestive Heart Failure

Congestive heart failure (also known as chronic heart failure) occurs when the heart is unable, for any reason, to pump powerfully enough or fast enough to empty its chambers; as a result, blood backs up into the systemic circuit, the pulmonary circuit, or both. Although CHF may develop in situations other than acute MI, the basic principles of diagnosis and treatment are similar, whatever the precipitating factors.

More than 2 million people in the United States have CHF, and an additional 500,000 cases are diagnosed each year. Nearly half of the patients with CHF classified as severe die within 1 year of diagnosis. Severe cases are those involving acute pulmonary edema with marked limitation to physical activity; those involving cardiogenic shock are life threatening. Heart failure occurs when the heart is unable to pump a sufficient quantity of blood to meet the oxygen requirements of the body and the heart itself. Congestive heart failure can have a number of causes, such as the following:

1. Wall abnormalities (dilated and hypertrophic)
2. Valve failure (mitral, tricuspid, aortic, and pulmonic)
3. Damage as the result of infarctions
4. Conduction abnormalities

In most cases, failure begins with a major infarction involving one or more of the left ventricle walls (septum, anterior, or lateral). Major infarctions can often involve the right side and inferior wall. In any case, subsequent inadequate coronary artery oxygenation combined with cardiac damage often leads to conduction path disturbances, particularly AV nodal blocks requiring pacemaker implantation.

Another problem occurs around the areas of a major infarction. The new nerve fibers develop with an increased density that results in hyperinnervation that can lead to VT and ventricular fibrillation, requiring ICD implantation.

In cases of infarctions involving the septum, synchronization between the ventricles is lost and the ejection fraction is reduced. Patients often require biventricular pacing to restore synchrony.

Left-Sided Heart Failure

The left ventricle is most commonly damaged during an acute MI. Likewise, in chronic hypertension, the left ventricle tends to be affected by the long-term effects of having to pump against an increased afterload (constricted peripheral arteries). In both cases, the right side of the heart continues to pump relatively normally and to deliver normal volumes of blood to the pulmonary circulation. By comparison, the left side of the heart may no longer be able to pump the blood being delivered from the pulmonary vessels. As a result, blood backs up behind the left ventricle, and the pressure in the left atrium and pulmonary veins increases. As the pulmonary veins become engorged with blood, serum is forced out of the pulmonary capillaries and into the alveoli. The serum mixes with air in the alveoli to produce foam (in pulmonary edema).

When fluid occupies the alveoli, oxygenation is impaired. The patient experiences that impairment as shortness of breath (dyspnea), particularly in the recumbent position (orthopnea, as with **paroxysmal nocturnal dyspnea**). Paroxysmal nocturnal dyspnea is severe shortness of breath occurring at night after several hours of recumbency, during which fluid pools in the lungs; the person is forced to sit up to breathe. Paroxysmal nocturnal dyspnea is caused by left-sided heart failure or the decompensation of chronic obstructive pulmonary disease. If left ventricular failure is the result of chronic overload (as opposed to acute MI), the patient is likely to give a history of a week or two of paroxysmal nocturnal dyspnea. To compensate for the impairment in oxygenation, the patient's respiratory rate increases (tachypnea); even so, if the patient's condition is advanced enough, cyanosis may become evident. In some patients with pulmonary edema, especially elderly patients, Cheyne-Stokes respirations may be present.

Fluid from the pulmonary vessels also leaks into the interstitial spaces in the lungs, and increasing interstitial pressure causes narrowing of the bronchioles. Air passing through the narrowed bronchioles creates wheezing noises, whereas air bubbling through the fluid-filled alveoli produces crackles. Furthermore, the patient may cough up the edema fluid in the form of foamy, blood-tinged sputum. As the airways narrow and the lungs grow heavier from the accumulation of fluid, the work of breathing increases, which puts an even greater strain on an already floundering heart. Dyspnea and hypoxemia produce a state of panic, which induces the release of epinephrine from the adrenal glands. The heart is pushed even harder, and its oxygen demand is increased precisely when fluid in the alveoli is reducing the amount of oxygen available.

To make matters worse, the sympathetic nervous system response produces peripheral vasoconstriction: Peripheral resistance (afterload) increases, and the weakened, hypoxic heart finds itself

trying to push blood out into smaller and smaller pipes. Clinically, peripheral vasoconstriction is apparent as pallor and elevated blood pressure. The massive sympathetic discharge also produces sweating of the pale, cold skin.

It is not unusual for a patient with left-sided heart failure to become frantic from air hunger. He or she may pace or thrash about or may even be combative and struggle with the rescue team. Furthermore, hypoxemia results in inadequate oxygen supply to the brain, often manifested as confusion or disorientation. If hypoxemia is severe, cardiac arrest may follow quickly.

Signs and Symptoms of Left-Sided Heart Failure

The signs and symptoms of left-sided heart failure include extreme restlessness and agitation, confusion, severe dyspnea and tachypnea, tachycardia, elevated blood pressure, crackles and possibly wheezes, and frothy, pink sputum. Sometimes, it may be difficult to distinguish the wheezing of asthma from that of left-sided heart failure.

Signs and Symptoms

Left-Sided Heart Failure

- Extreme restlessness and agitation
- Confusion
- Severe dyspnea and tachypnea
- Tachycardia
- Elevated blood pressure
- Crackles and possibly wheezes
- Frothy, pink sputum

Transport Management

Left-Sided Heart Failure

- If the patient is conscious and is able to maintain an airway, apply CPAP.
- Intubate the patient if he or she cannot maintain the airway; deep suction the trachea with the largest suction catheter available.
- Assist the patient to breathe with a transport ventilator with the ability to provide PEEP.
- Use waveform capnography to monitor ventilation response.
- If the blood pressure is elevated, give IV nitroglycerin (Nitro-Bid IV, Tridil).
- If the blood pressure is too low, it must be elevated. Give furosemide (Lasix) or a vasopressor such as dopamine (Intropin) or dobutamine (Dobutrex).
- In case of severe valve failure, give combination therapy of low-dose nitroglycerin and dopamine or low-dose dopamine and dobutamine.
- Obtain a 12-lead ECG.
- Monitor for arrhythmias.
- Provide pain control (morphine, hydromorphone [Dilaudid], or fentanyl citrate).
- If the patient is experiencing an acute MI and a long transport is involved, give a heparin bolus, then

a heparin drip, and then an eptifibatide (Integrilin) drip.
- Monitor for signs of bleeding.

Management of Left-Sided Heart Failure

If a patient is being transported by a critical care transport team, the patient has probably experienced or is having an acute MI.

Pulmonary edema occurs as the result of reduced ejection fraction and CO of the left ventricle. Because the CO from the right ventricle is normal, pulmonary hydrostatic pressure is increased, causing fluids to cross the alveolar capillary membranes, thus filling the alveoli.

The priorities when managing left-sided heart failure are as follows:

1. Remove the fluid from the lungs.
2. Reduce afterload.
3. Increase oxygen supply to the heart.
4. Decrease myocardial oxygen demands.

From a critical care point of view, if the patient is conscious and is able to maintain an airway, apply CPAP, which provides a positive end diastolic pressure that opens the terminal bronchi, expands the alveoli sacs, and creates enough pressure to overcome the increased pulmonary hydrostatic pressure, forcing fluids back into the capillaries.

If the patient's level of consciousness is such that he or she cannot maintain the airway, endotracheal intubation is required. Once a successful intubation has been achieved, deep suctioning of the trachea is required with the largest suction catheter available. Then a transport ventilator with the ability to provide PEEP is applied. Waveform capnography should be used to monitor ventilation response.

Once the airway is controlled, the blood pressure must be managed, and the excess fluids must be removed from the body.

If the blood pressure is elevated, it should be controlled by IV nitroglycerin (Nitro-Bid IV, Tridil); IV nitroglycerin is most commonly mixed as 50 mL of nitroglycerin in 250 mL of D_5W or normal saline. Nitroglycerin is titrated to control blood pressure. Nitroglycerin given IV is preferential to sublingual or paste because it uniformly controls vasodilation and is not subject to the see-saw problems associated with repeated sublingual application. If IV nitroglycerin is used, all other forms of nitroglycerin must be discontinued. IV nitroglycerin is usually started at 10 μg and increased in 10-μg increments until the desired blood pressure is obtained.

If the blood pressure is too low, it must be elevated to provide adequate perfusion pressure. Low blood pressure is a problem in mitral valve failure. In this case, a vasopressor such as dopamine or dobutamine will be required to maintain adequate pressure. In some cases, patients with severe valve failure may be treated with a combination of low-dose nitroglycerin (2–3 μg) to reduce afterload and dopamine (Intropin) as the pressor agent or low-dose dopamine (2–3 μg/kg) to reduce afterload and dobutamine (Dobutrex) as the pressor agent. All of these medications must be administered via an IV pump.

Furosemide (Lasix) should be given to eliminate excess fluids from the system. The dose should be based on local protocol. Furosemide is usually given as 0.5 to 1 mg/kg, not to exceed 80 mg. Furosemide takes 20 minutes to reach full effect, and the systolic blood pressure must be greater than 100 mm Hg.

All patients with CHF or pulmonary edema should have a 12-lead ECG obtained and be monitored for arrhythmias.

For pain control, morphine can be used when blood pressure is not an issue. If the patient is

hypotensive, hydromorphone (Dilaudid) and fentanyl citrate are better choices because they do not lower blood pressure.

If the patient is having an acute MI and a long transport is involved, a heparin bolus, then a heparin drip, and an eptifibatide (Integrilin) drip may be indicated. First, contraindications to anticoagulant or antiplatelet treatment (such as bleeding or recent surgery) must be ruled out. Blood samples should be obtained if not previously done: a red tube (blood banking) and a blue tube (coagulation studies). An IV bolus of heparin is administered per direction of the physician (usually 4,000–5,000 U) and is followed with an IV drip via an infusion pump (usually 700–1,000 U/h). If needed, an eptifibatide drip is administered via an infusion pump per a physician's direction. Heparin is an anticoagulant, and eptifibatide is an antiplatelet drug. Both have short half-lives, less than 2.5 hours. During transport, frequent observation of the patient is needed for signs of major bleeding. Minor bleeding from around the nasal cannula or teeth and mouth is common and no cause for alarm. If any evidence of major bleeding is noted, the drug must be discontinued.

Right-Sided Heart Failure

Right-sided heart failure most commonly occurs as a result of left-sided heart failure. As blood backs up from the left side of the heart into the lungs, the right side has to work increasingly harder to pump blood into the engorged pulmonary vessels. Eventually, the right side of the heart is unable to keep up with the increased workload, and it, too, fails. Right-sided heart failure may also occur as a result of pulmonary embolism or long-standing chronic obstructive pulmonary disease, especially chronic bronchitis.

Signs and Symptoms

Right-Sided Heart Failure

- Edema

Transport Management

Right-Sided Heart Failure

- Provide supportive care.
- Place the patient in a comfortable position, preferably a semi-Fowler's position.
- Treat any signs of associated left-sided heart failure.

When right-sided heart failure occurs, blood backs up behind the right ventricle and increases the pressure in the systemic veins, causing them to become engorged. Distention can be seen in the veins visible on the surface of the body, such as the external jugular veins. Over time, as the pressure within the systemic veins increases, serum is forced out of the veins and into the surrounding tissues, producing edema. Edema is most likely to be visible in dependent parts of the body, such as the feet in a person who is sitting or standing or the lower back in a bedridden patient. Edema is also present in parts of the body that are *not* visible; a painful liver that is easily palpable in the right upper quadrant, for example, signals engorgement and swelling within that organ (hepatomegaly).

The development of right-sided heart failure can actually improve left-sided heart failure because the failing right side of the heart can no longer pump as much blood into the lungs. The decrease in output from the right side, in essence, amounts to a decrease in preload for the left side of the heart and may

lessen pulmonary congestion.

Right-sided heart failure, by itself, is seldom a life-threatening emergency. Usually it develops gradually over days to weeks; likewise, it requires days to weeks to reverse the process by slowly ridding the body of excess salt and water. Treatment in the field of a patient with right-sided heart failure, therefore, is simply to make the patient comfortable, preferably in the semi-Fowler's position. Monitoring is always indicated in any patient with significant cardiac disease. If signs of associated left-sided heart failure are present, they should be treated, as outlined in the previous section.

Pulmonary Edema

The intervention CPAP (discussed in Chapter 6) is most commonly used to treat pulmonary edema while the patient is conscious and able to maintain an airway. Increasing the expiratory pressure forces open the terminal bronchi and the alveoli and increases the pressure within the alveoli to greater than the pulmonary hydrostatic pressure to force fluid within the alveoli back into the capillaries. For transport purposes, a CPAP unit with adjustable PEEP is best. Once CPAP is initiated, treatment with nitroglycerin (Nitro-Bid IV, Tridil), to reduce blood pressure, and furosemide (Lasix), to remove excess fluids, should be undertaken. Initial PEEP settings should be higher (5–10 cm water) but may be reduced after the furosemide and nitroglycerin have taken effect.

Transport Management

Pulmonary Edema

- Use CPAP with adjustable PEEP if the patient is conscious and able to maintain the airway.
- Give nitroglycerin (Nitro-Bid IV, Tridil) to reduce blood pressure.
- Give furosemide (Lasix) to remove excess fluids.

Intubation for patients with acute respiratory distress resulting from asthma or chronic obstructive pulmonary disease should be seen as a last choice. Bilevel positive pressure is an excellent option for this population. Bilevel positive airway pressure is also appropriate for patients with pulmonary edema. Also, most bilevel positive airway pressure machines are large and rarely used during transport. They offer patient advantages, such as humidification, heated air, and exhalation pressure relief. They can be hooked up to oxygen or medical air. For short transports, CPAP may be used in place of bilevel positive airway pressure.

Cardiac Devices

Although ECG is used routinely in the field for diagnostic purposes, **cardiac electrophysiology** is performed in the hospital setting (not during transport). This cardiac specialty involves evaluation and management of cardiac rhythm disturbances. The cardiac electrophysiologist specializes in the diagnosis and treatment of life-threatening ventricular tachyarrhythmias, as well as supraventricular tachyarrhythmias (SVTs, including atrial fibrillation), bradycardias, AV blocks, and syncope of cardiac origin.

In the hospital setting, an electrophysiologist may conduct an electrophysiology study to assess electrical activity of the heart by stimulating and recording that activity from multiple catheters at several sites in the heart. The study records and maps electrical signals from the heart to determine the location of a heart block (AV node vs bundle of His), the origin of tachycardia (supraventricular or ventricular), and

other important parameters, such as the assessment of drugs and devices for the treatment of arrhythmias. These clinical data assist in the following:

- Determining whether the patient's symptoms are related to a tachyarrhythmia
- Assessing the risk for lethal tachyarrhythmias
- Developing and testing appropriate therapies, based on the induced tachyarrhythmia and its mechanism

The CCTP's role during transport is to anticipate the rhythm disturbance for which the patient is being transferred and to correct it per ACLS protocols.

Special Populations

Cardiovascular complications can be exacerbated by pregnancy. It is not uncommon for CCTPs to transport a pregnant patient to a tertiary center for aortic or mitral valve issues, coronary artery disease, thromboembolic events (including pulmonary embolism), or (although rare) aortic dissection.

Therapeutic Options for Patients With Arrhythmias

Compared with a decade ago, a wide array of safe and effective therapies are available for patients with arrhythmias, and more are appearing rapidly. The primary in-hospital arrhythmia therapies are catheter ablation, pharmacologic treatment, and implantable devices, such as pacemakers and ICDs.

Radiofrequency Catheter Ablation

Ablation (destruction) of discrete areas in the heart may reduce or eliminate susceptibility to arrhythmias in certain patients. Radiofrequency catheter ablation is highly effective for WPW syndrome and other SVTs, including atrial flutter, atrial tachycardia, AV node re-entrant tachycardia **Figure 13-84**, and some VTs. Improvements in mapping techniques have made a wider variety of arrhythmias eligible for ablation.

If an ablation corrects the arrhythmia, the patient will not require critical care transport, but if an ablation is unsuccessful, the patient may need critical care transport to a hospital with cardiac surgery capability.

Radiofrequency catheter ablation has completely changed the approach to the long-term management of patients with recurrent SVTs. Electrophysiologists are now able to convert arrhythmias during outpatient procedures. Ablative therapy is effective 90% to 98% of the time, frequently offers a permanent cure, and has a very low incidence of complications.

For many patients with SVT, ablation eliminates the need for long-term medical therapy, which is beneficial for several reasons. Long-term antiarrhythmic therapy can result in drug-induced adverse events and reduce quality of life. These problems often result in inadequate patient adherence to the medication regimen, limiting drug effectiveness. Patients who do not take prescribed medications or are reluctant to undergo long-term drug therapy may be candidates for catheter ablation. Drugs may also be used to interfere with electrical conduction or impulse formation at the AV node, accessory pathway, or origin of a focal tachycardia. Examples include digoxin (Lanoxicaps, Lanoxin), calcium antagonists, beta-blockers, class IA agents (procainamide [Procanbid, Pronestyl, Pronestyl-SR, Procan SR], disopyramide [Norpace, Norpace CR], quinidine gluconate, quinidine sulfate), class IC agents (propafenone [Rythmol], flecainide [Tambocor]), and class III agents (amiodarone [Cordarone], sotalol [Betapace, Betapace AF]). Long-term digoxin therapy is contraindicated in patients with WPW syndrome and patients with the capability of rapid **antegrade conduction** over the accessory pathway.

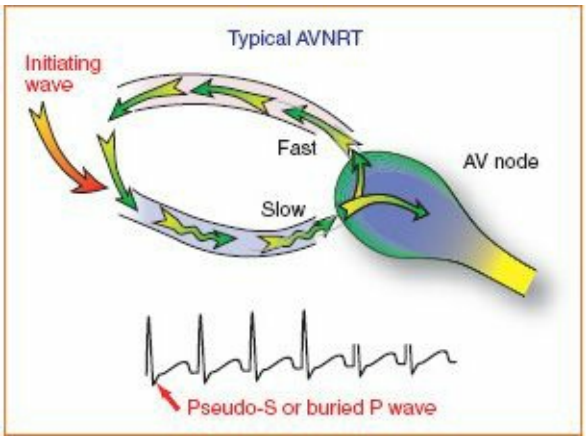

Figure 13-84 Atrioventricular (AV) node re-entrant tachycardia.

Cardiac Pharmacology

Cardiovascular drugs improve cardiac performance by altering the physiologic and biochemical events that control cardiac function. They may change heart rate, force of contraction, speed of conduction, excitability of cardiac tissue, phases of the action potential, and blood flow. They are used to halt or slow disease processes, augment heart rate reserves, control arrhythmias, and manage an overworked heart. **Table 13-10** summarizes the effects of cardiac drugs.

Implanted Pacemakers

An implanted pacemaker provides impulse generation in a diseased heart whose own impulses may be:

- Intermittent
- Irregular
- Occurring at an inappropriate rate for the patient's metabolic demand
- Absent

A block can occur at any point within the SA node, AV node, bundle of His, or distal conduction system.

Modern pacemakers support heart function in several ways. They provide effective and consistent cardiac depolarization, prevent unnecessary pacing by sensing cardiac activity, increase the rate to meet increased metabolic demand, and provide information about how the patient's heart and the implanted pacemaker are functioning.

Implantable Cardioverter-Defibrillators

New guidelines for **implantable cardioverter-defibrillator (ICD)** therapy reflect published data confirming the benefits of ICD therapy over antiarrhythmic drugs for the treatment of life-threatening ventricular tachyarrhythmias. ICDs have been proven to prevent sudden cardiac death and to reduce overall mortality considerably compared with antiarrhythmic drugs. Studies have also shown that ICDs are up to 99% effective in terminating life-threatening ventricular tachyarrhythmias.

Pacemakers

The first implantable pacemakers, developed in 1960, were asynchronous; they paced without regard to the heart's intrinsic action. The NBG (North American Society of Pacing and Electrophysiology [NASPE]/British Pacing and Electrophysiology Group [BPEG] Generic) codes appear later in this chapter in **Table 13-11**, which explains similar abbreviations related to pacemaker (also called pacer) function.

Single-chamber demand pacemakers appeared in the late 1960s. In 1979, the first **dual-chamber**

pacemaker was introduced. The first single-chamber, rate-responsive pacemaker came into use in 1985. Today, dual-chamber pacemakers use rate-responsive pacing to mimic the heart's rate response and meet metabolic needs, most recently using a combination of sensors to accomplish this.

In a normally functioning heart, the SA node stimulates depolarization of the ventricles. When the SA node becomes nonfunctional, arrhythmias affecting the life and functionality of the patient can occur. At this point, an artificial pacemaker must be installed. The primary indications for pacing are as follows:

1. Symptomatic sinus bradycardia refractory to atropine
2. Heart blocks (Mobitz II and third-degree heart block)
3. Sinus node disease (sick sinus)
4. Reflex syncope
5. Cardiac resynchronization
6. Chronotropic incompetence
7. Overdrive pacing for tachyarrhythmias

There are four major categories of cardiac pacemakers:

1. Transcutaneous
2. Implantable
3. Transthoracic or epicardial
4. Transvenous (external)

The most fundamental pacer is the transcutaneous pacemaker. It is the one most commonly used as an initial emergency pacer. Multifunction pads are attached to the patient's skin in the anterior-posterior positions over the patient's heart. The electrical pacing impulse is transferred to the heart through the skin and thoracic cavity. Although this is the quickest and most convenient method of pacing, it requires the most energy and is the least reliable owing to the quality of the skin-to-pad contact and the thoracic impedance that must be overcome. It is generally used as a temporary measure until a transvenous pacemaker can be placed. This pacemaker is the one most likely to be used by CCTPs if a patient requires emergency pacing en route.

Implantable pacemakers consist of a battery-operated pulse-generating module with attached pacer leads. An interventional cardiologist implants the lead or leads in the myocardial wall as needed. The pulse-generating module is then surgically implanted in the body, usually in a sac created between the pectoral muscle and the cutaneous layer of the skin. In some cases, the pacemaker electrode is screwed into the myocardial wall, and the pulse generator is installed below the xiphoid process.

TABLE 13-10 Cardiovascular Drug Actions and Uses

Drug	Action	Primary Uses
Drugs That Control Myocardial Ischemia		
Oxygen	Improves oxygen supply to tissue	Ischemic chest pain and cardiac arrest
Nitroglycerin (Nitro-Bid IV, Tridil)	Dilates blood vessels and improves coronary blood flow; reduces cardiac workload	Ischemic chest pain and acute MI
	Reduces cardiac workload and increases pain	

Morphine sulfate	threshold	Ischemic chest pain
Drugs That Control Heart Rhythm		
Lidocaine (Xylocaine)	Blocks the sodium channel and decreases excitability; suppresses ventricular ectopic activity	Persistent VT or fibrillation
Procainamide (Procanbid, Pronestyl, Pronestyl-SR, Procan SR)	Blocks the sodium channel and decreases conductivity; suppresses ventricular ectopic activity	Recommended when lidocaine treatment fails or is contraindicated
Beta-adrenergic blockers Propranolol (Inderal) Atenolol (Tenormin) Esmolol (Brevibloc)	Block the sympathetic response of the AV and SA nodes; reduce sinus activity and slow conduction	Atrial fibrillation and reduce the incidence of ventricular fibrillation after an MI
Atropine sulfate	Blocks the parasympathetic response of the SA node; increases heart rate and AV conduction	Symptomatic bradycardia, junctional escape rhythms, and second- or third-degree AV block, cardiac arrest
Isoproterenol (Isuprel)	Stimulates the heart's sympathetic response; increases heart rate and CO	Significant bradycardia refractory to other therapies; also denervated post–heart transplantation bradycardia
Verapamil (Calan, Covera, Isoptin, Verelan)	Blocks the calcium channel; slows sinus activity and suppresses AV conduction; slows heart rate, decreases blood pressure, decreases myocardial contractility; ultimately decreases myocardial oxygen demand; usually used as second-line drug after beta-blockers	Ischemic heart disease, LVH, lung disease, and hypertension
Diltiazem (Cardizem, Dilacor, Tiazac)	Blocks the calcium channel; slows sinus activity and suppresses AV conduction; slows heart rate, decreases blood pressure, decreases myocardial contractility; ultimately decreases myocardial oxygen demand; usually used as second-line drug after beta-blockers	Ischemic heart disease and LVH; atrial rhythms
Adenosine (Adenocard)	Reduces the sinus rate, slows AV conduction, and interrupts re-entrant pathways	Wide complex tachycardia, narrow complex tachycardia,

		conversion of SVT to normal sinus rhythm
Magnesium sulfate	Not completely understood; may increase systemic vasodilation and reduce myocardial oxygen demand	Polymorphic VT, pulseless VT, and ventricular fibrillation
Amiodarone (Cordarone)	Blocks the potassium channel and extends the refractory period; slows conduction	CHF and WPW syndrome
Sotalol (Betapace, Betapace AF)	Blocks the potassium channel and extends the refractory period; slows conduction	Ischemic heart disease
Drugs That Improve CO and Blood Pressure		
Epinephrine (Adrenalin)	Stimulates sympathetic response and increases heart rate and contractility	Cardiac arrest; also used in infusions to increase blood pressure
Norepinephrine (Levophed)	Constricts peripheral vessels and increases blood pressure	Cardiogenic shock and severe hypotension
Dopamine (Intropin)	Dilates blood vessels; increases heart rate and contractility at higher doses	Cardiogenic shock and hypotension
Dobutamine (Dobutrex)	Stimulates sympathetic response; exerts a positive inotropic effect	Refractory congestive heart failure and cardiogenic shock
Inamrinone (Inocor)	Dilates blood vessels; exerts a positive inotropic effect	Severe congestive heart failure that has not responded to other inotropic agents
Digitalis	Slows AV nodal conduction; exerts a positive inotropic effect; highly toxic	To control ventricular response rate in chronic atrial fibrillation
Drugs That Provide Diuresis or Prevent or Dissolve Blood Clots		
Diuretics Furosemide (Lasix) Bumetanide (Bumex)	Act on kidneys to increase urine output	Hypertension and pulmonary edema
Fibrinolytic agents TPA Streptokinase (Streptase) Tenecteplase (TNKase)	Dissolve blood clots and restore blood flow	Stop or limit MI

Reteplase (Retavase) Anistreplase (Eminase) Alteplase		
Anticoagulants Heparin (Liquaemin) Warfarin (Coumadin) Enoxaparin (Lovenox) Aspirin	Inhibit clot formation; heparin decreases thrombin and fibrin production; aspirin inhibits platelet aggregation	Prevent thromboembolism in patients at risk
Glycoprotein IIb/IIIa inhibitors Abciximab (ReoPro) Eptifibatide (Integrilin) Tirofiban (Aggrastat)	Inhibit platelet aggregation	ACS without ST-segment elevation

Implantable pacers can be unipolar or bipolar and come in a variety of types:

1. Atrial
2. Ventricular
3. Atrial and ventricular
4. Biventricular
5. Overdrive pacemakers for tachyarrhythmias

Pacemakers can operate on demand, or the patient's heart can be fully paced. A demand pacer intervenes when the patient's normal rhythm fails. In this case, the ECG will show the patient's normal rhythm with periodic pacer intervention. An ECG for a patient with a fully paced heart will show only the paced rhythm.

Most pacers today are atrial and ventricular, and many have an ICD built into them. Biventricular pacers are used in patients with ventricular asynchrony to restore synchrony and improve ejection fraction and CO. Pacer circuitry is less complicated than defibrillator circuitry and requires less power. Statistically, pacer circuits show a lower incidence of failure than ICDs. The most common sources of failure are the following:

1. Battery failure
2. Lead wire failure or detachment

Less common sources of failure are as follows:

1. Failure of the pulse-generator circuitry
2. Dislodgment from the myocardial wall

A third class of pacers is transthoracic or epicardial pacers. This type of pacing is done only by interventional cardiologists or cardiac surgeons and involves placing pacing electrodes directly into the heart through the thoracic cavity. This type of pacing is limited to the hospital and would only be encountered by the CCTP if called to move a patient post-operatively. Wires can be attached to the atria

and/or ventricles and are attached through a connector cable to the same type of temporary pulse generator used for transvenous pacing.

Finally, many patients are transported between facilities with transvenous pacemakers with an external pulse generator. The pacemaker lead wire is placed in the heart by an interventional cardiologist or an emergency department physician. This type of pacemaker is likely to be encountered by CCTPs performing interfacility transports and is discussed in more detail next.

Transvenous Pacemakers

Transvenous pacemakers are placed in a patient as a temporary method of pacing until the pacing problem is resolved or until a permanent pacemaker is implanted. The transvenous pacemaker is much move reliable than transcutaneous pacing. The pacer lead has direct myocardial contact, is located precisely in the most appropriate spot, and has an external pulse generator that allows direct control of the impulse parameters. The lead wires are placed by an interventional cardiologist or an emergency department physician, and the battery-operated pulse generator is externally connected to the pacing leads, as shown in **Figure 13-85**.

The external pulse generator provides the following controls:

1. Pulse rate
2. Current amplitude
3. Sensitivity
4. Automatic or manual mode

Figure 13-85 A temporary transvenous pacemaker.

The lead wires are externally connected to the pulse generator. Most transports require no adjustments; however, all of the previously mentioned controls can be changed as required by the patient's condition.

Generally, transvenous pacers require little attention and are quite reliable. It is recommended that CCTPs become familiar with the type of transvenous pacemaker used by local hospitals or that they get a tutorial on troubleshooting the device. Primary sources of problems are battery failure and lead disconnection at the generator. On long trips, having an additional battery and knowing how to install it are helpful. Before leaving the transferring facility, the pacer rate, capture current, and sensitivity settings should be noted and mechanical capture confirmed by taking a pulse. On occasion, a demand transvenous pacer may confuse peaked T waves or large P waves for the R wave and will not pace. In this case, the sensitivity should be lowered and mechanical capture should be confirmed by taking a pulse. If the pacer is in the automatic mode and capture is not happening, the manual mode should be used and the current (milliamps) adjusted until capture is achieved. It is important to note how the lead wires are attached so that they can be reattached if they become loosened during transport.

Pacing Fundamentals

The Pacing Impulse

Electricity is the flow of electrons along a conductive medium. A **pacing impulse** has current, voltage, and impedance. **Current** is the movement of electrons through an electrical circuit over time, measured in amperes. **Voltage** is the force that causes current to flow, measured in volts. Voltage in a pacing system, referred to as amplitude, reflects the strength or intensity of a pacing pulse.

Resistance to current, called **impedance**, is the sum of all factors that resist the flow of current along the conduction pathway, measured in ohms. One ampere is produced by 1 volt, acting through a resistance of 1 ohm. The main sources of resistance in a pacing circuit are the lead conductor, the electrode, and the concentration of electrically charged ions at the electrode-tissue interface (polarization). Electrode resistance improves pacing efficiency; lead conductor resistance and polarization do not. Review of the following definitions and formulas will help in understanding the basic concept of electricity as it pertains to pacing.

Ohm's law is an expression of the relationship between current (I), voltage (V), and resistance (R). Ohm's law states the following: Current = Volts/Resistance. In other words, I = V/R. Consequently, V = I × R and R = V/I. With these equations, volts, current, and resistance may be calculated if the other parameters are known. If the voltage drops by half, the current flow does also. Doubling impedance will also cut current flow in half. Voltage and impedance are important determinants of battery longevity.

A **joule** is a measurement of energy. Energy = Volts × Current × Time. Energy is then expressed in joules or microjoules, as appropriate for the device.

Pacing Circuit

A pacing system forms an electrical circuit in the patient's body by combining with body tissue and fluid. A **pacing circuit** consists of a power source, lead, cathode, anode, and body tissue, which form a conduction pathway along which electricity flows.

The pacemaker battery is the power source that generates electrical impulses. The lead conductor wire carries the impulses to the tissue. The **cathode** is an electrode with a negative charge that delivers the impulse to the myocardium. The impulses return through the **anode**, an electrode with a positive charge, after stimulating the heart. Body tissue and fluids between the anode and cathode are also part of the conduction pathway. Passage of the pacemaker's electrical impulse between the cathode and anode—through cardiac tissue and body fluids—is the event in the pacing circuit that stimulates cardiac depolarization. In a **bipolar system**, body tissue is part of the circuit only in the sense that it affects impedance at the electrode-tissue interface. In a **unipolar system**, contact with body tissue is essential to ground the **implantable pulse generator (IPG)**.

During pacing, an electrical impulse begins in the pacemaker battery, travels along the lead to the cathode, stimulates the heart, and then returns through body tissues to the anode to complete the pacing circuit **Figure 13-86**.

Pacemaker Components and Functions

Pacemakers stimulate cardiac depolarization, sense intrinsic cardiac activity, respond to metabolic need, and store diagnostic information. All pacemakers can provide fixed-rate pacing, in which the heart is paced at a predetermined rate. Most also provide rate-a daptive (rate-responsive) pacing, increasing and decreasing the pacing rate in response to input from rate sensors. This feature prevents the pacemaker from competing with normal cardiac function. In addition, modern pacemakers collect and store information about the patient's heart and the implanted pacemaker. This information allows clinicians to monitor pacing therapy, optimize programmed settings, and check battery and lead status. A basic pacing

system consists of the following:

- An IPG that contains a power source—the battery that generates the impulse—and sensing, timing, and output circuitry that controls pacemaker operation
- Leads—one or two insulated wires that deliver electrical impulses from the pulse generator to the heart and return electrical signals from the heart to the pulse generator
- Electrodes—conductors at the ends of the leads that deliver impulses to the heart

Most IPGs have a telemetry coil for sending and receiving programming instructions and receiving diagnostic data. Many have sensors that measure indicators of exertion and use the results to change heart rate.

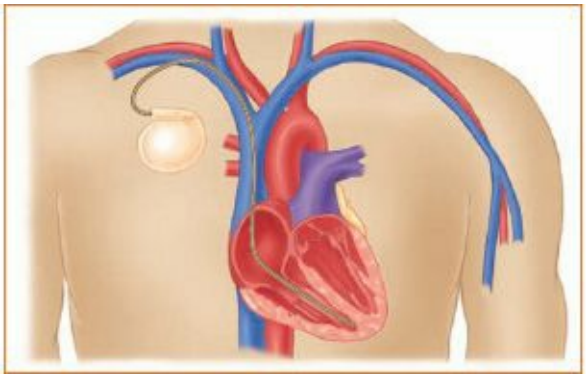

Figure 13-86 The pacing circuit. The electrical impulse travels along the lead, stimulates the heart, and returns through body tissues.

Leads

Lead insulation prevents contact between the conductor wire and body tissue, ensuring that stimulation occurs only at the tip of the electrode. About 95% of pacing leads are **endocardial (transvenous) leads**, threaded through veins—usually subclavian or cephalic—to the right atrium or ventricle **Figure 13-87**. Placement involves an introducer (hollow tube) and a stylet (stiff wire). The clinician uses imaging, usually fluoroscopy, to guide insertion and final placement. **Epicardial leads**, which attach to the external surface of the heart with sutures or another fixation device, account for the other 5%. Because epicardial placement requires a thoracotomy (chest incision), epicardial leads are desirable only when endocardial placement is not an option.

A pacing lead may be unipolar or bipolar. A **unipolar lead** has one conductor wire connecting to a single electrode. The cathode is in contact with the heart, and the IPG housing is the anode. A pacing pulse travels from the IPG to the tip of the electrode (cathode) to stimulate the heart and returns to the IPG housing through chest tissues to complete the pacing circuit. The current flows through a substantial part of the chest and forms a large current loop; the resulting pacing spike is easily visible on an ECG.

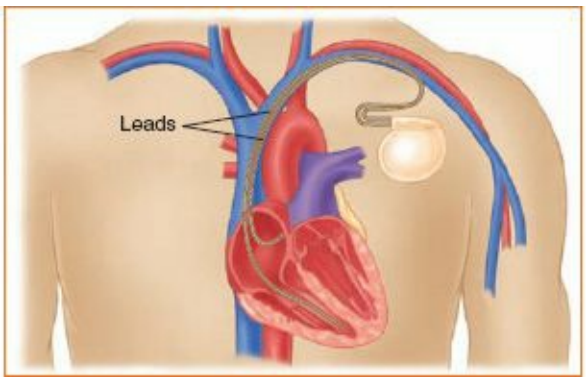

Figure 13-87 Endocardial (transvenous) pacing lead placement.

A **bipolar lead** has two conductor wires; both the anode and cathode are in contact with the heart. The anode, the ring electrode located 2 to 3 cm above the cathode, has a separate lead connecting it to the IPG. The pacing pulse travels from the IPG to the cathode and then through tissue to the ring electrode. It returns to the IPG by way of the second conductor wire. Because the current loop is small, passing through only a limited area of cardiac tissue, the pacing spike on the ECG is also small.

Electrodes

A cathode, an electrode that is in contact with heart tissue, is negatively charged when electrical current is flowing. The anode is the electrode that receives the electrical impulse after depolarization of cardiac tissue. It is positively charged when electrical current is flowing.

Small electrodes with a porous surface increase electrode resistance and reduce the effects of polarization. The porosity significantly increases the electrode surface area without increasing the radius and, thus, reduces the wasteful effects of polarization. The porous surface also promotes tissue ingrowth and improves sensing by providing a larger electrode-tissue contact area.

Steroid Elution

There are two types of transvenous pacemaker leads:

1. Passive fixation
2. Active fixation

The active fixation leads have higher stimulation than the passive fixation leads; however, they are preferred for the following reasons:

1. Passive fixation leads involve atrial appendage placement, which is difficult in patients with prior cardiac surgery
2. Active fixation leads allow for more placement areas
3. Active fixation leads reduce the incidence of dislodgement

To make the active fixation more beneficial, a steroideluting lead was developed. The steroid reservoir in the tip of the lead contained dexamethasone sodium phosphate. The inclusion of the steroid-eluting reservoir in the active fixation lead improved stimulation thresholds and was found to extend pulse-generator longevity.

Steroid elution reduces inflammation and the growth of fibrous tissue at the electrode site. Both inflammation and fibrosis reduce electrical excitability of cardiac tissue. Because steroids inhibit inflammation and fibrosis, steroid presence helps maintain a better electrode-tissue interface.

Steroid-eluting electrodes have a silicone plug that contains a small dose (<1 mg) of steroid. Body fluids seep into the electrode and gradually dissolve the steroid, which then flows in the body fluids to the electrode-tissue interface. Initially, the rate of steroid elution is high, but the rate decreases over time. The steroid typically lasts for several years.

Single-Chamber vs Dual-Chamber Systems

A single-chamber pacing system uses one lead that may be placed in the right atrium or right ventricle **Figure 13-88**. A dual-chamber pacing system uses two leads, one in each of these chambers **Figure 13-**

89. The dual-chamber approach compensates for two potential limitations of single-lead systems: the inability to coordinate atrial-ventricular timing (AV synchrony) and the lack of ventricular backup pacing in the absence of AV conduction.

NBG Codes

Developed by a joint effort of North American and British electrophysiology groups, the **NBG code** (NASPE/BPEG Generic) provides a succinct way to describe pacemaker functions and capabilities. These terms may be encountered in patient documentation; a general familiarity with them is very helpful in determining appropriate pacemaker function. **Table 13-11** lists the codes and their meanings.

The first letter in the NBG code represents the chamber where the pacing occurs. The options for where pacing can occur are the atrium, ventricle, both, none, or single (which can signify the atrium or ventricle). The second letter in the NBG code represents the chamber where the pacing is sensed. The options in this category are the same as those in the first category.

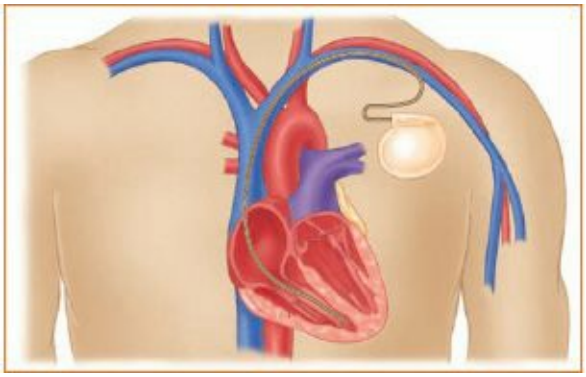

Figure 13-88 A single-chamber pacing system.

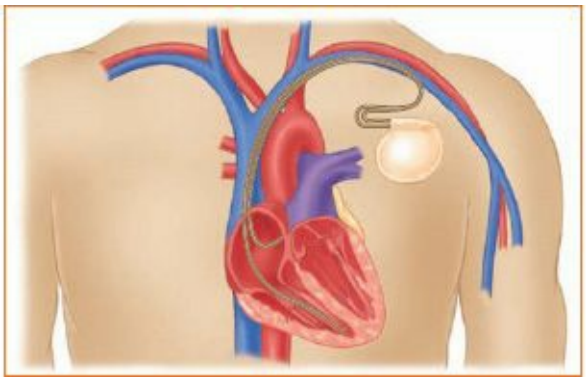

Figure 13-89 A dual-chamber pacing system.

TABLE 13-11 NBG Codes

I Chamber Paced	II Chamber Sensed	III Response to Sensing	IV Programmable Functions; Rate Modulation[a]	V Antitachyarrhythmia Functions
V: Ventricle	V: Ventricle	T: Triggered	P: Simple programmable[c]	P: Pace
A: Atrium	A: Atrium	I: Inhibited	M: Multiprogrammable[d]	S: Shock
D: Dual (A + V)	D: Dual (A + V)	D: Dual[b]	C: Communicating[e]	D: Dual[f]
O: None	O: None	O: None	R: Rate modulating	O: None
S: Single (A or V)	S: Single (A or V)		O: None	

[a] This sequence is hierarchical; it is assumed that if a pacemaker has rate modulation capabilities (R), it

also can communicate (C).

[b] Inhibited and triggered. In single-chamber mode, *triggered* means initiating a pacing pulse immediately after sensing an intrinsic event. In dualchamber mode, the term means that a sensed atrial event will initiate an AV delay.

[c] Rate and/or output.

[d] Rate, output, sensitivity, and so forth.

[e] Can send and receive information to and from the programmer.

[f] Pace and shock available.

The third letter indicates how the pacemaker responds to sensing. Options in this category include triggered, inhibited, dual, and none. The I setting, or inhibited response, indicates that the pacemaker is set to fire only under certain conditions. For example, the pacemaker may fire only when the patient's heart rate falls below a certain rate. In other words, when the pacemaker senses an impulse from the patient, it inhibits or does not fire its own impulse. The T setting, or triggered response, indicates that the pacemaker, after sensing an impulse from the patient, triggers a pacemaker impulse. D, for the dual setting, indicates that the pacemaker can perform in an inhibited and a triggered manner, as needed. The O setting, or no response, may be used when a technician wants to ignore sensed beats from the patient and fire the pacemaker regardless of any underlying patient rhythm.

The fourth letter represents the pacemaker's programmability and rate-modulation capability, which is simply a representation of how much programming can be done externally. Pacemakers may have many external programming options (M) or just a few (P). C, or communicating, indicates that the pacemaker can transmit data, as with telemetry. R, or rate modulation, means that the pacemaker can adjust its rate depending on the body's needs.

The fifth letter represents antitachyarrhythmia functions. P, or pacing, indicates that a tachyarrhythmia is converted by pacing. S, or shock, indicates that a tachyarrhythmia is converted by defibrillation administered by the pacemaker. D, or dual, indicates that the pacemaker can pace and administer a shock to address a tachyarrhythmia.

An example of an NBG code is a VVI pacemaker, in which pacing occurs in the ventricle, sensing occurs in the ventricle, and the response setting is inhibited. In day-to-day practice, only the first three letters of the NBG code are typically used.

Pacemaker Troubleshooting

Pulse-generator failure is a rare occurrence (0.46%, or 1.3 malfunctions per 1,000 persons annually). Pacemaker system malfunction occurs occasionally. The primary areas of failure are the following:

1. Battery failure
2. Problems at the lead electrode-tissue interface
3. Coiling or damage to the lead-generator interface
4. Insulation failure of the lead wires
5. Dislodgement of the lead at the implantation site (very rare)
6. Pacemaker programming
7. Pacemaker pocket stimulation (muscle tissue in the vicinity of the implanted pacemaker is stimulated by the pacer itself; more common in unipolar pacers than in other types)
8. Diaphragmatic stimulation
9. Electromagnetic interference (cell phones and other personal electronic devices)

Electromagnetic interference is the collective effect of high-frequency signals from environmental sources that produce electromagnetic fields in the frequency range of 50 to 60 Hz. Electromagnetic interference enters a pacemaker by conduction if the patient is in direct contact with the source or by way of radiation if the patient is in an electromagnetic field with the pacemaker lead acting as an antenna. Exposure to electromagnetic interference can affect pacers in various ways, all of which prevent it from functioning appropriately.

Table 13-12 details the four general types of in-hospital solutions available to correct abnormal pacing behavior; however, these cannot be done during transport except with temporary external pulse generators.

During transport, CCTPs must be aware of the signs of pacemaker failure. The cardiac monitor will show failure to capture, and a 12-lead ECG is helpful, but even more important is patient assessment. First, the CCTP should confirm that the patient's pulse corresponds to pacer presentation on the ECG and, next, should determine if the patient shows signs of decompensation, such as the following:

1. Syncope
2. Dizziness
3. Palpitations
4. Bradycardia
5. Heart blocks
6. Hypotension
7. Tachycardia
8. Extracardiac stimulation (sometimes shown by hiccoughs)

TABLE 13-12 Options for Correcting Pacer Malfunction

Solution	Use or Indication
Reprogramming	Correct oversensing, undersensing, and loss of capture As a temporary solution in some cases of an insulation break Adjust atrioventricular intervals and rate response to optimize pacing therapy
Repositioning the lead	A lead slips out of position and pacing and/or sensing is compromised Muscle, diaphragmatic, or phrenic nerve stimulation occurs Pacing the left side of the heart unintentionally (a lead may traverse the septal wall or innominate vein) Leads are reversed in the implantable pulse generator header block at implant
Replacing the lead or the pacemaker	Lead failure is confirmed The battery is depleted The patient is symptomatic (hemodynamically compromised) as a result of single-chamber pacing Passive fixation lead does not remain in place after attempts to reposition True circuit malfunction
Observation	Transient problems with the following: Lead maturation

Changes in drug therapy

If these conditions exist, alternative treatment should be initiated. First, look for obvious sources of malfunctions, such as cell phones or other personal electronic devices. If the patient is using such a device, it should be shut off and the patient should be reevaluated. If a device in the ambulance has just been turned on and the pacemaker malfunctions, the device should be shut off and the patient should be reevaluated. Another simple procedure that can be applied externally is to gently move the pulsegenerating module in the chest to attempt to uncoil the lead wires and improve lead-to-generator contact. If these quick fixes do not improve pacemaker performance, immediate treatment of the patient should begin. If bradycardia, heart blocks, or syncope exist, transcutaneous pacer (multifunction) pads should be applied, and transcutaneous pacing should be initiated. Hypotension should be treated with a fluid bolus or a vasopressor such as dopamine (Intropin). Tachycardia as the result of pacemaker runaway has virtually been eliminated, but if tachycardia is observed on the ECG, it should be confirmed by checking the pulse before considering treatment. Tachycardias that allow for adequate perfusion should be left as is, but tachycardias that result in inadequate perfusion should be treated per ACLS protocols.

Transport Management

Pacemaker Failure

- Shut off the patient's cell phone or other personal electronic device.
- If the pacemaker malfunction occurred after a device in the ambulance was turned on, shut off the device and reevaluate the patient.
- Gently move the pulse-generating module in the chest to attempt to uncoil the lead wires and improve lead-to-generator contact.
- If the malfunction persists, and the patient has bradycardia, heart blocks, or syncope, initiate transcutaneous pacing.
- Give a fluid bolus or a vasopressor (such as dopamine [Intropin]) to treat hypotension.
- Confirm tachycardia with a pulse reading; treat tachycardias that result in inadequate perfusion per ACLS protocols.

Identifying the exact cause of pacemaker failure is difficult for CCTPs without training in the use of an external diagnostic device. The easiest cause to diagnose is extracardiac stimulation evidenced by frequent hiccoughs. The hiccoughs are caused by pacing electrodes being placed too far into the apex of the ventricle, causing stimulation of the diaphragm.

Unfortunately, there is not much that can be done by CCTPs to correct implanted pacemaker malfunction because the device is not accessible to CCTPs. Even if the device were accessible, a CCTP would have to have had specific training in the repair of the particular device to initiate reprogramming. Some manufacturers provide a doughnut-type magnet that may be helpful if the problem is increased impedance at the lead-tissue interface. The magnet amplifies the current flow and may counteract the increased impedance.

Pacemakers and the ECG

Single-Chamber Systems

The sole electrode in a single-chamber system is implanted on the atrium or ventricle. Single-chamber systems require implantation of only one lead, but they do not provide AV synchrony or ventricular backup in the absence of AV conduction.

Pacing in the ventricular pacer (VVI/R) mode and loss of AV synchrony can lead to **pacemaker syndrome**, a variety of symptoms that result from hemodynamic deterioration and cause nonphysiologic timing of atrial and ventricular contractions. This asynchrony can result in an inability of the rate to respond to physiologic needs. Atrial pacemakers are appropriate only for patients who have proven AV conduction and have regular access to follow-up testing.

Atrial and Ventricular Tracings

Figure 13-90 shows an example of atrial pacing. The strip begins with an atrial pacemaker firing at a rate of 60 beats/min. A pacemaker spike precedes the p wave in these complexes. The ventricular rate is 60 beats/min. The paced p waves are conducted through the ventricles via a normal conduction pathway. Starting with the fourth complex, the intrinsic pacemaker begins depolarizing at a rate of 94 to 100 beats/min. There are no pacemaker spikes with these complexes. The pacemaker continues to sense the intrinsic atrial depolarizations. Implications for the CCTP depend on the patient's history (ie, what caused the intrinsic pacemaker to fail in the first place) and hemodynamic status.

Figure 13-91 shows an ECG from a patient with a ventricular pacer (VVI). Following the second paced ventricular beat, a capture beat appears and is conducted normally. The pacemaker does not fire during this capture beat because it is sensed as normal depolarization. When another capture beat fails to appear, the ventricular pacemaker senses this and fires, depolarizing the ventricles. It paces two beats, then another capture beat appears and is conducted. When this does not produce a sustained rhythm, the pacemaker senses this and begins firing again at a rate of 60 beats/min. The implication for the CCTP is that this patient's heart is probably failing, but still has the ability to generate electrical impulses periodically. Monitor the patient's hemodynamic status and treat accordingly.

Some of the newer pacers do not show a prominent spike; at times, several leads must be checked to identify the spike. It is a good idea to ask the sending nurse what type of pacer the patient has.

Dual-Chamber Systems

Dual-chamber systems feature two leads, one each in the atrium and the ventricle. This ensures AV synchrony and provides for ventricular depolarization even without AV conduction. This mode of pacing is known as atrial synchronous pacing, atrial tracking, or AV sequential pacing.

As discussed in Table 13-11, DDD and DVI are pacemaker acronyms that refer to dual-chamber pacemaker systems. DDD stands for dual sensed, dual paced, and dual mode (fixed or demand), and DVI stands for dual sensed, ventricular paced, and inhibited (demand) mode. DDD is the most common type of pacemaker in use today. Figures 13-92 through Figure 13-95 show samples of ECG rhythms from dual demand pacemakers.

Figure 13-92 shows a dual-chamber intrinsic atrial pacemaker depolarizing at a rate of approximately 60 beats/min. The pacemaker senses atrial electrical activity and does not need to provide atrial pacing. The atria depolarize but conduction is blocked and does not reach the ventricles. The ventricular mode of the DDD senses no conduction and fires to depolarize the ventricles at a rate of 60 beats/min. Pacemaker spikes precede each ventricular complex. This patient has a severe conduction problem with impulses not reaching the ventricles. CCTP implications would be to monitor the patient's hemodynamic status and treat accordingly.

Figure 13-90 An electrocardiogram from a patient with an atrial pacer (AAI). Mode: AAI; rate setting: 60.

Figure 13-91 An electrocardiogram from a patient with a ventricular pacer (VVI). Mode: VVI; rate setting: 60.

Figure 13-93 shows a demand dual-mode (DDD) pacer sensing intrinsic pacemaker depolarizing at a rate of approximately 80 beats/min. The electrical activity is conducting from the atria to the ventricles without interruption. The underlying rhythm is a regular sinus rhythm at a rate of approximately 78 beats/min. Implications for the CCTP are to always compare ECG findings with the clinical presentation of the patient.

Figure 13-94 shows a dual-demand mode (DDD) pacemaker rhythm. This strip shows a demand DDD pacemaker that does not sense any intrinsic electrical activity and depolarizes the atria as indicated by a spike preceding each p wave at a rate of 60 beats/min. With no ventricular activity and the atrial pacing not being transmitted through to the ventricles, the ventricular mode of the DDD fires, depolarizing the ventricles at a rate of 60 beats/min. The implication for the CCTP is that the patient's cardiac electrical activity is depending solely on the pacemaker. As always, compare ECG findings with clinical findings and treat accordingly.

Figure 13-95 shows another demand dual-mode (DDD) pacemaker rhythm. The underlying rhythm appears to not be producing an atrial intrinsic pacemaker rhythm. The DDD pacer senses this and paces a rhythm at 60 beats/min. Note the pacemaker spike preceding each p wave. The electrical impulse generated by the pacemaker is transmitted through to the ventricles without interruption, allowing the ventricles to depolarize "normally" from above. This indicates that there is no AV block. The ventricular portion of the pacemaker continues to sense the ventricular conduction and does not need to fire. There should be no implications for the CCTP with this rhythm (unless this started after the transport began and could indicate a deteriorating condition).

Atriobiventricular Pacing

A CCTP may transport a patient with heart failure to a facility for pacemaker insertion. Heart failure, also known as CHF, is a condition that occurs when the heart is damaged and unable to pump blood adequately. Mortality and morbidity rates are high for patients with CHF.

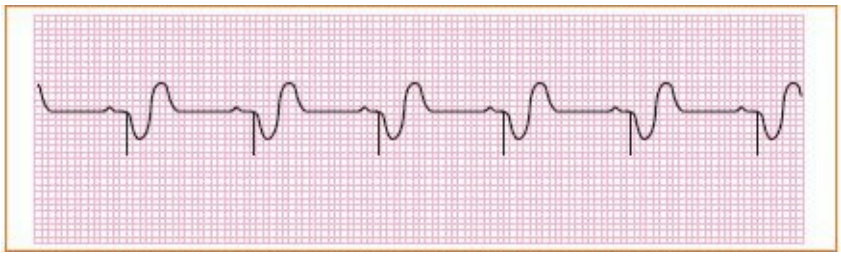

Figure 13-92 Mode DDD; lower rate setting, 60; upper rate setting, 120.

Figure 13-93 Mode DDD; lower rate setting, 60; upper rate setting, 120.

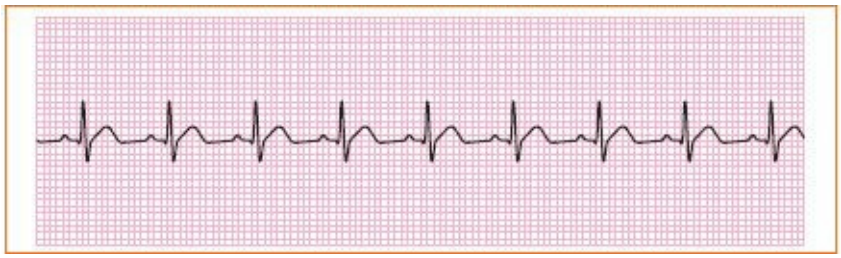

Figure 13-94 Mode DDD; lower rate setting, 60; upper rate setting, 120.

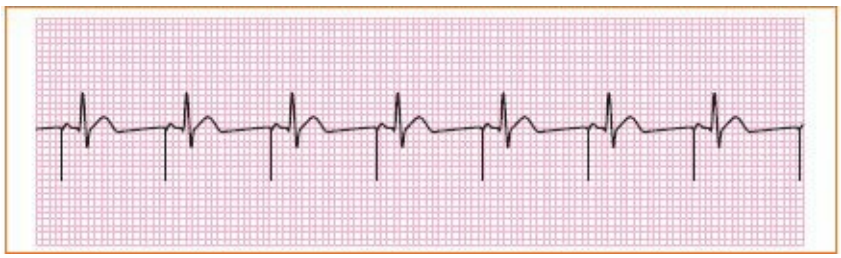

Figure 13-95 Mode DDD; lower rate setting, 60; upper rate setting, 120.

One effective new treatment for CHF uses a modified cardiac pacemaker or ICD to resynchronize the heart chambers. Once functioning in an organized manner, the heart pumps blood more efficiently and the effects of heart failure are reduced. The biventricular pacemaker coordinates the right and left ventricles of the heart. This coordination is accomplished by placing pacing leads in both ventricles and then optimizing their synchronization.

In a typical biventricular implant, one lead is placed in the atria and one lead is placed in each ventricle (right and left) **Figure 13-96**. A biventricular pacing waveform would be indistinguishable from that of a dual-chamber pacer on a typical monitor lead as the ventricles are paced simultaneously **Figure 13-97**. Analysis by 12-lead ECG and history would lead to a more definitive answer regarding the type of device implanted.

Implantable Cardioverter Defibrillators

Implantable cardioverter defibrillators automatically attempt to convert a fibrillating heart to sinus rhythm using a shock from voltage **Figure 13-98**. Since their introduction in 1985, the estimated number of implants has increased steadily to more than 50,000 each year. As the numbers rise, so does the frequency of patients with ICD-related issues.

Basic Function

Components

Each patient with an ICD has a custom ICD system consisting of a housing (can) and a variable number of pacing and high-voltage leads. The leads can be placed in the abdominal or pectoral region **Figure 13-99A**; the lead is itself often one of the electrodes in the system. Most ICDs are implanted with one or two transvenous leads used for pacing and shocking. The leads enter the venous system through the subclavian or cephalic vein, for placement into the right ventricle or the superior vena cava. Early ICD implants required that pacing leads and high-voltage patches be placed directly on the epicardial surface **Figure 13-99B**. Patients with mechanical heart valves are also limited to epicardial placement.

Sensing and Therapies

An ICD delivers therapy when it determines that the heart is in a tachyarrhythmia, based on the ventricular rate. The ICD counts the number of R-R intervals that are faster than a programmed threshold. When the count reaches the threshold, the device delivers electrical therapy. Because an ICD bases its decision on the ventricular rate alone, atrial arrhythmias and electromagnetic interference can lead to inappropriate shocks.

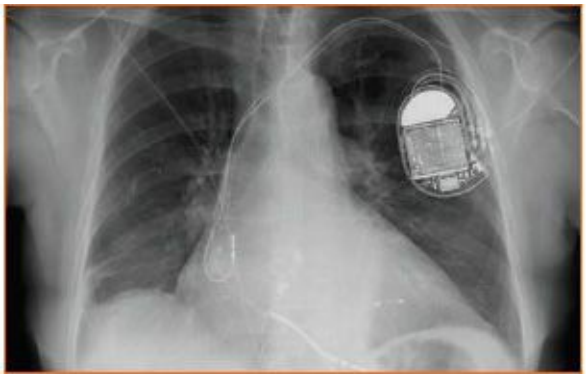

Figure 13-96 An implanted atriobiventricular pacing system.

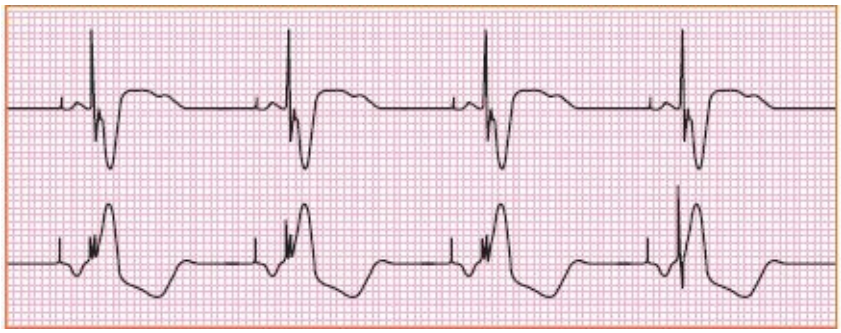

Figure 13-97 An example of a 12-lead electrocardiogram with atriobiventricular pacing.

For ICD purposes, fast heart rhythms are loosely classified into two groups: VT and ventricular fibrillation. An ICD may deliver antitachycardia pacing or cardioversion shocks for episodes of VT. Antitachycardia pacing is a series of 6 to 15 pacing pulses with cycle lengths of 70% to 95% of the

arrhythmia **Figure 13-100A**. In Figure 13-100A, when VT is sensed, antitachycardia pacing begins as indicated by pacemaker spikes (arrow at right). Cardioversion shocks are high-voltage shocks that are synchronized to an intrinsic R wave **Figure 13-100B**. The device delivers unsynchronized defibrillation shocks for episodes of ventricular fibrillation. In Figure 13-100B, when ventricular tachycardia is sensed, a single cardioversion shock is administered as indicated by the large spike. The rhythm is converted to a supraventricular rate of about 70 beats/min. There appears to be in a first-degree AV block with a prolonged P-R interval.

Implantable Cardioverter Defibrillator Troubleshooting

Because an ICD is an implantable device within the patient, it is not accessible to CCTPs. The device must be deimplanted (in the hospital) to correct the malfunction.

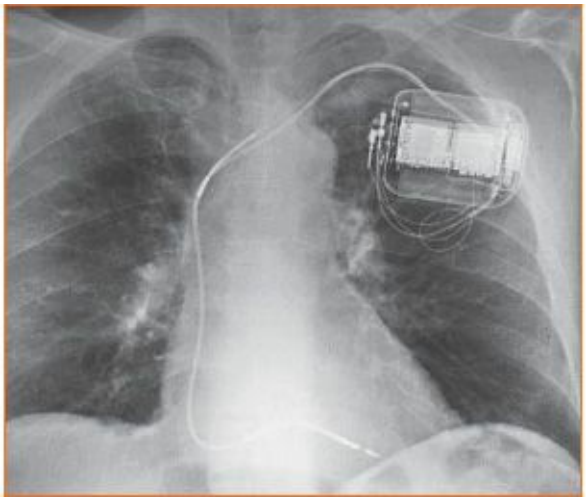

Figure 13-98 An implantable cardioverter defibrillator is attached directly to the heart and continuously monitors heart rhythm, delivering shocks as needed. The electricity from the device is so low that it has no effect on rescuers.

The most common sources of failure are the following:

1. Wire (lead) detachment or insulation failure
2. Battery failure or abnormalities
3. Pulse-generator failure
4. Movement of the wire tip in the ventricle

In addition, dual-chamber ICDs are subject to all of the problems described in the pacemaker section earlier in this chapter.

Information Gathering

If an ICD fires during the care of a patient, everything possible should be done to gather information that will help specialists confirm later whether the therapy was appropriate. After such an event, the patient's electrophysiologist will want to review the transport documentation and data from the ICD. Programming equipment that is unique to the ICD model makes it possible to retrieve detailed information from the device.

Many patients who have been shocked before recognize the symptoms of ventricular arrhythmias and can correctly identify appropriate and inappropriate therapies. A number of historical factors can have a role in ICD malfunction or offer clues about the nature of the problem. Among the most useful are the

following:

- Number of times shocked. Patients with VT "storms" have been known to have the device giving more than 100 shocks in a 24-hour period. When a patient has an atrial arrhythmia that conducts rapidly to the ventricle, it is common to deliver repeated unsuccessful therapies.
- Recent medical procedures. Many medical procedures can damage an ICD system, especially when directed to areas of the body in proximity to the ICD. Diathermy, lithotripsy, magnetic resonance imaging, and radiation treatments are among the most common offenders.

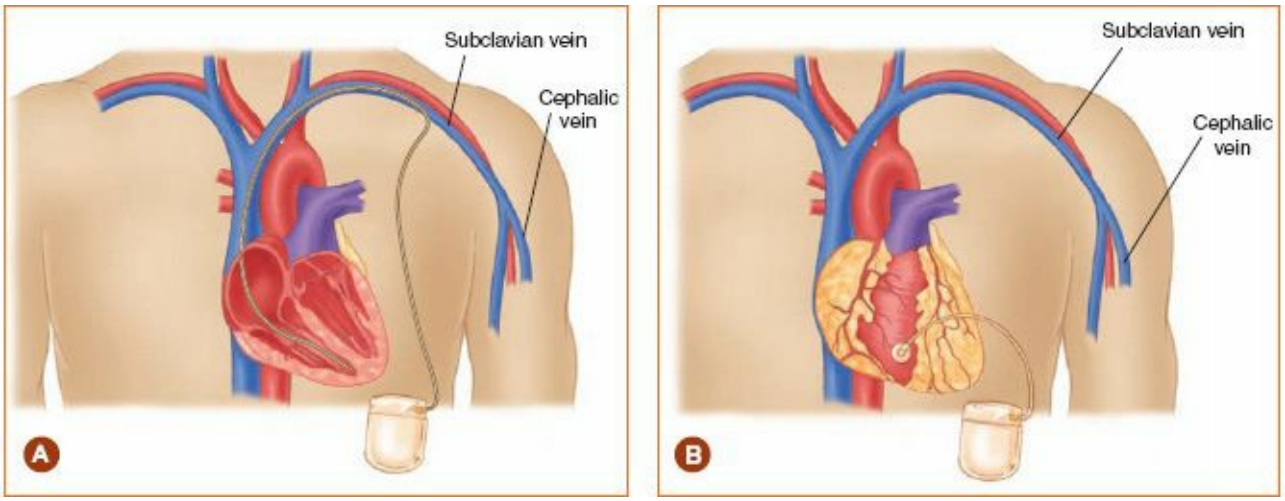

Figure 13-99 Typical implantable cardioverter defibrillator (ICD) systems. **A.** The ICD enters the heart through the abdominal or pectoral region. **B.** The ICD is directly on the epicardial surface.

- Recent changes in medical condition or in patient adherence to the medication regimen. It is not uncommon for patients to stop taking antiarrhythmic drugs if they have been arrhythmia free for several months or years.
- Coexisting pacemaker. Before the introduction of dual-chamber defibrillators in 1998, many patients received a dual-chamber pacemaker and a ventricular defibrillator. Interactions between the two devices can inhibit appropriate therapy or trigger inappropriate therapy.
- Activity at the time of shock. During exercise, the ICD may deliver inappropriate shocks to sinus tachycardia.
- Proximity to water or an electrical source. Poorly grounded water pipes can produce trickle electrical currents that the ICD may pick up as a rapid heart rate. Likewise, a nearby source of electromagnetic interference can cause the ICD to discharge inappropriately.

Identifying the Problem

Occasionally, a patient with an ICD will experience multiple inappropriate defibrillator discharges as the result of defibrillator malfunction. This is uncomfortable and agitating to the patient and may cause damage to the myocardium if allowed to continue. The ICD can be temporarily disabled by a magnet to prevent further discharges. Manufacturers of ICDs can provide special magnets (usually doughnut shaped) that are placed directly over the pulse generator. The magnet creates a magnetic field that trips a reed switch in the ICD. When the magnet is applied, detection of tachycardia and therapy are discontinued. For most applications, a single magnet is all that is required; however, for obese or edematous patients, two magnets may be necessary. Before using the magnet, multifunction pads must be placed on the patient and hooked to the monitor; then the ICD can be deactivated. However, ICD manufacturers discourage deactivation of a malfunctioning ICD during transport. Certain ICD manufacturers make an external interrogation device that will help identify the source of the problem and, in some cases, allow reprogramming, but CCTPs should receive special training before using such a device.

In a cardiac arrest, external defibrillation can be delivered **Figure 13-101**, but the paddles or pads should not be placed directly over the ICD. CPR can also be performed on a patient with an ICD, with no danger to providers, the patient, or the implanted device. When delivering defibrillation, it is important to use A-P paddle placement and position the pads or paddles away from the ICD.

Figure 13-101 A commonly used monitor-defibrillator.

Figure 13-102 and Figure 13-103 illustrate some of the common problems with ICDs. The ICD stores these data during the episode for later retrieval with programming equipment.

In **Figure 13-102**, the ICD is oversensing the pacing spikes of a pacemaker. The VS markers align with each ventricular pacing spike. The underlying rhythm appears to be ventricular fibrillation. The top portion of the strip shows an ICD/DDD pacer firing atrial/ventricular spikes that are not capturing or correcting the rhythm. The bottom strip shows a single spike at a rate of around 80 beats/min that is not capturing. CCTP implications include first checking the clinical status of the patient, and if he or she is unconscious and unresponsive (which would be expected with this ECG), performing CPR, defibrillation, and medication administration per ACLS protocols.

Figure 13-102 An electrocardiogram in which the implantable cardioverter defibrillator is oversensing the pacing spike.

Figure 13-103 An example of pacemaker lead malfunction.

Figure 13-103 shows an example of lead malfunction. Intervals in the range of 120 to 150 milliseconds are usually not physiologic; they more likely indicate electromagnetic interference or a problem with the sensing lead. In this figure, there appears to be an irregular rhythm conducting at a rate of 60 to 80 beats/min. This ECG indicates the ventricular pacemaker is sensing at an irregular rate as well (malfunction). There are no clear pacemaker spikes indicating that it is firing appropriately. CCTP implications would include monitoring the patient for hemodynamic stability and initiating CPR and external pacing as indicated.

Atrial Tachycardia Implantable Cardioverter Defibrillators

Atrial fibrillation is one of the most common arrhythmias found. Significant risks associated with atrial fibrillation are thromboembolism and a resulting increased incidence of stroke. Conventional methods to convert atrial fibrillation have centered on antiarrhythmic medications and external cardioversion. Recently, internal cardioversion and/or antitachycardia pacing with an atrial ICD has been shown to be

the preferable mode of treatment. Advances in lead design and the use of biphasic energy waveform have made this possible. With biphasic waveform, lower energy levels may be used to effectively convert atrial fibrillation to a normal sinus rhythm.

Three modes for activating the atrial tachycardia ICD are generally use. In the patient-activated mode, a small handheld remote can be used by the patient to initiate therapy. This would occur after the device had notified the patient that atrial fibrillation was present. A second mode would involve the physician activating the device to provide appropriate therapy. In addition, the ICD may be programmed to automatically deliver therapy on detection of the arrhythmia. These ICDs commonly act as pacemakers also, and the atrial and ventricular leads may be dual purpose.

Transport Considerations for Cardiac Electrophysiology Devices

Devices to improve cardiac electrophysiologic performance are frequently encountered during critical care transport. Implantable cardioverter-defibrillators are currently the recommended therapy for the prevention of death from ventricular arrhythmias. Of all ICDs implanted in the world, 65% are done in the United States, despite the fact that only approximately 34% of the patients who should receive an ICD in the United States actually have one implanted. Once utilization improves, patients with ICDs will become increasingly common. When the epidemiology of pacemaker placement was first evaluated in the United States in 1995, there were more than 450,000 people with pacemakers in the general population. Annual pacemaker insertion procedures increased more than 20% in the following 5 years. CCTPs should expect to transport patients who have or need a pacemaker or ICD and should be prepared to manage any adverse situations related to either device.

Figure 13-104 shows an algorithm for online medical control during critical care transport and should assist in understanding the process. This algorithm can apply to cardiac transports and to other types of transports.

Preparation

The management of patients with a pacemaker or ICD begins well in advance of any transport request. CCTPs should receive training on any transthoracic, transcutaneous, or transvenous pacemaker device that the agency uses. In larger urban settings, CCTPs may encounter transthoracic, transcutaneous, and transvenous pacemakers from a wide variety of manufacturers at the different sending facilities, requiring additional scrutiny when picking up or dropping off patients at these facilities. In addition, agencies transporting critically ill cardiac patients should have a magnet capable of temporarily reprogramming an implanted pacemaker or ICD readily available. It may be necessary to review the instructions for a particular device while en route to a patient transport if transthoracic, transvenous, or transcutaneous pacing is anticipated and the CCTP has not used the particular equipment recently.

Table 13-13 lists information and assessments needed for critical care transport of cardiac critical care patients.

TABLE 13-13 Information and Assessments Needed for Transport of Critical Cardiac Patients

Information needed before	1. List of patient's current medications 2. Patient's allergies to medications 3. 12-lead electrocardiogram and rhythm history 4. History leading to present condition 5. Patient's past medical history

transport	6. Treatments administered to date 7. Problems encountered to date 8. Nurse's report before transport 9. Review with nurse any drips patient is receiving or may require. 10. Review with respiratory therapist any special respiratory requirements.
Overall assessment before transport	1. Level of consciousness, Glasgow Coma Scale 2. Anxiety (may need to be controlled) 3. Overall appearance 4. Pain (level, location, radiation, quality) 5. Blood pressure 6. Heart rate and pulse quality 7. Oxygen saturation 8. If the patient requires a ventilator: a. Breaths/min b. Tidal volume c. Positive end-expiratory pressure d. Peak inspiratory pressure e. Capnography carbon dioxide level and waveform f. Oxygen saturation as measured by pulse oximetry 9. If the patient has an arterial line: a. Check the French size. b. Check for bleeding or a hematoma at the catheter site. c. Check that there is sufficient pressure coming from the pressure bag into the arterial line. 10. Check all IV sites to be sure that they are patent. 11. If there are any drips being infused, ensure that the pumps are operable, note the drip rate, and ensure that there are sufficient fluids or medications. 12. Observe the cardiac monitor rhythm and rate. 13. Note and correct any gastric disturbances because they may induce subdiaphragmatic pressure. 14. All critical care transport patients should receive a thorough head-to-toe exam before transport; for cardiac patients, particular attention should be given to assessing jugulovenous distention, bruits, heart sounds (ie, S_3 and S_4), and valve closure sounds; all lung fields should be auscultated and chest rise should be noted.
Tests to know and review	1. Electrolytes, particularly potassium, sodium, magnesium, and calcium 2. Glucose 3. Coagulation tests, international normalized ratio if receiving warfarin (Coumadin) 4. Troponin, brain-type natriuretic peptide, D-dimer 5. Ejection fraction

	6. Cardiac index
Complications and interventions	1. Increased chest pain: increase the nitroglycerin drip rate; administer morphine sulfate, hydromorphone (Dilaudid), or fentanyl citrate. 2. Increased blood pressure: increase the nitroglycerin (Nitro-Bid IV, Tridil) drip rate; consider a beta-blocker (such as metoprolol [Lopressor, Toprol XL]).

Patient Acceptance

Accepting a patient from a sending hospital for critical care transport is often a complicated endeavor. CCTPs must obtain a patient report, typically from the sending nurse or physician, which includes the history of present illness, medical history, medications, allergies, hospital course, results of recent laboratory and diagnostic studies, current clinical status, relevant social information, presence of advance directives, and any anticipated changes or interventions during the transport. During patient acceptance, CCTPs must perform a physical examination of the patient appropriate for the particular medical condition, clinical status, and the duration and method of transportation. Any medication infusions, including concentrations and rate calculations, should be confirmed and double checked for accuracy with the sending nurse, physician, or other provider. Ventilator settings, monitoring equipment, indwelling devices, and fluid infusions must also be continued or modified as appropriate for the patient's condition and capabilities of the transport team. Copies of patient medical records, laboratory results, and diagnostic studies should accompany the patient for transport. All of these actions should ideally occur in the shortest time possible, facilitating prompt patient transfer to a higher level of care.

Any patient with a transthoracic, transvenous, transcutaneous, or implanted pacemaker device must have electrical and mechanical pacemaker capture assessed and confirmed. A CCTP may make a potentially lethal error if he or she mistakenly assumes that electrical capture present on an ECG tracing represents true mechanical capture. Mechanical capture is demonstrated by palpable pulses (or evidence of myocardial contraction on ultrasound) with each pacemaker complex on the ECG. It is possible for electrical capture to be present on the ECG without any actual contraction and pumping of the heart, disguising an underlying arrhythmia or cardiac arrest. Unrecognized lack of mechanical capture may have lethal consequences.

It is not always possible to continue using the same transcutaneous pacemaker machine or transvenous or transthoracic pacemaker pulse generator for transport that is being used at the sending facility. Switching from a device used in a sending facility to a device used by the transport team is often the source of anxiety for CCTPs and other providers. Transvenous and transthoracic pacemaker leads are typically compatible with pulse-generator devices from multiple, if not all, manufacturers. Care must be taken to ensure equipment compatibility and correctly match rate and current settings as the devices are switched. CCTPs must carefully check the patient for electrical and mechanical capture, in addition to other clinical indicators, when there has been a change from one pacemaker to another. If a CCTP does not have a compatible device available, it may be worth considering using the device from the sending facility for the transport and returning it promptly after the transport has been completed, although this may not be possible in many situations. Certain transcutaneous pacemaker machines have adapters to allow the use of pads from multiple manufacturers. If adapters are not available, it may be necessary to completely change transcutaneous pacing pads for transport.

CCTPs should also inquire about whether the patient has an ICD. The presence of an ICD would require an alternative site (not over the device) for transcutaneous pacing or defibrillation if needed during transport. An improperly functioning ICD has the potential to inappropriately discharge, causing patient discomfort, myocardial damage, and changes on the ECG. In a 2009 study, 11.5% of the subjects with ICDs had inappropriate shocks, and almost 8% of the subjects with ICDs *only* had inappropriate ICD discharges. CCTPs may use a pacemaker-type magnet to temporarily suspend cardioversion or defibrillation when an ICD administers continued inappropriate shocks.

A properly functioning ICD may terminate certain potentially lethal arrhythmias without the need for a CCTP to perform any external cardioversion or defibrillation during transport. It is still essential to have an external cardioverter-defibrillator immediately available. CCTPs may experience a mild sensation if they are in contact with a patient as an ICD discharges, but no serious injuries to bystanders or health care providers have been reported.

Patient Transport

The transport environment continually poses challenges for CCTPs providing patient care. Limited patient access, lack of supporting resources, adverse environmental conditions, and a myriad of safety concerns must be encountered with each transport. CCTPs must manage all of these factors when transporting critically ill cardiac patients with electrophysiologic devices **Figure 13-105**.

Two factors in the transport environment require special consideration for patients with pacemakers or ICDs. Electromagnetic interference is the major cause of pacemaker dysfunction, particularly in older pacemakers lacking adequate internal shielding. Modern chip-based pacemakers are less susceptible to electromagnetic interference. Neither small single-engine airplanes nor larger commercial aircraft pose an increased risk for electromagnetic interference affecting implanted pacemakers or ICDs. CCTPs should be aware that devices such as headphones and microphones with internal magnets may cause interference in older pacemakers when placed within 1″ to 2″ of the device. The American Heart Association recommends that any type of headphone remain more than 3 cm from the pacemaker to avoid the risk of electromagnetic interference. If patients are provided with headsets or intercom systems during air transport, CCTPs should take care to keep these items safely away from the pacemaker device, which is usually visible as a mass under the patient's skin.

Figure 13-105 The CCTP must manage the challenges of the transport environment when transporting a cardiac critical care patient.

Patient Turnover

CCTPs are expected to provide the receiving hospital with a thorough patient report, including the same elements outlined in the section on patient acceptance. In addition, CCTPs should provide the intensive care unit, catheterization laboratory, operating room, or other receiving unit staff with an accurate report of any patient changes and interventions provided during the transport. Certain high-risk items, such as endotracheal tube placement, central line status, IV sites for vasoactive medications, and the presence of mechanical pacemaker capture, should be specifically confirmed with the accepting provider on patient turnover to avoid any question that problems with these items occurred during patient transport. Oral patient report should be supplemented with a written document outlining the preceding information that is left with the receiving provider at the completion of the transport. CCTPs should carefully document the patient condition on acceptance and turnover; the conveyance of patient belongings, medical records, and diagnostic test multimedia; and the name(s) of the health care provider(s) who accepted the patient at the receiving facility. Although failure to accurately document this information may place a CCTP at significant legal, regulatory, or financial risk, should adverse events occur, the primary reason for documentation is continuity of care.

CCTPs should expect frequent encounters with patients who have or need a device to improve

cardiac electrophysiology. Proper training and education will improve a CCTP's ability to assess and manage these patients in the transport setting.

Flight Considerations

Pacemaker malfunction does not usually occur as a result of the flight environment. There are some isolated reports of helicopter vibration affecting pacemaker function; occasionally, rate-responsive pacemakers increase their firing rate as a result of vibration during helicopter transport. However, in a study involving helicopter transport of dozens of patients with pacemakers, no pacemaker malfunctions occurred. This does not usually occur in the fixed-wing environment, although it could occur if there is significant turbulence. CCTPs working on medical helicopters should be aware of this potential and should remain prepared to intervene if necessary.

Finally, always remember that as altitude increases, supplemental oxygen is important.

Summary

Providers' ability to diagnose and treat patients with cardiac arrhythmias has been greatly enhanced by advances in technology, and keeping up-to-date with the latest developments on this front is imperative for all CCTPs. This chapter reviewed how to interpret 12-lead ECGs in the context of the critical care transport setting. One of the most valuable skills that can be learned is the ability to better identify an early MI, relay this information to the receiving facility or treating physician, and decrease the time to treatment. In addition to identifying an MI, acquiring a diagnostic-quality 12-lead ECG in the field, even if it is normal, will provide the treating staff with a baseline to compare serial ECGs done in the follow-up evaluation of the patient.

Over the years, pacemakers and ICDs have evolved through a variety of designs with varying functions and capabilities. Although detailed information about a patient's implanted device is often available to CCTPs, general familiarity with basic concepts will always be helpful in determining whether these devices are functioning properly.

Pacers and ICDs share numerous basic components and functions. Modern devices all sense heart rate and use programmed circuitry to decide whether or how to respond. The exact types of sensing they perform and the therapies they deliver are where the types of devices differ the most.

Knowing the NBG codes is perhaps the single most valuable tool in a CCTP's approach to a patient with a pacemaker. Studying as many ECGs as possible of real patients with pacers and ICDs will help CCTPs prepare for identifying and managing problems in transport. In any case of suspected or certain malfunction, it will be important to the electrophysiologist that the CCTP obtain ECG recordings, ensure availability of data from the device, and provide detailed written documentation of the incident.

Case Study

JUST AS YOU ARE FINISHING YOUR LUNCH, dispatch advises you of an emergency transfer of a critical cardiac patient from Community Hospital to St Patrick's Hospital. Your crew, consisting of an EMT-B driver, yourself, and a fellow paramedic, responds in 12 minutes to the Community emergency department.

On arrival, you obtain a report from the transferring physician, Dr Jans, who states your patient is a 67-year-old, 111.36-kg Native American man who arrived in the emergency department approximately 45 minutes ago complaining of severe substernal chest pain and also had hypertension. The patient's 12-lead ECG revealed no acute ST-segment changes, but showed a new-onset left BBB when compared with a

prior ECG that was obtained during a routine visit to his primary care provider 4 months earlier. His medications in the emergency department included 324 mg of aspirin; 0.4 mg nitroglycerin, 2 doses; 3 mg of morphine IV; 300 mg of clopidogrel (Plavix); and 20 mg of eptifibatide (Integrilin). Presently, the patient is receiving a continuous infusion of nitroglycerin (Nitro-Bid IV, Tridil) at 20 µg/min and an eptifibatide infusion at 222 µg/min. The patient is being transferred to Dr Webb at St Patrick's catheterization laboratory for emergency cardiac catheterization.

As you assess the patient, you obtain the following readings: a heart rate of 94 beats/min, sinus rhythm; a respiratory rate of 18 breaths/min, clear and equal breath sounds bilaterally; a blood pressure of 174/110 mm Hg; a temperature of 99.1° F; pulse oximetry reading of 95% with 4 L/min of oxygen via nasal cannula; carbon dioxide, 42 mm Hg; heart tones normal with no rubs, gallops, or murmurs; and peripheral edema 1 + in the lower extremities.

Further interview of the patient reveals a past medical history of hypertension and hepatitis. Presently, he takes no medications and has no allergies. He stated that the pain started approximately 90 minutes ago and began radiating to his left arm. Initially, the pain was 10 on a 10-point scale, but after morphine was given, has decreased to 2 on a 10-point scale. As your partner secures the patient onto the stretcher, you transfer the infusions to your transport IV pump.

As you review the patient's lab studies, you note the following values of interest:

- Glucose: 98 mg/dL (normal range, 74 to 110 mg/dL)
- Chloride: 110 mmol/L (normal range, 98 to 107 mmol/L)
- Potassium: 4.1 mmol/L (normal range, 3.5 to 5.1 mmol/L)
- Calcium: 8.6 mg/dL (normal range, 8.5 to 10.1 mg/dL)
- Magnesium: 1.7 mEq/L (normal range, 1.5 to 2.0 mEq/L)
- Blood urea nitrogen (BUN): 13 mg/dL (normal range, 7 to 25 mg/dL)
- Creatinine: 1.3 mg/dL (normal range, 0.6 to 1.3 mg/dL)
- BUN/creatinine ratio: 10.0 calculated (normal range, 12.0 to 20.0 calculated)
- Prothrombin time: 14.1 seconds (normal range, 14.0 to 16.0 seconds)
- Activated partial thromboplastin time: 53.0 seconds (normal range, 45.0 to 55.0 seconds)
- Myoglobin: 24 ng/mL (normal range, 10 to 95 ng/mL)
- Troponin T: 1.6 ng/mL (normal range, 0.0 to 0.2 ng/mL)
- Brain-type natriuretic peptide: 140 µg/mL (normal range, 0.0 to 100.0 µg/mL)
- Alanine aminotransferase: 392 U/L (normal range, 30 to 65 U/L)
- Aspartate aminotransferase: 110 U/L (normal range, 15 to 37 U/L)

You load the patient into the ambulance and proceed on an emergency basis to St Patrick's Hospital, approximately 110 miles away. As you reassess the patient, your partner increases the nitroglycerin to 25 µg/min in an attempt to maintain the systolic blood pressure around 155 mm Hg. The patient appears to be in a moderate amount of distress; however, he denies having any discomfort. You opt to administer 3 mg of morphine IV, to which he replies "Thanks, that helps me relax and not hurt quite as bad."

Your partner repeats a 12-lead ECG to compare with the one that was done in the emergency department and the one from 4 months ago. The ECG remains unchanged from the one done in the emergency department, with no ST-segment elevation or depression. The remainder of the transport remains unremarkable, with the patient delivered to Dr Webb and the waiting catheterization laboratory team.

1. If this patient did not have any ECG changes, how are you able to determine that he was experiencing

an MI?

2. Why was this patient receiving nitroglycerin? Eptifibatide?
3. What are the side effects of these medications?
4. What are the possible complications that may be experienced en route with this patient?

Analysis

Because of your critical care training, you are able to recognize that this patient is experiencing an NSTEMI based on the given lab values. You know that myoglobin will be the first cardiac marker to increase (usually within 2 hours after muscle damage), and that troponin will increase 3 to 6 hours after infarction and is the most specific cardiac marker.

Nitroglycerin is indicated in MI situations owing to its vasodilatory properties on systemic and coronary vessels. The enhanced coronary perfusion, along with the decrease in cardiac workload, results in increased oxygen and blood supply to ischemic cardiac tissue. The possible side effects of using nitroglycerin for this patient are hypotension, reflexive tachycardia, and cardiac arrhythmias.

Eptifibatide is indicated in patients with unstable angina or NSTEMI to reduce the risk of acute ischemic events. Eptifibatide is an antiplatelet medication that selectively blocks the platelet glycoprotein IIb/IIIa receptor. Possible side effects of eptifibatide are uncontrollable bleeding, anemia, and thrombocytopenia.

Owing to the nature of this patient's situation and the different medications that have been administered, careful monitoring en route is essential. Some of the potential problems en route would be hypotension from inadvertent nitrate overdose, cardiogenic shock caused by pump failure, respiratory arrest due to narcotic potentiation, and, ultimately, cardiopulmonary arrest.

That evening as you are delivering yet another patient to the emergency department at St Patrick's, you see Dr Webb and ask about the status of the patient you brought in earlier. He replies that the patient underwent cardiac catheterization that revealed significant narrowing of the left main coronary artery. Owing to the severity of the narrowing, placing a stent was contraindicated, so the patient underwent an emergency coronary artery bypass graft in which a section of the left internal mammary artery was removed and grafted to the left anterior descending artery. The patient is expected to make a complete recovery and be released in 7 to 10 days.

Prep Kit

Ready for Review

- Oxygenated blood reaches the heart through the coronary arteries, which are vulnerable to blockage and narrowing by plaque formation, a condition called atherosclerosis.
- The major heart sounds are the two normal sounds, S_1 and S_2, and the two abnormal sounds, S_3 and S_4.
- S_1 (the "lub" sound) occurs near the beginning of ventricular contraction (systole), when the tricuspid and mitral valves close. Any delay in the closing of these two valves, heard as a split sound, is considered abnormal.
- S_2 (the "dub" sound) occurs near the end of ventricular contraction (systole), when the pulmonary and aortic valves close. The two valves can close simultaneously or with a slight delay between them under normal physiologic circumstances.

- S_3 (“dub-lub-dub”) is the result of the end of the rapid filling period of the ventricle during the beginning of diastole. In older adults, it often signifies heart failure.
- S_4 (“lub-dub-dub”) coincides with atrial contraction at the end of ventricular diastole. If heard at any other time, the patient may have resistance to ventricular filling.
- The cardiac cycle comprises one complete phase of atrial and ventricular relaxation (diastole), followed by one atrial and ventricular contraction (systole).
- During diastole (normally 520 milliseconds), the left atrium fills passively with blood under the influence of venous pressure, and approximately 80% of ventricular filling occurs.
- In systole (normally 280 milliseconds), ventricular filling is completed, the AV valves snap shut, the two ventricles contract (ventricular systole), and the semilunar valves are forced open. Blood squeezed out of the right ventricle moves into the pulmonary arteries; blood from the left ventricle is pushed into the aorta.
- If the right side of the heart fails, blood backs up behind the right atrium, evidenced by distention of the external jugular veins, and fluid leaks into the surrounding tissues, causing edema in the subcutaneous and internal tissues.
- If the left side of the heart fails, blood backs up behind the left atrium, and fluid is squeezed into the alveoli, producing pulmonary edema, evidenced by dyspnea, bubbling crackles, and frothy sputum.
- Blood pressure is influenced not only by the output of the heart and the volume of blood present in the system, but also by the relative constriction or dilation of arteries, which is controlled by the autonomic nervous system.
- Key parameters associated with the heart’s functioning include cardiac output (the amount of blood that is pumped out by either ventricle), stroke volume (the amount of blood pumped out by either ventricle in a single contraction), and heart rate (the number of cardiac contractions per minute).
- Changes in the heart’s contractility (the degree of contraction of its muscle without changing the stretch on the muscle) may be induced by medications that have a positive or negative inotropic effect.
- The heart can generate its own electrical impulses without stimulation from nerves (automaticity) and has specialized conduction tissue that can rapidly propagate electrical impulses to the muscular tissue of the heart.
- The dominant pacemaker in the heart is the sinoatrial (SA) node; if the right coronary artery is occluded, as in a myocardial infarction (MI), the SA node will become ischemic.
- Depolarization of the heart—the process by which muscle fibers are stimulated to contract—occurs because of an influx of sodium and calcium ions into the myocardial cells. It results in a “wave of depolarization” as the electrical charges pass in all directions from one cell to another.
- Repolarization occurs when the sodium and calcium channels close and potassium channels open; thus, sodium ions move out of the cell and potassium ions flood back in.
- In the absolute refractory period, the heart muscle has been drained of energy; it will not contract during this period. In the relative refractory period, the heart is partially charged, albeit not strongly enough to create a full contraction.
- The electrical conduction events in the heart can be recorded on an ECG as a series of waves and complexes. Depolarization of the atria produces the P wave; as the electrical impulse slows through the atrioventricular (AV) node and AV junction, it can be seen on the ECG as the PR interval; depolarization of the ventricles produces the QRS complex; repolarization of the atria and ventricles produces T waves.

- A U wave may be present after the T wave, although there is no definitive agreement as to what it represents.
- The 12-lead electrocardiogram (ECG) graphically represents electrical activity in cardiac tissue.
- Today's cardiac monitor/defibrillators typically combine continuous 3-lead ECG monitoring, 12-lead electrocardiography, semiautomatic and manual defibrillation, external pacing, capnography, pulse oximetry, blood pressure, end-tidal carbon dioxide, cardiac output, and other capabilities.
- Assessment of the patient's cardiac status—which takes place before monitoring—should include analysis of the cardiac rhythm and 12-lead ECG to determine any underlying electrical disturbances caused by changes in the heart's structure or function as the result of disease, ischemia, injury, or infarction.
- Cardiac monitoring—the continuous observation of the patient's condition in relation to his or her cardiac rhythm—typically uses lead configurations for viewing from one to three leads simultaneously.
- A "gold standard" for 12-lead ECG interpretation is the ability to perform serial evaluations for comparison; however, it is important to use consistent lead placements to ensure that all providers compare "apples to apples."
- The electrode is the sensing device that connects directly to the skin; the lead is the designated position of the electrode (that is, limb and precordial leads). The cable is the physical wire that connects the electrode to the ECG monitor.
- The six limb leads (I, II, III, aVR, aVL, and aVF) provide a view of the heart in a vertical plane (the frontal plane); the six precordial leads (V_1 to V_6), or chest leads, show a horizontal plane. The combination of limb leads and precordial leads provides a three-dimensional view of the heart.
- If the flow of electrical activity proceeds unimpeded toward a positive lead, it appears as a positive deflection on the ECG. If the flow of electrical activity flows away from a positive lead, it is deflected negatively. An electrical impulse that crosses perpendicular to a positive lead is called isoelectric.
- If the heart's electrical impulse is deflected by a change in structure or function, it will be less positive, aberrantly conducted, or deflected away from the selected electrode.
- Placement of additional or nonstandard right-sided heart leads V_4R, V_5R, and V_6R and posterior heart leads V_7, V_8, and V_9 is indicated in suspected right ventricular and posterior MIs and when a patient has clinical findings suggestive of acute coronary ischemia, but the standard 12-lead ECG is normal or nondiagnostic.
- Before running the ECG with right-sided leads, the standard 12-lead ECG should be completed. Then, using the precordial (chest) leads, the additional leads are attached as follows: V_4R, V_5R, V_6R, V_7, V_8, and V_9.
- Confirm placement of leads before transport and several times during transport.
- A "new" 12-lead ECG should be recorded and evaluated before transport and repeated at regular intervals, when any changes in the ECG are noted, and on arrival at the receiving facility.
- The transport of a patient with ST-segment elevation MI to definitive care should not be delayed for the sake of obtaining additional ECGs.
- The supine position is recommended for obtaining ECGs; however, an adequate ECG can be obtained with the patient in a semisitting (semi-Fowler's) position.
- Before obtaining a 12-lead ECG, standardization or calibration of the device at 1 mV = 10 mm high

and 200 milliseconds wide is necessary.

- In the limb leads, the P wave is typically upright in leads I, II, aVL, and aVF. It is frequently biphasic in lead III and is purely negatively deflected in lead aVR.
- In the precordial leads, the P wave is typically upright in leads V_5 and V_6. Lead V_1 is biphasic, and leads V_2 and V_4 are variable.
- The PR interval spans the time from the start of atrial depolarization to the start of ventricular depolarization; it also includes the delay in conduction that occurs at the AV junction. It usually lasts from 120 to 200 milliseconds.
- The QRS complex is a representation of ventricular depolarization. Septal depolarization is not always seen on the ECG; when it is, a small Q wave may be seen in leads I, aVL, V_5, and V_6.
- The keys to being able to quickly read an ECG are experience and consistency. Interpretation of 12-lead ECGs is a skill that must be practiced repeatedly using a standard method of analysis.
- Interpretation of rhythms and arrhythmias is a fundamental building block for ECG analysis.
- The 12-lead ECG shows groupings of complexes that are recorded simultaneously by each lead. The rhythm strip, which typically appears at the bottom of the ECG, records for the entire time the 12-lead ECG is being obtained.
- Each cell in the heart can produce its own electrical impulse (vector), which varies in intensity and direction. The axis is the direction of the wave of depolarization as it passes through the heart.
- The sum of all the electrical impulses is called the mean electrical axis. It should progress in a downward and leftward direction; if there is a change in the patient's normal or preexisting axis, a change has occurred in the structure or function of the heart.
- To calculate the direction and intensity of the electrical axis, the hexaxial system, which relies on a circular diagram oriented in the frontal (coronal) plane, can be used.
- Before transporting a critically ill patient, a baseline ECG should be acquired and analyzed on the cardiac monitor and abnormalities should be noted, including in the mean electrical axis. An axis that deviates outside the normal range or is different from the patient's preexisting axis usually has clinical implications. In such a case, the ECG should be checked for corresponding changes suggestive of the underlying cause of the deviation.
- Cardiac causes of axis deviation include ischemia, infarction, left or right ventricular hypertrophy, ectopic beats and rhythms, dextrocardia, and conduction defect of the left posterior-inferior fascicle of the left bundle branch.
- Other conditions that are not cardiac in origin can also contribute to a shift in axis—for example, anatomy (such as tall, thin stature), young age, chronic obstructive pulmonary disease, obesity, and pregnancy.
- A disruption of the electrical impulse in the right and left atria will result in a change in the shape of the P wave.
- An injury to the tricuspid and mitral valves or disruption of the electrical impulse in the AV node can result in lengthening or shortening of the PR interval.
- Injuries in the bundle of His, the left and right bundle branches, the fascicles, and the Purkinje fibers can result in a bundle or fascicular block.
- With a right bundle branch block (BBB), the representative complex displayed on the ECG includes a prolonged QRS interval of 120 milliseconds or more; a slurred S-wave in leads I and V_6; and the

RSR' pattern in V_1, with the R' wave taller than the R wave.

- There is no specific treatment required for isolated right BBB, but the patient should be seen for periodic follow-up evaluations.
- With a left BBB, the representative complex displayed on the ECG includes a prolonged QRS interval of 120 milliseconds or more; wide R waves in leads I and V_6 with no Q wave; and wide, deep S waves in lead V_1 and possibly a small r wave.
- Left BBB usually means that there is a serious cardiac problem within the conduction system or ischemia from coronary artery disease. Patients with this condition require complete cardiac evaluation.
- A hemiblock is a block in the electrical conduction of one of the two fascicle branches of the left bundle branch. It causes little to no widening of the QRS complexes.
- The criteria for diagnosing left anterior hemiblock are left axis deviation within –30° to –90°; a qR complex or large R wave in lead I; and an rS complex in lead III (likely to also appear in lead II and aVF).
- The criteria for diagnosing left posterior hemiblock are right axis deviation of +90° to 180°; rS wave in lead I and qR wave in lead III; and exclusion of right atrial enlargement and/or right ventricular hypertrophy.
- A bifascicular block (ie, two conduction pathways blocked at the same time) includes concurrent findings of right BBB with left anterior hemiblock or left posterior hemiblock. A new onset of bifascicular block with ischemia is not stable and often deteriorates into a complete heart block, especially in the presence of an acute MI.
- When transporting a critically ill cardiac patient with an existing bifascicular block consisting of right BBB and left anterior hemiblock, if signs of ischemia or infarction develop, the patient will likely need acute pacemaker placement, especially in the presence of second- or third-degree AV block. Medical control should be contacted, the patient should be prepared for external cardiac pacing, and the receiving facility should be notified to be urgently prepared for pacemaker placement.
- A trifascicular block is the combination of a bifascicular block (right BBB with a block in the left anterior or left posterior fascicle) that occurs with a first-degree heart block (prolonged PR interval); its presence after an MI implies extensive cardiac damage. True trifascicular blocks require immediate temporary pacing followed by the placement of a permanent pacemaker.
- Hyperacute T waves that appear as a result of ischemia and infarction appear only in the leads that view the area of ischemia and infarction.
- In addition to presence after an MI, ST-segment elevation is observed with left BBB, ventricular rhythms, left ventricular hypertrophy, pericarditis, and early repolarization. A persistent ST-segment elevation may indicate the formation of a ventricular aneurysm.
- The combination of hypertrophy and dilation means that the heart has a larger muscle mass in the affected area. The larger the muscle mass, the higher the concentration of electrical impulses or vectors.
- Left atrial enlargement produces a P wave with a notched double-humped appearance. The characteristic findings in right atrial enlargement are tall, peaked P waves in the inferior leads II, III, and aVF that have an amplitude of 2.5 mm or more. The tall, peaked P waves are known as P pulmonale.
- Patients with left ventricular hypertrophy (LVH) have a higher risk for coronary artery disease, making

them more susceptible to the sequelae of that disease, and are more susceptible to increased mortality than patients who experience an MI without LVH. Increased R-wave amplitude in the leads that look at the left ventricle forms the basis of ECG diagnosis of LVH.

- Patients with right ventricular hypertrophy exhibit a right shift in axis in leads I and aVF and in precordial leads V_1 and V_2 for increased R-wave deflection.
- When hypertrophy is uncomplicated by ischemia, the changes in QRS complexes are used to make the diagnosis. When subendocardial ischemia is present as well, changes to the ST segment and T wave appear as a strain pattern.
- It is important to distinguish between the strain pattern and the ST-segment and T-wave changes seen in ischemia and infarction because the ST-segment and T-wave changes can be immediately life threatening.
- In people with Wolff-Parkinson-White syndrome (WPW), the bundle of Kent (accessory pathway) does not have the same ability to slowly conduct electrical impulses as it does through the AV node, which puts the person at risk for extremely fast heart rates that cause hemodynamic instability. On the ECG, WPW is signaled by the presence of a slurred upstroke known as a delta wave.
- The two tachyarrhythmias that occur most often in WPW are paroxysmal supraventricular tachycardia and atrial fibrillation. CCTPs should be aware of the potential for a wide complex tachycardia developing that is difficult to distinguish from ventricular tachycardia (VT).
- Treatment of unstable WPW tachyarrhythmias may require electrical cardioversion; management with drug therapy produces unpredictable results.
- Pericarditis (inflammation of the pericardium) may cause ST-segment elevation, T-wave flattening or inversion, and the appearance of low voltage in all leads.
- Long QT syndrome is characterized by a prolonged QT interval on ECG and has a tendency to deteriorate into ventricular tachyarrhythmias, including torsade de pointes, which can lead to syncope and sudden cardiac death. The rhythm is too fast to maintain effective cardiac output, so the patient loses consciousness—often without warning.
- The deterioration of long QT syndrome poses a management challenge for CCTPs. Carefully evaluating the ECG, reviewing the patient's medications, and obtaining a medical history will help provide clues to the diagnosis and alert CCTPs to the possibility of a tachyarrhythmia developing during transport.
- Treatment for torsade de pointes includes correcting the underlying cause, overdrive pacing, and administering magnesium sulfate. Other therapies for patients in unstable condition may include electrical cardioversion and defibrillation.
- Wide complex tachycardia is any cardiac rhythm of more than 100 beats/min with a QRS duration of 120 milliseconds or more. This rhythm can be of ventricular or supraventricular origin; identifying the origin of the arrhythmia can lead to the correct diagnosis and proper therapeutic interventions.
- The most useful ECG criterion in establishing the diagnosis of VT is the presence of AV dissociation with more ventricular than atrial events.
- In a patient with right BBB with a QRS duration of greater than 140 milliseconds, VT is the likely diagnosis. In left BBB, a QRS duration of greater than 160 milliseconds indicates VT.
- If the electrical axis is 180° to –90°, the wide complex tachycardia is not likely to be supraventricular tachycardia (SVT). Electrical concordance across the precordium (all QRS complexes pointing in the same direction in ECG leads V_1 through V_6) is more likely VT and is rarely consistent with SVT.
- Patients with wide complex tachycardia who have low blood pressure, pulmonary edema, severe chest

pain, or other evidence of poor perfusion should be promptly treated using synchronized cardioversion.

- When a patient in wide complex tachycardia remains in hemodynamically stable condition, more time can be spent reviewing the history, physical examination, and ECG findings, to make the correct diagnosis.
- When a patient has wide complex tachycardia of an uncertain cause, yet remains in hemodynamically stable condition, amiodarone (Cordarone) is the drug of choice because it can terminate SVT and VT. It is also useful in patients with a poor ejection fraction.
- Procainamide (Procanbid, Pronestyl, Pronestyl-SR, Procan SR) can be used with caution in a patient with wide complex tachycardia who remains in hemodynamically stable condition, although this drug can cause a sudden drop in blood pressure with rapid IV administration and is contra-indicated in patients with complete heart block.
- Lidocaine (Xylocaine) is useful for VT of ischemic origin but does not terminate SVT.
- If SVT is suspected, adenosine (Adenocard) is a useful and diagnostic medication. When irregular wide complex tachycardia is the result of atrial fibrillation and preexcitation over an accessory pathway, however, adenosine may lead to ventricular fibrillation.
- Following termination of wide complex tachycardia, preventive treatment for maintaining a stable rhythm should be initiated—usually in the form of an antiarrhythmic drug (eg, continuation of the drug that terminated the wide complex tachycardia).
- In patients presenting with a wide complex tachycardia rhythm, BLS is the first step in patient management, closely followed by ACLS practices. If the patient is in hemodynamically unstable condition, wide complex tachycardia should be managed as if it were VT until proven otherwise, with synchronized cardioversion the initial therapy of choice.
- Polymorphic or pulseless VT should be treated as ventricular fibrillation: give immediate defibrillation; secure the airway; provide CPR; perform endotracheal intubation; support ventilations; and administer an antiarrhythmic medication.
- When changes in electrolytes—especially potassium and calcium—occur, their effects are often seen on the ECG.
- Hyperkalemia—the most dangerous of all electrolyte abnormalities—can cause death and prevent some drugs used in resuscitation efforts from being effective. On the ECG, hyperkalemia can cause changes in the appearance of all waveforms, and it can cause virtually any arrhythmia. Rapid recognition and correction of this electrolyte disturbance is essential.
- Hypokalemia does not cause the dramatic changes on the ECG, but rather is associated with mild, nonspecific changes such as ST-segment depression, a slightly decreased amplitude of the T waves, minimal prolongation of the QRS interval, and the presence of a prominent U wave.
- ECG changes associated with hypercalcemia include a shortened ST segment, a shortened QT interval, a prolonged PR interval, and flattened or inverted T waves. A variable degree of heart block may also develop.
- Hypocalcemia that occurs acutely can be the result of medications or surgical effects. It causes the opposite effects of hypercalcemia.
- There is a higher incidence of adverse effects with calcium channel blockers and beta-blockers, but the mortality rate is higher in digoxin toxicity. The margin between toxic and therapeutic doses of digoxin is small.

- At toxic levels, the excessive increase of intracellular calcium associated with digoxin elevates the resting potential and predisposes the heart to arrhythmias. The most common ECG changes in digoxin toxicity include AV, junctional, or ventricular ectopic beats; first-degree AV block; slow ventricular response in atrial fibrillation; and an accelerated AV or junctional rhythm. More severe arrhythmias may include severe bradycardia, high-degree heart blocks, and malignant ventricular rhythms.
- Early recognition and aggressive treatment of digoxin toxicity are lifesaving.
- If one of the coronary arteries becomes blocked, the muscle it supplies will be deprived of oxygen (ischemia). If this oxygen supply is not quickly restored, the ischemic area of heart muscle will eventually die (undergo infarction).
- In atherosclerosis, plaque infiltrates the arterial wall and decreases its elasticity; it also narrows the arterial lumen and interferes with blood flow through the vessel. The narrowed, roughened area of the arterial intima provides a locus for the formation of a fixed blood clot (thrombus) that may obstruct the artery, and calcium may begin to precipitate from the bloodstream into the arterial walls, causing arteriosclerosis.
- Atherosclerosis is rarely the primary cause of medical emergencies but is a major contributor to other conditions that may become medical emergencies.
- Arterial bruits (turbulence or "swishing" sounds heard with a stethoscope placed over the carotid arteries) signal the presence of atherosclerosis and contraindicate the use of carotid sinus massage.
- Other peripheral vascular disorders associated with atherosclerosis include claudication, a severe pain in the calf muscle caused by narrowing of the arteries in this muscle and leading to a painful limp, and phlebitis, inflammation, swelling, and pain along the veins that can lead to the formation of blood clots and thrombophlebitis, which is venous inflammation associated with a thrombus (blood clot).
- The most dangerous complication of peripheral vascular disorders is pulmonary embolism, in which a thromboembolus travels to the heart and through its right side, lodging in the pulmonary arterial tree.
- Signs of peripheral vascular occlusion may include pain, redness, swelling, warmth, and tenderness in the extremity; claudication; and arterial bruits.
- If a blockage or potential embolus is suspected, the CCTP should administer IV heparin, monitor the affected limb via ultrasound or Doppler (if available), and maximize blood flow to the extremity by using warm compresses.
- A patient being transported over a long distance with a blood clot that has the potential to become a pulmonary embolus should have a baseline ECG before transport and must undergo frequent 12-lead ECG monitoring. ST-segment depression in the limb and precordial leads accompanied by an increase in right axis deviation may indicate a pulmonary embolus.
- Acute coronary syndrome comprises any group of clinical symptoms consistent with acute myocardial ischemia. Acute myocardial ischemia typically presents as chest pain as the result of insufficient blood supply to the heart muscle because of coronary artery disease.
- Acute coronary syndrome includes conditions that cause an episode of ischemic discomfort (chest pain) as the result of disruption of plaque within a coronary artery. These substances promote a chain reaction of platelet activation, adhesion, aggregation, thrombin formation, and, ultimately, thrombus formation, with the end product being complete occlusion of the coronary artery or one of its branches.
- The 12-lead ECG is used to categorize two groups of patients who have experienced acute coronary syndrome: patients with ST-segment elevation MI (STEMI) and patients without STEMI (NSTEMI, which is further classified based on the presence or absence of unstable angina).

- A 12-lead ECG should be performed within 10 minutes of contacting a patient with chest discomfort or other signs and symptoms suggestive of STEMI. If the findings are not conclusive, but the patient remains symptomatic and there is have a high degree of suspicion, serial 12-lead ECGs should be performed while maintaining continuous ST-segment monitoring.
- All patients with acute coronary syndrome (ACS) should receive antithrombin and antiplatelet therapy, regardless of the presence or absence of ST-segment elevation. Patients with STEMI are candidates for prompt reperfusion therapy, pharmacologic or catheter based, to restore blood flow in the occluded artery; patients with NSTEMI should receive anti-ischemic therapy and be considered for catheter-based therapy.
- Marked ST-segment depression in leads V_1 through V_4, with tall R waves in the right precordial leads and upright T waves, is suggestive of a true posterior MI. Placement of additional electrodes in the posterior position to form leads V_7, V_8, and V_9 is recommended to confirm the diagnosis because primary percutaneous coronary intervention may be appropriate in patients with true posterior MI.
- Lethal ventricular arrhythmias may develop in patients with STEMI, so continuous ECG monitoring is required.
- Most patients whose ECG displays ST-segment elevation will ultimately have a STEMI.
- In case of ACS, the role of the critical care transport team is to transport the patient from a basic hospital to a cardiac hospital with the least possible decline in the patient's condition and to prevent further loss of heart muscle. If transport times will be long or the degree of blockage is severe to the point of being life threatening, tissue plasminogen activators may be required.
- Angina occurs when the supply of oxygen to the myocardium is insufficient to meet the demand. When obtaining a history from a patient with chest pain, it is important to distinguish between stable angina (follows a recurrent pattern) and unstable angina (follows no pattern).
- In the critical care transport environment, nitroglycerin (Nitro-Bid IV, Tridil) should be given intravenously to patients with stable angina, especially for long transports.
- Unstable angina is characterized by noticeable changes in the frequency, severity, and duration of pain and often occurs without predictable stress. It is often a warning sign of an impending MI.
- An MI occurs as a result of the cardiac muscle being deprived of coronary blood flow long enough for myocardial tissue death to ensue. Causes include narrowed vessels, coronary artery occlusion, spasm of a coronary artery, and reduction of overall blood flow.
- Acute MI is the leading cause of death in the United States. The majority of infarctions involve the left ventricle.
- The infarcted tissue is invariably surrounded by a ring of ischemic tissue—an area that is relatively deprived of oxygen but is still viable. The ischemic tissue is often the source of cardiac arrhythmias.
- The three initial components for the diagnosis of an MI are history and physical examination, testing for cardiac enzymes, and interpretation of ECG changes associated with an MI.
- Biomarkers for MI include troponin I, troponin T, creatine kinase, and myoglobin; all of these biomarkers increase in the setting of MI.
- Increased oxygen demand caused by an increased workload or a decrease in supply caused by coronary artery disease or a blocked artery can lead to ischemia, injury, and, ultimately, infarction. Ischemia and injury are reversible, and rapid intervention when they occur can often prevent infarction.
- On the ECG, findings associated with ischemia include ST-segment depression and an inverted T wave. With MI, the T wave inverts symmetrically; when other causes (such as ventricular hypertrophy

with strain and BBB and cerebral hemorrhage) are to blame, the T-wave inversion is often asymmetric or "slurred."

- If ischemia continues uninterrupted, the injured area does not repolarize completely, leading to an elevated ST segment.
- If ischemia and injury continue uninterrupted, infarction can occur; the infarcted tissue no longer generates or transmits electrical impulses. Thus, no direct wave is recorded on the ECG, and electrical impulses are deflected away from the area of infarct and are represented by Q waves.
- For Q waves to be significant (ie, indicating pathology), they must be more than one third the total height of the QRS they appear with and wider than 30 milliseconds in duration.
- The prognosis and therapeutic implications for a patient who has had an MI are determined largely by which area of the heart has died.
- Q waves from old infarctions can be present with findings of a new MI and can contribute to making the correct diagnosis from the ECG more challenging. For this reason, CCTPs should review an "old" ECG from the patient's chart, acquire a new 12-lead ECG before transport, and make serial evaluations along the way.
- In anterior wall MI, the normal pattern of R-wave progression may not occur, a phenomenon called poor R-wave progression.
- An anteroseptal MI is common with an occlusion of the left anterior descending artery and is often associated with hemodynamic compromise and cardiogenic shock. This pattern of MI may be identified by analyzing the septal leads V_1 and V_2 and the anterior leads V_3 and V_4.
- In an acute anteroseptal MI with lateral extension, changes can be seen in all precordial leads (specifically V_5 and V_6 for the lateral extension) and in leads I and aVL; there is not always significant Q-wave formation, but reciprocal changes can be found in leads II, III, and aVF.
- Hyperacute T-wave changes occur only during the first 15 to 30 minutes of an acute MI. If these changes are found during transport, the CCTP is in a unique position to initiate care, even if it is only early notification of the receiving facility to decrease the door-to-treatment time.
- In an acute lateral wall MI, ECG changes are often seen in the lateral leads I, aVL, V_5, and V_6. Reciprocal changes may be seen in the inferior leads II, III, and aVF.
- With an inferior wall MI, characteristic ECG changes can be seen in inferior leads II, III, and aVF. Reciprocal changes are seen as ST-segment depression in leads I and aVL unless the high lateral wall is included in the infarction.
- Without signs of acute infarction, pathologic Q waves are considered age indeterminate because without a good patient history, there is no other way to tell how old the patient is. In an acute inferolateral MI, ECG changes are seen in inferior leads II, III, and aVF and in lateral leads I, aVL, V_5, and V_6. ST-segment changes will be found in leads V_2 to V_4 if the infarct extends anteriorly, and classic ST-segment and T-wave changes will be evident in the lateral precordial leads V_5 and V_6.
- In an acute apical MI, direct ECG changes can be found in inferior leads II, III, and aVF; lateral leads I and aVL; and precordial leads V_2 through V_6. Because of the diffuse ECG changes, this type of MI can be confused with pericarditis. Right ventricular infarction is strongly associated with an inferior wall MI, so when it is present, CCTPs should keep a high index of suspicion and check for other criteria. Right ventricular infarction should be suspected with ST-segment elevation in (septal) lead V_1 and (inferior) leads II, III, and aVF.

- With a posterior wall MI, the diagnosis is made by looking for reciprocal changes in leads V_1 and V_2—specifically, ST-segment depression, upright T waves, and tall R waves.
- When there is reciprocal evidence of a posterior wall MI, there should also be a high index of suspicion, and posterior leads (V_7, V_8, and V_9) should be recorded for comparison.
- Patients with cardiomyopathy may have shortness of breath, chest pains, palpitations, or syncope; sudden cardiac death is also possible.
- Congestive heart failure occurs when the heart cannot pump powerfully enough or fast enough to empty its chambers; as a result, blood backs up into the systemic circuit, the pulmonary circuit, or both.
- In left-sided heart failure, the left side of the heart is no longer able to pump the blood being delivered from the pulmonary vessels. Blood backs up behind the left ventricle, the pressure in the left atrium and pulmonary veins increases, and serum is forced out of the pulmonary capillaries and into the alveoli.
- Pulmonary edema occurs as the result of reduced ejection fraction and cardiac output of the left ventricle when serum mixes with air in the alveoli.
- The priorities when managing left-sided heart failure are to remove the fluid from the lungs, reduce afterload, increase oxygen supply to the heart, and decrease myocardial oxygen demands.
- Right-sided heart failure most commonly occurs as a result of left-sided heart failure, but may also occur as a result of pulmonary embolism or long-standing chronic obstructive pulmonary disease, especially chronic bronchitis.
- The edema associated with right-sided heart failure is most likely to be visible in dependent parts of the body (eg, the feet in a person who is sitting or standing or the lower back in a bedridden patient). It is also present in parts of the body that are not visible, such as the liver.
- Electrophysiology studies are not done during transport, but in the hospital setting may be performed to assess electrical activity of the heart.
- The primary in-hospital arrhythmia therapies are catheter ablation, pharmacologic treatment, and implantable devices, such as pacemakers and implantable cardioverter-defibrillators.
- The transcutaneous pacemaker is most commonly used as an initial emergency pacer (a temporary measure). It is the quickest and most convenient method of pacing, but also requires the most energy and is the least reliable owing to the quality of the skin-to-pad contact and the thoracic impedance that must be overcome.
- Many patients are transported between medical facilities with transvenous pacemakers accompanied by an external pulse generator. Generally, these transvenous pacers require little attention and are quite reliable; the primary sources of problems are battery failure and lead disconnection at the generator. Voltage (the force that causes current to flow) and impedance (resistance to current) are important determinants of battery longevity in a pacemaker.
- The main sources of resistance in a pacing circuit are the lead conductor, the electrode, and the concentration of electrically charged ions at the electrode-tissue interface. Electrode resistance improves pacing efficiency; lead conductor resistance and polarization do not.
- Passage of the pacemaker's electrical impulse between the cathode and the anode—through cardiac tissue and body fluids—is the event in the pacing circuit that stimulates cardiac depolarization.
- Pacemakers stimulate cardiac depolarization, sense intrinsic cardiac activity, respond to metabolic needs, and store diagnostic information. All pacemakers can provide fixed-rate pacing; most also provide rate-adaptive (rate-responsive) pacing, increasing and decreasing pacing rate in response to

input from rate sensors.

- Endocardial (transvenous) leads are threaded through veins—usually subclavian or cephalic—to the right atrium or ventricle. Epicardial leads are attached to the external surface of the heart with sutures or another fixation device.
- Steroid-eluting electrodes have a silicone plug that contains a small dose of steroid, which reduces inflammation and the growth of fibrous tissue at the electrode site.
- Pacemaker system malfunction may occur as a result of battery failure, problems at the lead electrode-tissue interface, coiling or damage to the lead-generator interface, insulation failure of the lead wires, dislodgement of the lead at the implantation site (very rare), pacemaker programming, pocket stimulation, diaphragmatic stimulation, or electromagnetic interference.
- If pacemaker failure occurs during transport, the cardiac monitor will show failure to capture a signal; a 12-lead ECG (compared with the patient's pulse) and patient assessment (signs of decompensation) may then be used to confirm the pacing failure.
- Pacing in the ventricular pacer mode and loss of AV synchrony in a single-chamber pacemaker can lead to pacemaker syndrome, which results from hemodynamic deterioration and causes nonphysiologic timing of atrial and ventricular contractions.
- Atriobiventricular pacemakers, which coordinate the right and left ventricles of the heart, may be used as a treatment for congestive heart failure to resynchronize the heart's chambers.
- Implantable cardioverter-defibrillators (ICDs) automatically attempt to convert a fibrillating heart into a sinus rhythm using a shock from voltage. Each patient with an ICD has a custom ICD system consisting of a housing (can) and a variable number of pacing and high-voltage leads.
- Most ICDs are implanted with one or two transvenous leads used for pacing and shocking. The leads enter the venous system through the subclavian or cephalic vein for placement into the right ventricle or the superior vena cava.
- An ICD bases its decision to deliver a shock (to treat tachyarrhythmias) on the ventricular rate alone; thus, atrial arrhythmias and electromagnetic interference can lead to inappropriate shocks.
- If an ICD fires during care of a patient, the provider should gather the following information: the number of times shocked, recent medical procedures, recent changes in medical condition or changes in patient adherence to the medication regimen, presence of a coexisting pacemaker, patient's activity at the time of shock, and proximity to water or an electrical source.
- If a patient with an ICD experiences multiple inappropriate defibrillator discharges as the result of defibrillator malfunction, the CD can be temporarily disabled by use of a magnet to prevent further discharges.
- In a cardiac arrest, a CCTP can deliver external defibrillation to a patient with an ICD, although the paddles or pads should not be placed directly over the ICD. Providers can also perform CPR on a patient with an ICD.
- Significant risks associated with atrial fibrillation are thromboembolism and resulting increased incidence of stroke. Methods to convert atrial fibrillation include antiarrhythmic medications, external cardioversion, and (the preferred method) internal cardioversion and/or antitachycardia pacing with an atrial ICD.
- CCTPs should expect to transport patients who have or need a pacemaker or ICD and should be prepared to manage any adverse situations related to either device. They should receive training on any transthoracic or epicardial, transcutaneous, or transvenous pacemaker device that their agencies use

and should be prepared to use a magnet to temporarily reprogram an implanted pacemaker or ICD if their agencies transport critically ill cardiac patients.

- When accepting a patient from a sending hospital for critical care transport, any patient with a transthoracic or epicardial, transvenous, transcutaneous, or implanted pacemaker device must have electrical and mechanical pacemaker capture assessed and confirmed by a CCTP.
- Switching from a device used in a sending facility to a device used by the transport team is often the source of anxiety for CCTPs and other providers. If the CCTP does not have a compatible device available, it may be worth considering using the device from the sending facility for the transport and returning it promptly after the transport has been completed.
- The presence of an ICD would require an alternative site (not over the device) for transcutaneous pacing or defibrillation if either of those measures is needed during transport. It is essential to have an external cardioverter-defibrillator immediately available when transporting a patient with an ICD.
- Electromagnetic interference is the major cause of pacemaker dysfunction, particularly in older-style pacemakers lacking adequate internal shielding; they may be vulnerable to interference from headsets and intercom systems in air transport.
- Rate-adaptive pacemakers appear to be sensitive to helicopter vibrations—a factor that CCTPs working on medical helicopters should take into consideration.
- During patient turnover, high-risk items such as endotracheal tube placement, central line status, IV sites for vasoactive medications, and the presence of mechanical pacemaker capture should be specifically confirmed with the accepting provider.

Vital Vocabulary

ablation Removal of a pathway or function by electrocautery or radiofrequency.

absolute refractory period The early phase of cardiac repolarization, wherein the heart muscle cannot be stimulated to depolarize.

acute coronary syndrome (ACS) The term used to describe any group of clinical symptoms consistent with acute myocardial ischemia.

anode The electrode in a pacing circuit that is positively charged when current is flowing.

antegrade conduction Conduction in the normal direction between cardiac structures.

antiarrhythmic A type of medication used to treat and prevent cardiac rhythm disorders.

bifascicular block The combination of a right bundle branch block and a block of one of the fascicles of the left bundle, the left anterior or left posterior fascicle.

biphasic A term used to describe a wave with negative and positive components; usually used in conjunction with P and T waves.

bipolar lead A conduction lead comprising two electrodes attached at specific body sites with different polarity used to examine electrical activity by monitoring changes in the electrical potential between them.

bipolar system A closed system consisting of bipolar leads and a module to generate impulses and measure response.

cable The physical wire that connects the electrode to the ECG monitor.

cardiac electrophysiology The cardiac specialty that involves evaluation and management of rhythm

disturbances.

cardiac monitoring The continuous observation of the patient's condition in relation to his or her cardiac rhythm.

cathode The electrode in a pacing circuit that is negatively charged when current is flowing.

chronotropic A type of medication that affects the rate of contraction of the heart.

current The movement of electrons through an electrical circuit over time, measured in amperes.

delta wave The slurring of the upstroke of the first part of the QRS complex that occurs in Wolff-Parkinson-White syndrome.

depolarization The process of discharging resting cardiac muscle fibers by an electrical impulse that causes them to contract.

dextrocardia A congenital cause of right axis deviation, in which the heart develops in a right-facing position, creating a mirror image of the normal left-facing heart.

digoxin A cardiac glycoside that produces positive inotropic and negative chronotropic activity in the heart and is primarily indicated in the treatment of chronic heart failure and to control the ventricular rate in atrial tachyarrhythmias.

discordant A term that describes T waves that are in the opposite direction from the terminal portion of the QRS complex in bundle branch blocks.

dromotropic Affecting the velocity of conduction.

dual-chamber pacemaker An artificial pacemaker with two leads (one in the atrium and one in the ventricle) so electromechanical synchrony can be achieved.

electrical alternans An ECG pattern in which the QRS vector changes with each heartbeat. This pattern is pathognomonic of cardiac tamponade.

electrode In the context of a 12-lead ECG, an electrical sensor placed on the chest to record the bioelectrical activity of the heart. In the context of a pacemaker, a conductor in contact with cardiac tissue at the end of a pacing lead; it delivers impulses to that tissue.

endocardial (transvenous) leads Pacemaker leads guided by angiography and attached to the endocardium.

epicardial leads Pacemaker leads attached to the epicardium (outer surface of the myocardium); placement and troubleshooting are done in the hospital and require surgery and anesthesia.

hemiblocks Blocks of one of the fascicles of the left bundle branch, the left anterior or left posterior fascicle.

hexaxial system The system developed to describe the coronal plane that is created by the limb leads (I, II, III, aVR, aVL, and aVF).

hypercalcemia An increased level of calcium in the blood.

hyperkalemia An increased level of potassium in the blood.

hypertrophy An increase in the size of the cells as the result of synthesis of more subcellular components, leading to an increase in tissue and organ size.

hypocalcemia A low level of calcium in the blood.

hypokalemia A low blood serum potassium level.

impedance Resistance to the flow of current along an electrical pathway, measured in ohms.

implantable cardioverter-defibrillator (ICD) A small, battery-powered electrical impulse generator that is implanted in patients at risk for sudden cardiac death as the result of ventricular fibrillation or pulseless ventricular tachycardia.

implantable pulse generator (IPG) The largest implanted element in a pacemaking system, containing the battery and control circuitry.

inotropic An effect on the contractility of muscle tissue, especially cardiac muscle.

intra-atrial conduction delay Delayed conduction within one of the atria, often associated with left or right atrial enlargement.

intra-atrial pathways The anterior or Bachman bundle, middle bundle, and posterior internodal system, through which the electrical impulse passes after the SA node; represented by the P wave on the ECG; also called intranodal pathways.

isoelectric When referring to a wave, the wave is neither positive nor negative.

joule A measurement of energy.

lead In the context of the 12-lead ECG, the designated position of the electrode, or the name of the electrode placement. In the context of a pacemaker, an insulated wire that carries signals in a pacemaking system between the implantable pulse generator and the heart tissue.

left anterior fascicle The portion of the electrical conduction system responsible for innervating the anterior and superior areas of the left ventricle. It is a single-stranded cord terminating in the Purkinje cells.

left posterior fascicle The portion of the electrical conduction system responsible for innervating the posterior and inferior areas of the left ventricle. It is a widely distributed, fanlike structure terminating in the Purkinje cells.

limb leads The ECG lead electrodes attached to the limbs that form the hexaxial system, dividing the heart along a coronal plane into the anterior and posterior segments.

long QT syndrome A prolonged QT interval on the ECG primarily caused by a congenital disorder and that under certain conditions tends to deteriorate into ventricular tachyarrhythmias and can lead to syncope or sudden cardiac death; the patient loses consciousness, often without warning.

mean electrical axis The sum of all electrical impulses.

NBG code A code of five letters used to categorize pacemakers by their functions and capabilities, developed by a joint effort of North American and British electrophysiology groups.

Ohm's law The principle given by the equation $V = IR$, which states that applied voltage is equal to the current times the resistance of the circuit.

pacemaker syndrome The occurrence of symptoms relating to the loss of atrioventricular synchrony in ventricularly paced hearts or symptoms caused by inadequate timing and ventricular contractions in paced hearts.

pacing circuit The conduction pathway along which the pacing impulse flows; formed by a power source, one or two lead-electrode pairs, and body tissue.

pacing impulse The electrical impulse sent to the heart to stimulate the heart to beat.

paroxysmal nocturnal dyspnea Severe shortness of breath occurring at night after several hours of recumbency, during which fluid pools in the lungs; the person is forced to sit up to breathe; caused by left-sided heart failure or decompensation of chronic obstructive pulmonary disease.

paroxysmal supraventricular tachycardia A supraventricular tachycardia that starts and ends abruptly.

pericarditis An inflammatory process involving the pericardium.

P mitrale A double-humped, M-shaped P wave that is 120 milliseconds wide or greater with the tops of the humps 40 milliseconds apart or greater; found in limb leads I, II, and III; represents left atrial enlargement.

poor R-wave progression An abnormal R-wave pattern; one of the factors that may signify anterior infarction.

P pulmonale A tall P wave that is 2.5 mm high or greater, found in leads II and III; indicates right atrial enlargement.

precordial leads Another term used to describe the chest leads in an ECG.

PR interval The interval of time that occupies the space between the beginning of the P wave and the beginning of the QRS complex.

QRS complex Deflections in the ECG produced by ventricular depolarization.

reciprocal changes An ECG pattern in which a lead shows a pattern that is the opposite of the one shown in the lead located 180° from the other; for example, the electrode over the area of infarction records ST-segment elevation, whereas the electrode over the lead that is 180° away records ST-segment depression.

refractory period A short period immediately after depolarization in which the myocytes are not yet repolarized and are unable to fire or conduct an impulse.

relative refractory period The period in the cell-firing cycle at which it is possible but difficult to restimulate the cell to fire another impulse.

repolarization A state in which the cell becomes more negative, moving away from equilibrium with the extracellular fluid; this is an active process.

single-chamber demand pacemaker A pacemaker with the pacing lead placed in only one chamber of the heart, in which the generator stimulus is inhibited by a signal derived from the heart's depolarization, thus minimizing the risk of pacemaker-induced fibrillation.

ST-elevation myocardial infarction (STEMI) A myocardial infarction that shows ST-segment elevation on the ECG; patients with STEMI have a high probability of coronary thrombus occlusion.

strain pattern An ECG pattern that involves ST-segment changes and flipped, asymmetric T waves associated with right or left ventricular hypertrophy.

ST segment The section of the ECG complex from the end of the QRS complex to the beginning of the T wave; represents the period of inactivity between ventricular depolarization and repolarization; mechanically, represents the time that the myocardium is maintaining contraction.

torsade de pointes An undulating sinusoidal rhythm in which the axis of the QRS complexes changes from positive to negative and back in a haphazard manner.

trifascicular block The combination of bifascicular block (right bundle branch block with a block in the left anterior fascicle or left posterior fascicle) that occurs with a first-degree heart block (prolonged PR interval).

T wave The upright, flat, or inverted wave following the QRS complex of the ECG, representing ventricular repolarization.

unipolar lead A lead in which one of the electrodes is placed in the heart and the other lead is placed in

an area of zero potential.

unipolar system A type of pacemaker system in which contact between the pacemaker itself and the body tissue actually forms the ground lead for the implantable pulse generator.

voltage The force that causes current to flow in a circuit, measured in volts; also called *amplitude* in a pacing system.

wide complex tachycardia A cardiac rhythm of greater than 100 beats/min with a QRS duration of 120 milliseconds or greater; can be of ventricular or supraventricular origin.

Wolff-Parkinson-White (WPW) syndrome A syndrome characterized by short PR intervals, delta waves, nonspecific ST-T wave changes, and paroxysmal episodes of tachycardia caused by the presence of an accessory pathway.

Hemodynamic Monitoring

Authors

Mike McEvoy, PhD, RN, CCRN, REMT-P, CIC

Christopher Handley, BS, EMT-P

Dave Steel, NREMT-P

Objectives

1. Discuss the principles of and indications for invasive hemodynamic monitoring (p 563–564).
2. Interpret the following hemodynamic values and discuss their meaning:
   - Central venous pressure (CVP)
   - Systolic blood pressure (SBP)
   - Diastolic blood pressure (DBP)
   - Mean arterial pressure (MAP) Pulse pressure
   - Pulmonary artery pressures (systolic, diastolic, and mean)
   - Pulmonary capillary wedge pressure (PCWP)
   - Cardiac output (CO)
   - Cardiac index
   - Pulmonary vascular resistance (PVR)
   - Systemic vascular resistance (SVR)
   - Stroke volume (SV)
   - Mixed venous saturation (Svo_2) (p 576–583)
3. List normal hemodynamic values for the various types of invasive hemodynamic measurements (p 576).
4. Describe the significance of each pressure reading used in patient management (p 576–583).
5. Describe how a central venous line works and list the sites where it may be placed (p 564–570).
6. Describe the types of catheters used for central venous lines (p 565–566).
7. Discuss indications, contraindications, and complications for central venous lines (p 564–565).
8. Describe the equipment and steps for inserting a central venous line (p 566–570).
9. Explain how to troubleshoot problems encountered when inserting a central venous line (p 569).
10. Describe how an arterial line works and list the sites where it may be placed (p 570).
11. Describe the types of catheters used for arterial lines (p 573–574).
12. Discuss the indications, contraindications, and complications for arterial lines (p 570).
13. Describe the equipment and steps for inserting an arterial line (p 571).
14. Discuss the concepts of preload, afterload, and the Frank-Starling curve (p 577, 581).
15. Demonstrate the proper placement of and zeroing procedure for a pressure transducer (p 584–585).
16. Describe proper transport procedures for invasive hemodynamic monitoring (p 586).
17. Describe troubleshooting procedures for common problems with invasive hemodynamic monitoring

during transport (p 587).

18. Discuss flight considerations related to invasive hemodynamic monitoring (p 588).

Introduction

Two major developments led to the advancement of the intensive care unit (ICU) in the last 40 years. First, in the late 1960s, the value of delivering mechanically assisted ventilation was discovered. Second, in the 1970s, the introduction of the bedside pulmonary artery catheter (PAC) revolutionized hemodynamic monitoring in the ICU. These catheters are used not only in the ICU for hemodynamic monitoring, but also during ground and air transport by CCTPs.

Invasive hemodynamic monitoring methods attempt to assess the physiologic condition of the three principle components of the cardiovascular system: heart, vascular network, and fluid volume. The core hemodynamic assessments center on the capability of the patient's heart to pump the requisite amount of blood to the body. Other hemodynamic assessments allow CCTPs to ascertain the compliance, tone, and resistance of the vascular network. Further assessments can be performed to gauge the fluid status of the patient.

Invasive hemodynamic monitoring is one of the cornerstones of care for critically ill patients. Assessment of a patient's hemodynamic status builds on patient monitoring. The CCTP must be familiar with these critical care assessments to provide adequate interhospital care. Hemodynamic monitoring can aid CCTPs in assessing the severity of a patient's condition, the benefits of blood product and vasoactive drug administration, the effectiveness of ventricular-assist devices and intra-aortic balloon pump support, and, most important, the early warning signs of possible deterioration in a patient's condition.

Invasive hemodynamic measurements are obtained via a closed catheter system **Figure 14-1**. A bag of crystalloid fluid is placed within a pressure bag that assists the flow of fluid through the system's catheter as it passes through a stopcock and a transducer, ultimately ending up in the desired location in the body. Once the catheter is in place, a cable is connected to the catheter's transducer and to the monitor, which reads the respective waveform and displays the appropriate measurement.

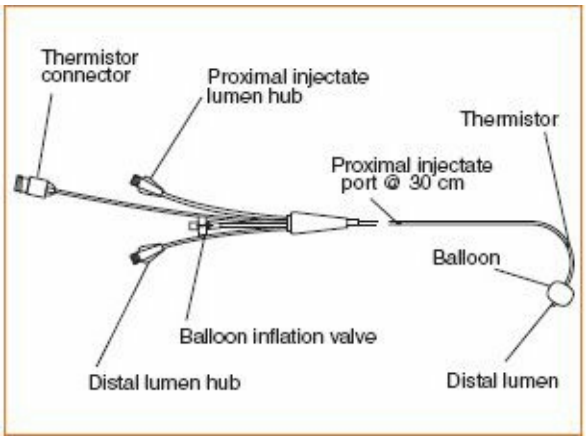

Figure 14-1 A closed catheter system. Courtesy of Edwards Lifesciences. Used with permission.

Invasive hemodynamic monitoring is not a panacea for patient assessment because the catheters are associated with line infection, sepsis, thrombophlebitis, thromboembolism, and associated tissue injury. Measurements may also be misread from inadvertent patient repositioning; moving the patient will produce incorrect measurements unless the equipment is also repositioned appropriately. Physicians typically place these invasive catheters in patients with a diagnosis of shock, pulmonary edema, complicated myocardial infarction, sepsis, pulmonary embolism, diagnostic monitoring, or major cardiac surgery. Catheter placement is usually outside the scope of CCTPs.

Asepsis

Asepsis is an element of care for patients with central lines and hemodynamic monitoring equipment that cannot be overemphasized. The incidence of catheter-related bloodstream infections is a prime focus of critical care practitioners worldwide. Because central venous catheters disrupt the integrity of the skin, they provide a pathway for bacteria and fungi to enter the bloodstream. The mortality of bloodstream infections in critically ill patients approaches 20%, and most of these infections are attributed to the use of central venous catheters. There are five key practices that have been shown to decrease the incidence of catheter-related bloodstream infections: hand hygiene, maximal barrier precautions during insertion, chlorhexidine skin antisepsis, optimal catheter site selection, and prompt removal of unnecessary lines.

The CCTP should be certain to carry and frequently use an alcohol-based hand gel during transport and to carefully disinfect access sites used on patients. For line placement, skin should be prepared with antiseptic-detergent 2% chlorhexidine in 70% isopropyl alcohol using a back-and-forth friction scrub of at least 30 seconds. The antiseptic solution should not be wiped off or blotted from the skin and must be allowed to dry completely (for approximately 2 minutes) before puncturing the site. Older antiseptic solutions, such as povidone-iodine solution, are no longer considered effective skin antisepsis.

Noninvasive Hemodynamic Monitoring

Understanding hemodynamic monitoring begins with noninvasive and less invasive techniques of measurement. In fact, as technology evolves, less invasive devices will most likely replace many of the invasive monitoring devices that CCTPs have become accustomed to using. Physical assessment techniques, such as capillary refill, skin color, skin turgor, skin temperature, lung sounds, heart sounds, and mental status, should coincide with high-tech invasive hemodynamic measurements. Although invasive monitoring devices are designed and used to provide data not available from physical assessment alone, CCTPs should never be so caught up in the technology and complicated measurements that they lose sight of basic physical and cardiovascular assessments.

Blood pressure is one of the most often used and perhaps least understood assessments. Direct monitoring of blood pressure is accomplished by the use of an arterial line. Indirect monitoring of blood pressure is accomplished with a device that senses pulsatile flow, most commonly using a sphygmomanometer (that is, blood pressure cuff) to measure the systolic and diastolic blood pressures. **Systolic blood pressure (SBP)** is the measure of pressure on the arterial walls during systole, whereas **diastolic blood pressure (DBP)** is the measure of the pressure on the walls of the arteries during diastole. The formula for blood pressure is cardiac output (CO) multiplied by systemic vascular resistance (SVR) or BP = CO × SVR. Other methods that indirectly measure blood pressure include assessment of pulses, electronic blood pressure cuffs (also called noninvasive blood pressure [NIBP] units), and Doppler ultrasound machines. It is extremely important to note that these indirect measurements assess flow, whereas direct monitoring devices (that is, arterial lines) measure pressure. Because pressure and flow are entirely different parameters, readings obtained by indirect and direct methods cannot be expected to correlate exactly.

When using indirect monitoring devices, CCTPs should be careful to avoid errors in measurement. Blood pressure cuff size and position of the extremity during measurement are the two most common factors contributing to inaccuracies. The cuff bladder size should be matched to the size of the patient's extremity where blood pressure is measured. Determining the bladder size is often difficult in the critical care setting; many practitioners instead choose a cuff that covers two thirds of the extremity being measured. A cuff selected for an upper arm, for example, would be properly sized if it covered two thirds of the distance from the elbow to the shoulder. Using a cuff that is too large will result in readings that are lower than actual; a cuff that is too small will yield readings higher than actual. The significant potential

for error mandates that the transport unit carry various sizes of BP cuffs appropriate for the ages and sizes of the patient population most commonly transported.

Positioning of the extremity in which BP is measured also affects accuracy. Proper assessment requires that the extremity be at mid-heart level when BP is measured. Elevation of an arm (or leg, if that is where the cuff is placed) above mid-heart level will yield falsely low readings, whereas placing the extremity below mid-heart level will yield false high readings. This issue can be particularly problematic when measuring BPs in side-lying patients.

Often, NIBP units are incorporated into transport monitors and used to obtain indirect BP measurement at predetermined intervals automatically. The NIBP units measure heart rate and mean arterial pressure (MAP) only. The NIBP computer software then calculates the patient SBP and DBP values by using the measured parameters to determine the time spent in systole and diastole computed against the MAP. The CCTP should evaluate the heart rate obtained in every NIBP reading against the actual patient pulse, the heart rate displayed on a pulse oximeter, or an electrocardiographic (ECG) heart rate display. If the NIBP-evaluated heart rate differs significantly from the actual patient heart rate, the calculated SBP and DPB should be considered unreliable. Because MAP is actually measured by the NIBP unit, this value is often used in making patient care and treatment decisions.

Figure 14-2 Assessment of the patient's heart rate using a pulse oximeter.

Some textbooks suggest that pulses correlate to SBP. The presence of a carotid pulse suggests an SBP of greater than 60 mm Hg, a femoral pulse suggests an SBP of greater than 70 mm Hg, and a radial pulse suggests an SBP of greater than 80 mm Hg. More recent studies failed to find any reliable correlation between BP and the location of pulses. There are data to suggest that skilled critical care clinicians can become fairly accurate at estimating the SBP from palpation of a femoral pulse.

Heart rate is a key sign of hemodynamic instability in emergency and critical care patients. Assessment of the pulse can be performed by arterial palpation; however, in the high noise environment of an ICU or a CCTP vehicle, the heart rate obtained from a pulse oximeter is more reliable than manual assessment **Figure 14-2**. Correlation with an ECG display or pulse oximetry pleth (waveform) provides additional reassurance.

The **Allen test** can be used to assess extremity perfusion and ulnar artery function. With this technique, the patient's hand is initially held above his or her head while the fist is clenched and the radial and ulnar arteries are compressed **Figure 14-3A**. The hand is then lowered and the fist is opened **Figure 14-3B**. Pressure is kept on the radial artery, whereas ulnar pressure is released. After ulnar pressure is released, the color should return to the hand within 6 seconds.

Invasive Hemodynamic Monitoring

Monitoring of hemodynamic status in the critical care transport environment often involves placing

catheters in the venous and/or arterial vasculature. The catheters are connected by using rigid tubing to a pressure transducer (sensor) that will measure the pressure conducted from the patient. As mentioned, placing these invasive catheters requires considerable skill and practice and is usually outside the scope of CCTPs. Although CCTPs may not place the catheters directly, they will provide care to patients with pressure monitoring catheters. Therefore, CCTPs must be familiar with the methods for using each type of catheter and have the knowledge to interpret the data provided. They must also be familiar with common complications involved with these invasive catheters, including what must be done if the catheter is prematurely removed.

Central Venous Lines

Central venous lines are invasive catheters placed inside the central venous system that provide access to the core vessels of the body. The right internal jugular vein **Figure 14-4** is the easiest site to access and insert a central venous line because of desirable anatomy and a relatively low rate of complications. Subclavian sites are more preferable because they best minimize infection risks. Femoral and brachial veins are also common sites, although femoral lines are strongly discouraged in adults because they have the highest risk for infection of any central venous line location.

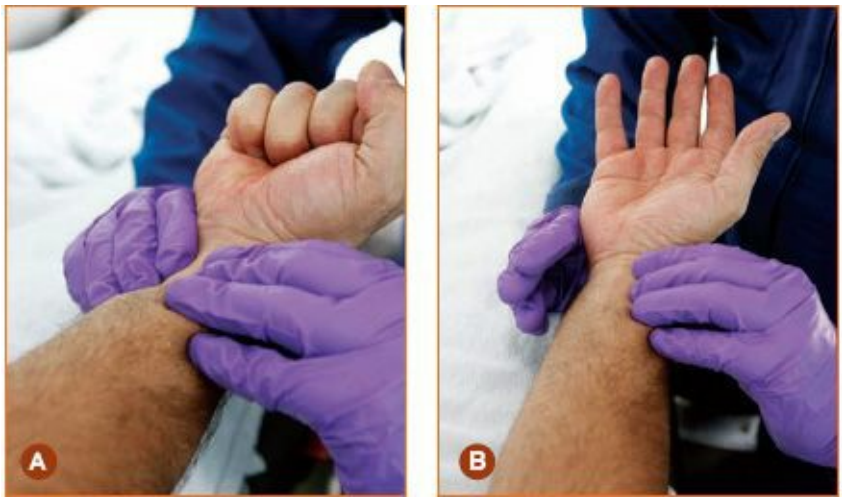

Figure 14-3 The Allen test. **A.** The patient raises his or her hand above his or her head with the fist clenched. The CCTP compresses the radial and ulnar arteries. **B.** The patient lowers his or her hand with the fist open and the CCTP releases ulnar pressure while keeping pressure on the radial artery.

The catheter is inserted until the tip resides just outside the right atrium (in the superior vena cava). This position allows for central venous pressure (CVP) readings (also known as right atrial [RA] readings). Monitoring of the CVP is used to determine right ventricular preload and intravascular volume status and to assess right-sided heart function. The normal range for the CVP is 2 to 6 mm Hg. A CVP reading can be misinterpreted because of thoracic pressure fluctuations during spontaneous and assisted respiration. For this reason, CCTPs should obtain a CVP measurement during end expiration to ensure its accuracy. Most patient care monitors designed for critical care measure the CVP with a presumption that the patient is being mechanically ventilated.

Indications

In addition to pressure monitoring, central lines often include outlet ports for obtaining blood specimens and for the delivery of IV fluids or medications. Central venous lines are frequently used when providers are unable to establish adequate peripheral vascular access or require access to central circulation for medications that cannot safely be given through peripheral sites. Central venous lines provide a means for

the following:

- Rapid fluid replacement
- Medication administration
- Rapid access to central circulation
- Invasive monitoring

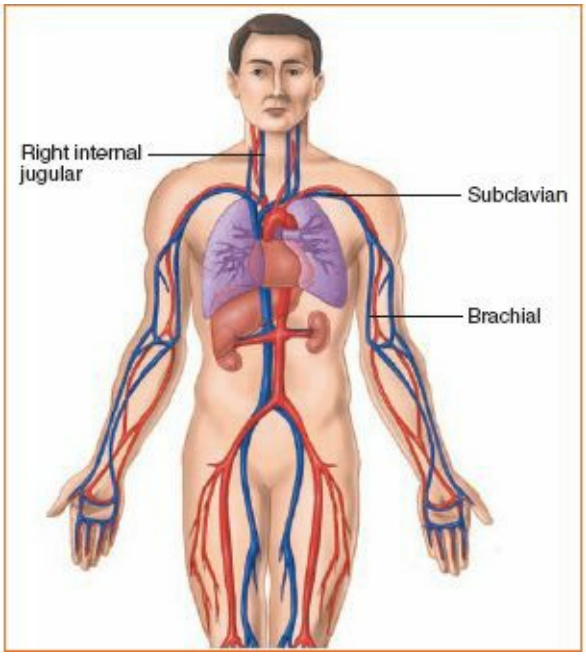

Figure 14-4 The right internal jugular vein is the easiest site to access and insert a central venous line. The subclavian, brachial, and femoral veins are also common sites.

Contraindications

There are few contraindications for central venous access. Relative contraindications include the following:

- Significant coagulopathy
- Local trauma to site of insertion
- Infection at site of insertion

Complications

Insertion of a central line is associated with some risk to the patient, including infection or bleeding at the insertion site. The most common complication is pneumothorax or hemothorax from an unsuccessful attempt at subclavian insertion. Additional complications include the following:

- Air embolism
- Infection (bloodstream)
- Thrombosis
- Phlebitis
- Limb ischemia
- Arterial puncture
- Improper placement (within the body)
- Myocardial perforation (resulting in pericardial tamponade)

- Thoracic duct injury (with left internal jugular or subclavian approaches)
- Nerve injury
- Catheter occlusion
- Sluggish infusion
- Catheter damage with resultant air embolism or infection
- Blood withdrawal problems (inability to obtain specimens)

Types of Central Venous Catheters

The most commonly used central line in critical care has three lumens and is simply referred to as a **triple-lumen catheter** Figure 14-5. All three lumens can be used for phlebotomy or fluid and drug administration; as an alternative, two lumens can be used for fluid administration and the other for CVP monitoring. In some cases, one port of a triple-lumen catheter may be reserved for total parenteral nutrition and should not be used during transport. There are additional types of central venous catheters—some that have one or two access ports and some that are installed under the skin (tunneled) and are designed for long-term multiple use for IV medication administration, dialysis, and parenteral nutrition. Tunneled central line devices are generally designed for long-term use. Emergency use of these catheters should be guided by direction from the receiving facility and local protocols.

Figure 14-5 HICKMAN® tri-fusion catheter. © C. R. Bard, Inc.

The HICKMAN® catheter Figure 14-6 is a semipermanent central venous catheter used for venous access and for drawing blood. Placement of this line can be into the cephalic, subclavian, external, or internal jugular vein with the distal tip advanced to just above the right atrium. The proximal end of the catheter exits from the lower portion of the anterior chest wall via a subcutaneous tunnel. Daily flushing of this line is necessary to prevent it from clotting and is also required every time the line is used to draw blood.

Complications associated with the HICKMAN® catheter include clotting of the line, catheter breakage, and infection of the catheter or insertion site. If the line becomes clotted, it should not be force flushed because the catheter could rupture or, more important, a thrombus could be released into the circulatory system. If catheter breakage should occur, a clamp should be placed between the break and the patient's skin until repair of the catheter can be accomplished. Infection at the insertion site is evidenced by erythema, edema, or discharge. Catheter infection is often evidenced as bacteremia, with fever and chills progressing into septic shock if not recognized and promptly treated. All complications should be reported to the receiving facility as soon as possible.

The GROSHONG® catheter Figure 14-7 is thinner, is more flexible, can have up to three lumens, and is equipped with a subcutaneous cuff. The catheter exits the skin near the nipple. There is a pressure-sensitive, two-way valve on the adjacent lateral wall that allows for the tip of the catheter to be closed. Because venous pressure maintains the valve in the closed position, there is no backflow of blood into the

catheter. The advantages of this design are that clamping and frequent heparin flushing are not necessary, although a saline flush is needed after each use or once daily. This type of catheter can also last between 6 weeks and 6 months or longer and allows the patient the freedom to do most activities.

Figure 14-6 A HICKMAN® catheter. © C. R. Bard, Inc.

Figure 14-7 GROSHONG® catheter. © C. R. Bard, Inc.

The port-a-cath is a titanium chamber with a catheter that threads under the skin into the subclavian vein to the right atrium. The titanium chamber is 1″ × 1″ × 0.5″ and has a selfsealing rubber top, which is implanted under the skin of the anterior part of the chest in the pectoral region. The catheter can be used for the infusion of fluid or medications and for blood draws and is accessed using a Huber needle, which is inserted through the skin and into the rubber top of the portal. A Huber needle is a specially designed noncoring needle that minimizes damage to the port and bends at a 90° angle to allow it to be secured to the chest wall once inserted into the port. The advantages of this catheter are that it may remain in place for years with proper care, it allows the patient to be active, and it does not require daily care. This catheter must be flushed with heparin once every 30 days if not in use. The risks of the port-a-cath are similar to those of external catheters and include kinks, ruptures, and, rarely, infections.

The peripherally inserted central catheter (PICC) **Figure 14-8** is used when medium-duration, long-term access is needed (usually limited to several months). This catheter can be used in ways similar to other centrally placed lines. This catheter is inserted via the brachial or other arm vein and is advanced to the superior vena cava, with the tip of the line just outside the atrium. The PICC requires regular flushing with heparin or saline solution to prevent clotting. Low-dose warfarin may be added to the patient's daily medications to augment line patency if clotting problems have occurred in the past. The disadvantages of this catheter include limited arm mobility and limitations on aggressive exertion (eg, swimming), in addition to other risks associated with placement of centrally placed catheters.

Figure 14-8 A PowerGroshong® peripherally inserted central catheter. © C. R. Bard, Inc.

Central Venous Catheter Placement

Although central venous catheters are rarely placed by CCTPs, for the student's background knowledge, this section explains how they are placed.

Equipment

The following equipment is needed to insert a central venous line:

- Catheters (various sizes and lengths)
- 5- and 10-mL syringes
- Saline flush solution
- Chlorhexidine-isopropyl alcohol solution
- J-tipped guide wire
- IV tubing
- IV fluids Suture materials
- Occlusive dressing
- Sterile drape
- Tape
- Local anesthetic

Steps

The most common technique for line insertion is the **Seldinger technique**.

Skill Drill 14-1 outlines the steps for inserting a central venous line using this technique:

1. Use universal precautions.
2. Prepare all equipment and flush all lumen ports.
3. Locate landmarks **Step 1**.
4. Palpate for entry location **Step 2**.
5. Clean and prepare the site using a sterile technique.
6. Administer a local anesthetic.
7. Insert the needle with connected syringe at the site, aspirating until blood is drawn into the syringe **Step 3**.

8. Remove the syringe and insert the guide wire into the needle. Feed the needle into the vein, never losing contact with the guide wire **Step 4**.
9. Remove the needle while holding the guide wire in place **Step 5**.
10. Pass the dilator over the guide wire to the skin. Use a scalpel to make a small (0.5- to 1-cm) incision in the skin to facilitate passing of the dilator **Step 6**.
11. Remove the dilator, maintaining contact with the guide wire **Step 7**.
12. Insert the catheter over the guide wire and into the vessel, removing the guide wire as the catheter advances **Step 8**.
13. Aspirate blood, and flush all ports to ensure patency **Step 9**.
14. Secure the line to the patient's skin using sutures or staples **Step 10.**
15. Dress the site, and follow up with a radiograph to ensure proper line placement. It is imperative that line placement be radiographically confirmed before departing with the patient.

The following lists outline specific procedures for insertion of central lines in the femoral, internal jugular, and subclavian veins.

Steps for femoral vein insertion include the following:

1. Prepare the equipment.
2. Clip hair from the area, and, if necessary, drape the area.
3. Cleanse the area with chlorhexidine–isopropyl alcohol solution.
4. Locate the femoral artery.
5. Numb the area using a local anesthetic.
6. Puncture the area two finger breadths below the inguinal ligament, medial to the artery, directing the needle cephalad at a 45° angle with the skin until the needle can no longer be advanced **Figure 14-9**.
7. Maintain suction on the syringe and pull the needle back slowly until blood appears in the syringe.
8. Lower the needle so that it is more parallel to the frontal plane. Remove the syringe and insert the catheter.

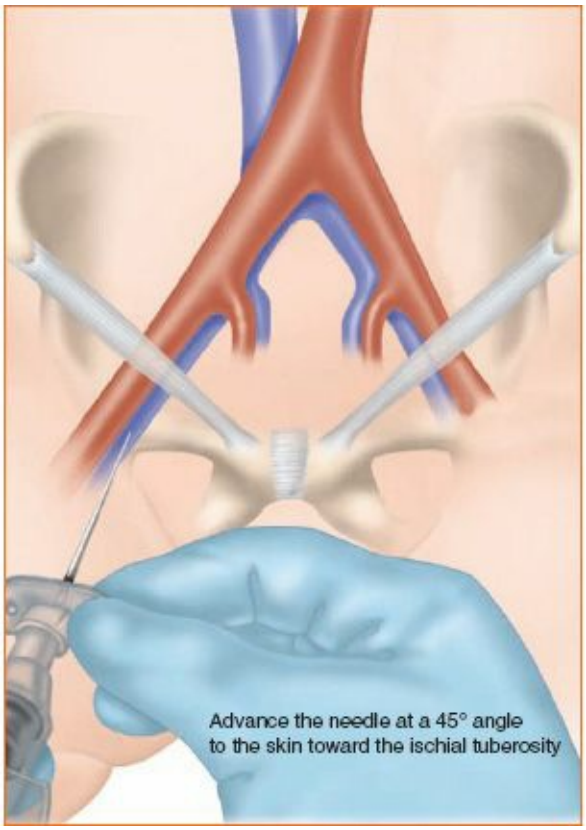

Figure 14-9 Femoral vein insertion. Adapted from: Henretig FM, King CC, eds. *Textbook of Pediatric Emergency Procedures*. Baltimore, MD: Williams and Wilkins; 1997.

Steps for internal jugular vein insertion include the following:

1. Prepare the equipment.
2. Determine the depth of catheter placement by measuring from the point of insertion to the following surface markers on the chest wall **Figure 14-10**:
   - **a**. Sternoclavicular joint to the subclavian vein
   - **b**. Midmanubrial area to the brachycephalic vein
   - **c**. Manubrial-sternal junction to the superior vena cava
   - **d**. 5 cm below the manubrial-sternal junction (the right atrium of the heart)
3. Place the tip of the catheter above the right atrium for administration of fluids.

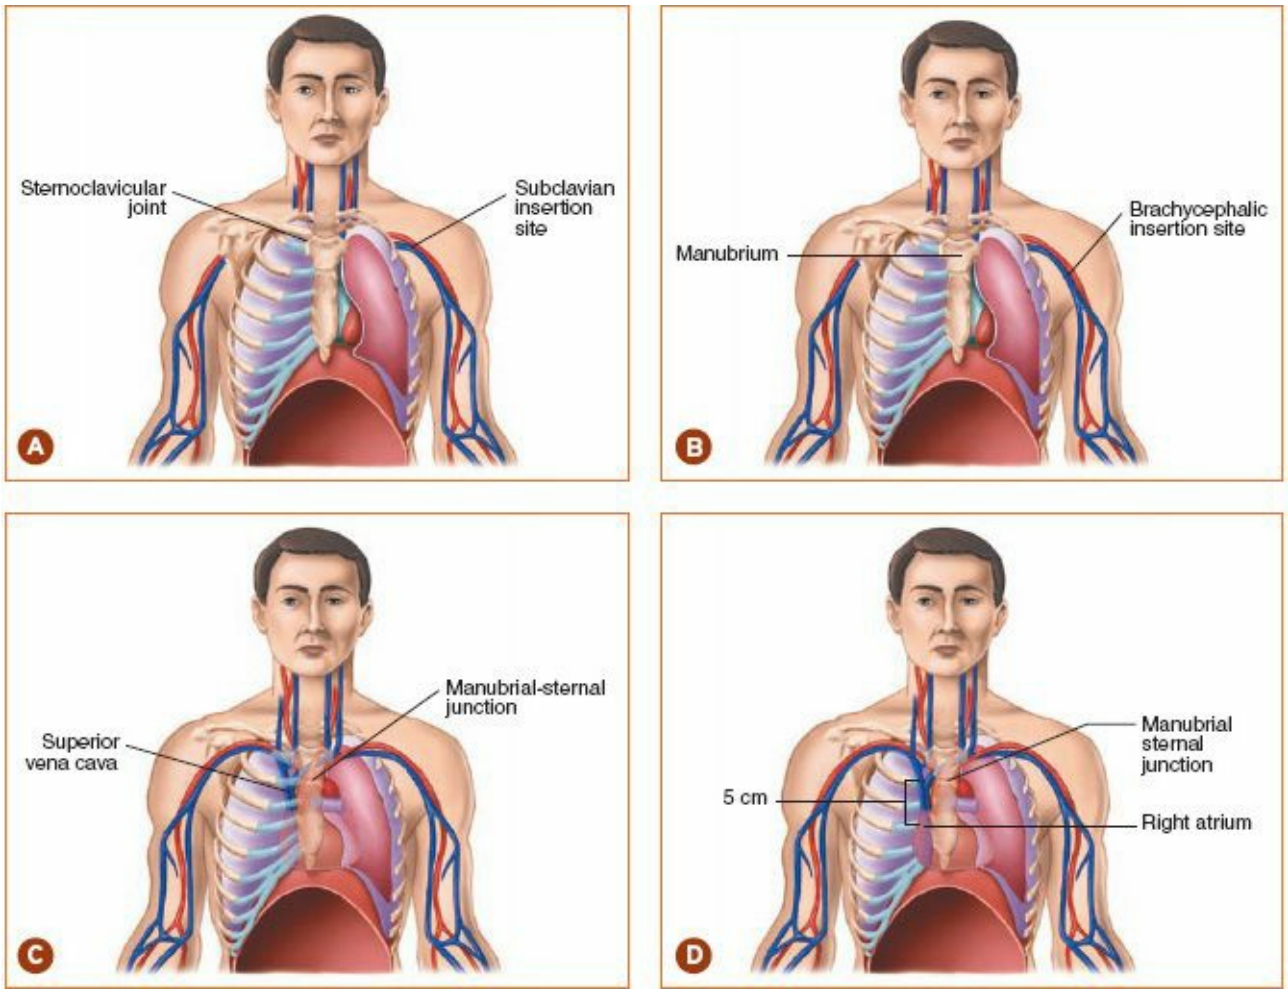

Figure 14-10 Determine the depth of catheter placement by measuring from the point of insertion to the following surface markers on the chest wall. **A.** Sternoclavicular joint to the subclavian vein. **B.** Midmanubrial area to the brachycephalic vein. **C.** Manubrial-sternal junction to the superior vena cava. **D.** Five centimeters below the manubrial-sternal junction (right atrium of the heart).

4. Place the patient in a supine, head-down position of 15°. Extend the patient's head and turn it away from the side of venipuncture.
5. Cleanse the area with chlorhexidine–isopropyl alcohol and drape the area. Maintain sterility.
6. Administer a local anesthetic.
7. Insert the needle at a 45° to 60° angle directed caudally **Figure 14-11**. Advance to a depth of 3 to 5 cm, depending on patient size.
8. If the vein is not entered, redirect the needle tip slightly more medially and repeat; do not direct the needle across the midline because the carotid artery may be punctured.
9. After entering the vein, advance the guide wire through the needle—minimal to no resistance is met. Monitor the ECG during insertion for atrial ectopy.
10. With the guide wire in place, withdraw the needle and advance the catheter to the predetermined depth.

Figure 14-11 Internal jugular vein insertion.

Skill Drill 14-1

Inserting a Central Venous Line

1 Locate landmarks.

2 Palpate for entry location.

3 Insert the needle with connected syringe at the site, aspirating until blood is drawn into the syringe.

4 Remove the syringe, insert the guide wire into the needle, and feed the guide wire into the vein.

5 Remove the needle while holding the guide wire in place.

6 Pass the dilator over the guide wire to the skin. Use a scalpel to make a small (0.5- to 1-cm) incision in the skin.

7 Remove the dilator, maintaining contact with the guide wire.

8 Insert the catheter over the guide wire and into the vessel, removing the guide wire as the catheter advances.

9 Aspirate blood and flush all ports to ensure patency.

10 Secure the line to the patient's skin using sutures or staples.

Steps for subclavian vein insertion include the following:

1. Position the patient in a 15° head-down position.
2. Stand at the side of the bed.
3. Turn the patient's head away from the side to be cannulated.
4. Puncture the skin at the junction of the medial (middle of the clavicle) and middle third of the clavicle **Figure 14-12**.
5. Advance the needle beneath the clavicle toward the sternal notch to a depth of 3 to 5 cm.
6. Once the lumen of the vein has been entered, rotate the needle cephalad and clockwise 90° and proceed to insert the guide wire and catheter.

Troubleshooting

The most common problems that occur when inserting a central venous line are listed in **Table 14-1**. The table lists potential solutions to the problems.

TABLE 14-1 Common Problems Encountered When Inserting a Central Venous Line

Problem	Possible Actions to Resolve the Problem
Sluggish infusion	Check for kinks in the catheter. Reposition the catheter. Remove the injection cap and check for clots. Flush vigorously with 20 to 30 mL of normal saline.
Inability to withdraw blood	Check for kinks in the catheter. Make sure the catheter clamp is open. Flush vigorously with 20 to 30 mL of normal saline. Use repositioning maneuvers. Remove the injection cap and attach the syringe. Flush with saline.
Catheter damage	Clamp the catheter between the damaged area and the skin. Cover the damaged area with a sterile dressing. Do not attempt to repair.

Arterial Lines

Arterial lines (sometimes called A-lines) are inserted into the patient's arterial vascular system. The transducer converts the pressure waveform into an electrical signal and displays the waveform and its corresponding values on the transport (or bedside) monitor. In the United States, pressure waveforms are usually measured in millimeters of mercury or centimeters of water pressure. Arterial lines may be inserted in the radial, brachial, femoral, axillary, and dorsalis pedis arteries **Figure 14-13**. The radial artery is the preferred site because of its easy access and because the patient's hand can receive collateral circulation from the ulnar artery. It is best to use the patient's nondominant hand. In addition to the benefit of a continuously displayed BP reading while titrating vasoactive agents, the arterial line is an alternative trigger source for an intra-aortic balloon pump and enables access for arterial blood samples for arterial blood gas analysis.

Indications

Direct BP measurement using an arterial line is indicated for patients who require constant BP measurement. Direct BP measurement is also more accurate than indirect measurements (cuff pressures) in patients with low-flow states or high SVR conditions (ie, any patient in shock). The current indication for an arterial line is any patient in shock who is not rapidly responsive to therapy, including not only patients who are hypotensive, but also patients who are hypertensive and require powerful vasodilator therapy to reduce their vascular resistance. Arterial lines are also used routinely in patients receiving vasoactive or antihypertensive infusions.

Contraindications

There are several contraindications to arterial lines, including the following:

- Ischemia of the extremity
- Infection at the puncture site
- Raynaud disease
- Prior vascular surgery in the area of the insertion site

Complications

Complications from arterial line insertion include the following:

- Arterial line thrombosis
- Embolization
- Hematoma
- Insertion site infection
- Median nerve neuropathy (radial artery insertion)
- Pseudoaneurysm of the artery
- Ischemic necrosis
- Digit, hand, leg, or foot ischemia
- Hemorrhage
- Arterial air embolism
- Arteriovenous fistula
- Arterial aneurysm

Arterial Line Placement

Although some CCTPs may be trained and credentialed to insert central venous catheters, they generally do not place arterial lines. They may, however, need to assist in the procedure. For the reader's background knowledge, this section explains how they are placed.

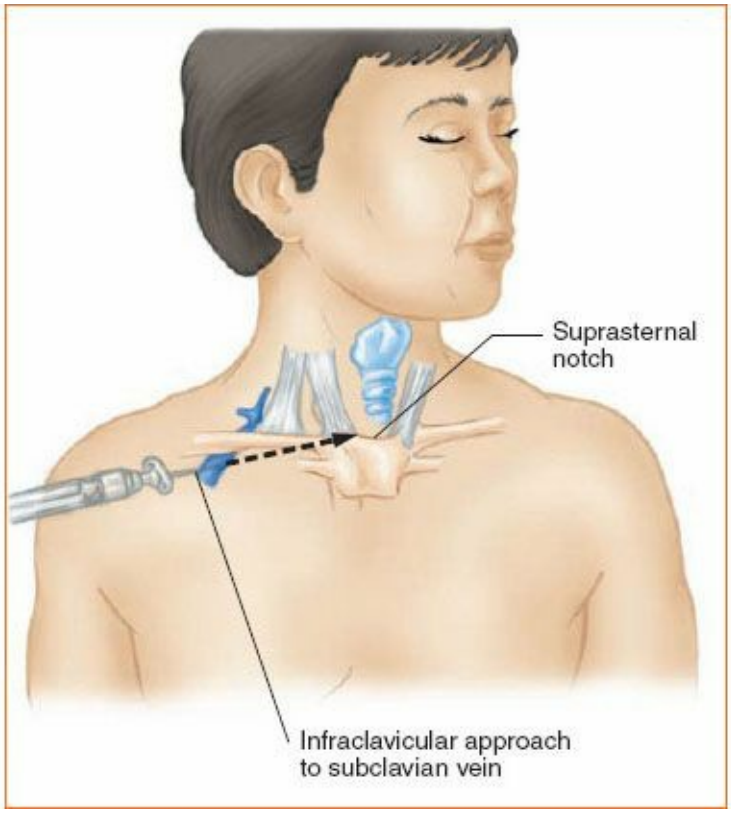

Figure 14-12 Subclavian vein insertion.

Equipment

The following equipment is needed to insert an arterial line:

- 20-gauge radial over-the-needle catheterization kit with guide wire
- 18- to 20-gauge 6″ femoral artery catheterization kit with guide wire
- Tape
- Sterile 2″ × 2″ gauze sponges; 4″ × 4″ gauze sponges
- Local anesthetics
- Sedation medications
- Sterile gloves, gown, mask, and drapes
- Chlorhexidine–isopropyl alcohol solution Pressure transducer Tubing
- Pressure monitor
- Suture material or commercial suture kit

Steps

Skill Drill 14-2 outlines the steps for inserting an arterial line using the modified Seldinger technique:

1. Use universal precautions.
2. Using a sterile technique, prepare all equipment.
3. Position the patient by placing rolled gauze under the wrist area, hyperextending the wrist **Step 1**.

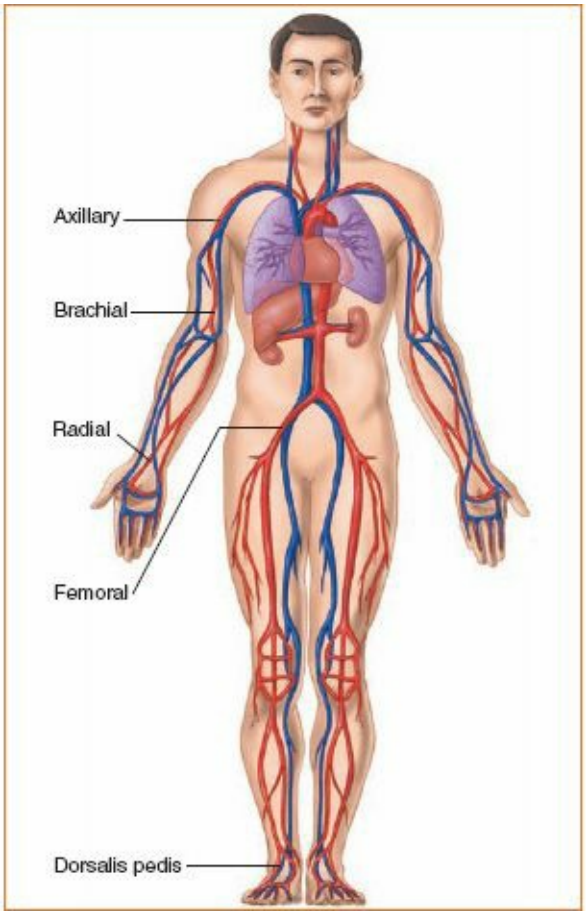

Figure 14-13 The radial artery is the preferred site for an arterial line. Other possible sites are the brachial, femoral, axillary, and dorsalis pedis arteries.

4. Select and clean the insertion site; ensure IV access. Use sterile drapes if available to reduce infection risk **Step 2**.
5. Palpate the artery at the distal radius **Step 3**.
6. Anesthetize the area **Step 4**.
7. Insert the needle over the radial artery approximately 1 cm distal to the wrist joint **Step 5**.
8. Advance the needle at an approximately 20° to 45° angle. Entry into the artery will be indicated by pulsating arterial blood.
9. Immobilize the needle with your free hand.
10. Advance the guide wire, and then remove the needle, leaving only the guide wire in the artery **Step 6**.

Skill Drill 14-2

Inserting an Arterial Line

1 Place rolled gauze under the wrist area, hyperextending the wrist.

2 Select and clean the insertion site; ensure IV access. Use sterile drapes if available to reduce infection risk.

3 Palpate the artery at the distal radius.

4 Anesthetize the area.

5 Insert the needle over the radial artery approximately 1 cm distal to the wrist joint. Advance the needle at an approximately 20° to 45° angle, watching for entry into the artery, indicated by pulsating arterial blood.

6 Immobilize the needle with your free hand. Advance the guide wire, and then remove the needle, leaving only the guide wire in the artery.

7 Place the arterial catheter over the guide wire.

8 Remove the guide wire, leaving only the cannula in place.

9 Connect the tubing to the pressure transducer. Secure the catheter to the skin with sutures and apply a sterile dressing to the insertion site.

11. Place the arterial catheter over the guide wire **Step 7**.
12. Remove the guide wire, leaving only the cannula in place **Step 8**.
13. Connect the tubing to the pressure transducer **Step 9**.
14. Secure the catheter to the skin with sutures and apply a sterile dressing to the insertion site.

The steps for femoral artery cannulation are also listed here for reference:

1. Prepare the equipment.
2. Use a complete aseptic technique.
3. Ensure IV access.
4. Palpate the femoral artery below the inguinal ligament.
5. Anesthetize the area.
6. Enter the skin over the femoral artery approximately 1 to 2 cm below the inguinal ligament **Figure 14-14**.
7. Advance the needle at an approximately 45° angle. Entry into the artery will be indicated by pulsating arterial blood.
8. Immobilize the needle with your free hand.
9. Advance the guide wire through the needle. Remove the needle, leaving the guide wire in place.
10. Pass the arterial catheter over the guide wire; remove the guide wire.
11. Connect the tubing to the pressure transducer.

12. Secure the catheter with sutures and apply a sterile dressing.

Pulmonary Artery Catheters

Like a central line, a **pulmonary artery catheter (PAC)** is inserted into the venous system of a patient. The PAC is a flow-directed catheter with a balloon at the tip that allows blood flow to carry the catheter through the heart into the pulmonary artery, where it terminates. The PAC is also known as a Swan-Ganz catheter (or simply a "swan") after Harold Jeremy Swan and William Ganz, who introduced this catheter in 1970.

The Pulmonary Artery Catheter Education Project (http://www.pacep.org) is an online, state-of-the-art educational program on how to use the PAC in the clinical environment. Supported by multiple critical care organizations and associations, the Pulmonary Artery Catheter Education Project Web site is an excellent resource for CCTPs to develop and enhance their knowledge base.

A PAC uses the same access routes as a central line. The PAC is fed into the vena cava and then through the right atrium **Figure 14-15**. Once past the lumen of the introducer sheath, the catheter tip balloon is inflated with 1.5 mL of air to help facilitate further placement. With the balloon inflated, the catheter is "floated" through the right atrium into the right ventricle and ultimately "wedges" into a proximal branch of the pulmonary artery. Once in place, the balloon is deflated to allow blood flow around the catheter.

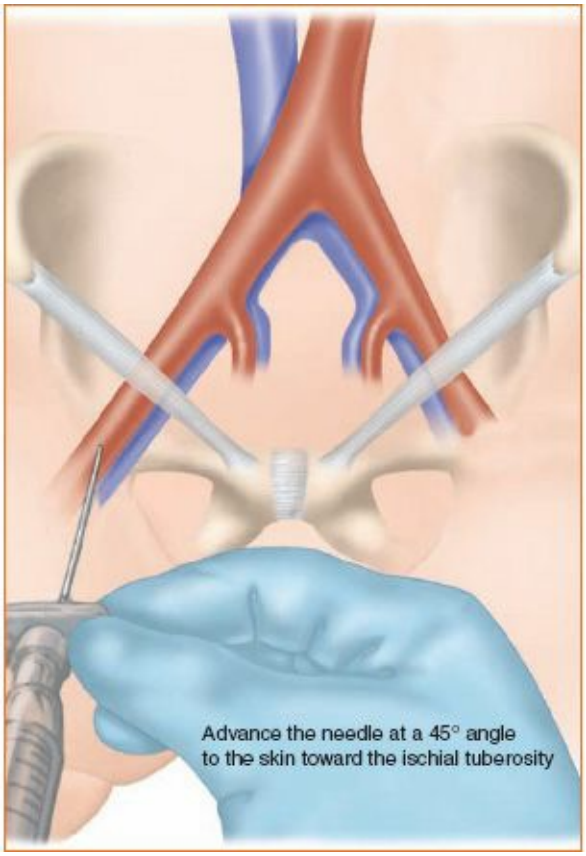

Figure 14-14 Femoral artery cannulation toward ischial tuberosity. Adapted from: Henretig FM, King CC, eds. *Textbook of Pediatric Emergency Procedures*. Baltimore, MD: Williams and Wilkins; 1997.

A PAC is 110 cm long and contains multiple lumens that terminate at various points along the length of the catheter, corresponding to different locations in the heart. The PACs are marked at 10-cm intervals beginning at the distal tip of the catheter, with one thin black line representing 10 cm, two thin black lines representing 20 cm, and three thin black lines representing 30 cm, up to one thick black line representing 50 cm, one thick black line accompanied by a thin black line representing 60 cm, one thick black line and

two thin lines representing 70 cm, and so on. During initial assessment, CCTPs should note the centimeter measurement of the PAC at the introducer. This information will help to determine if the catheter moves into or out of the patient during transport.

Two of the lumens are connected to pressure transducers that continuously display measurements. The first pressure reading is the RA pressure, and the second pressure reading is the pulmonary artery pressure. The RA pressures are displayed as mean pressures, whereas pulmonary artery pressures are displayed as systolic, diastolic, and mean values. Once the PAC is properly placed in the pulmonary artery, inflation of the PAC balloon results in blockage of blood flow from the right ventricle behind the balloon tip and the appearance of a pulmonary capillary wedge pressure (PCWP) waveform on the monitor. The PCWP waveform, like the RA pressure, is measured as a mean value.

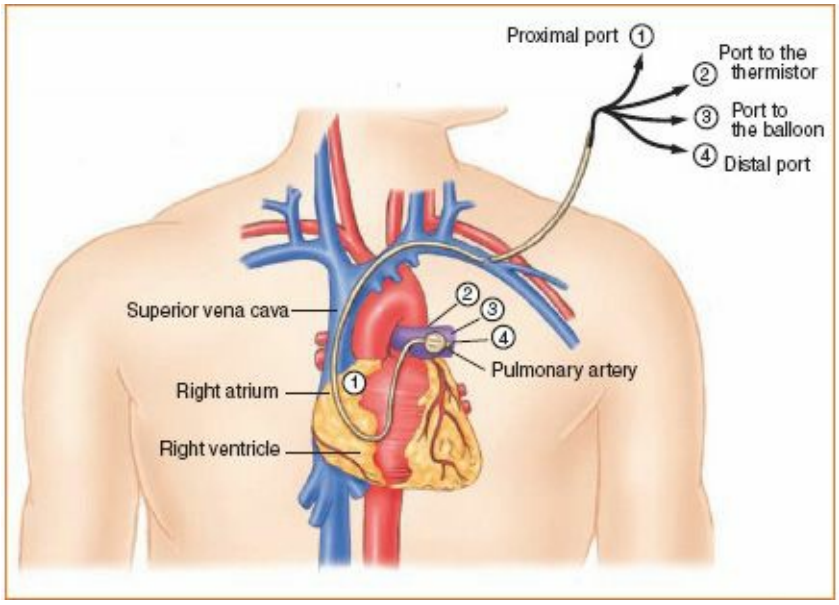

Figure 14-15 Pulmonary artery catheter placement. Once in place, the tip is deflated to allow blood flow around the catheter.

Complications of PAC insertion are nearly the same as complications of central line insertion, with the addition of pulmonary artery perforation or rupture, pulmonary infarction, arrhythmias, tricuspid and pulmonic valve injury, tamponade, or knotting of the catheter. The greatest potential complication of PAC use is probably misinterpretation of the data by clinicians, resulting in inappropriate therapy and potentially worsening outcomes.

A **thermistor** used for thermodilution CO measurement is connected to the distal end of the PAC. This thermistor provides continuous reading of pulmonary artery temperature, considered the gold standard for core body temperature measurement. Some PACs also have a fiberoptic oximetric catheter at the distal tip for continuous monitoring of mixed venous oxygen saturation **Figure 14-16**. Although variations exist, manufacturers have standardized coloring of PAC lumens. All PACs have a blue RA (proximal) port, a yellow pulmonary artery (distal) port, a red balloon inflation port, and a yellow temperature thermistor port. Some PACs have additional RA and/or right ventricular ports that can be used for infusions or pressure monitoring. There are also specially designed PACs with integrated pacing wires that can be used for transvenous cardiac pacing and PACs with an integrated thermal filament that allows for continuous CO measurement using pulsed electrical signals.

Indications

Commonly accepted indications for pulmonary artery catherization have little or no evidence basis and are largely generated by clinician experience. Broadly speaking, a PAC is thought to be warranted when

clinicians have a specific question about a patient's hemodynamic status that has not or cannot be answered readily by noninvasive assessment. Despite common use in cardiac, vascular, and other high-risk surgery and frequent insertion for management of end-stage heart failure, there have yet to be any outcome studies demonstrating improved outcomes with PAC use in critically ill patients. Conversely, there are also no clear data that there should be a moratorium on use of PACs. Instead, clinicians are advised to carefully consider the risks and benefits in critically ill patients on a case-by-case basis.

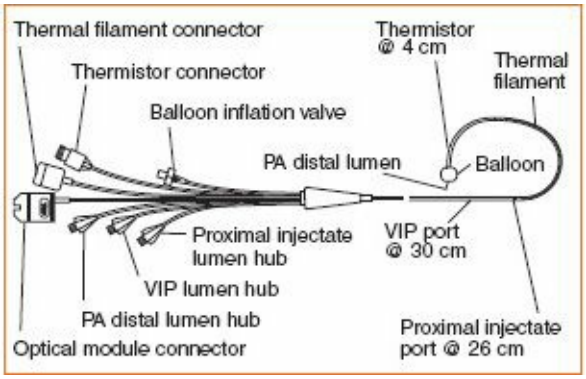

Figure 14-16 A pulmonary artery catheter with a thermistor. Courtesy of Edwards Lifesciences. Used with permission.

Some situations in which the use of a PAC might be considered include the following:

- Differentiation among causes of shock
- Determining mechanisms responsible for pulmonary edema
- Diagnosis or detection of pericardial tamponade
- Evaluation or diagnosis of intracardiac shunt(s)
- Evaluation of pulmonary hypertension
- Perioperative and postoperative management of patients with unstable cardiac status
- Management of complex myocardial infarction
- Management of patients undergoing cardiac and major vascular surgery
- Guidance for titration of inotropic, vasopressor, or vasodilator therapy
- Management of severe preeclampsia
- Fluid volume status management
- Assessment of cardiac performance

Contraindications

Like central venous catheterization, there are few absolute contraindications for pulmonary artery catheterization, although the risks of PAC use are greater than those associated with the use of central venous catheters alone. Relative contraindications to the use of PACs include the following:

- Significant coagulopathy
- Local trauma to the site of insertion
- Infection at the site of insertion
- Inability to float the PAC into the pulmonary artery

Equipment

The following equipment is needed to insert a PAC:

- The PAC
- A PAC introducer kit (must be 0.5F to 1F larger than the PAC)
- Sterile gowns and drapes for complete draping of patient and bedside area
- ECG and pulse oximetry monitoring
- Transducer set up
- Patient monitor and cables to connect to transducers
- Thermodilution CO set **Figure 14-17**
- Appropriate antiseptic solution (usually chlorhexidine)
- 2% Lidocaine and atropine (to treat arrhythmias during the procedure)

Steps

The steps for inserting a PAC are as follows. This skill would not be performed by CCTPs, but the steps are useful to understand as background knowledge:

1. Assemble and connect the transducers to the monitor.
2. Zero the transducers (described later in the section on "Leveling and Zeroing the Pressure Transducer").
3. Assemble the equipment.
4. Position the patient in reverse Trendelenburg (head-down) position, arms by his or her side, with his or her head turned in the opposite direction of the intended cannulation site.
5. Ensure that cardiac and pulse oximetry monitoring devices are in place and functioning.
6. Establish a sterile field. Open the introducer supplies.
7. Prepare the insertion site.
8. Administer a local anesthetic agent.
9. Prepare the introducer equipment while awaiting anesthetic effects.
10. Cannulate the vein at the selected insertion site using a needle that is 18 gauge or larger and attached to an empty 10-mL syringe.

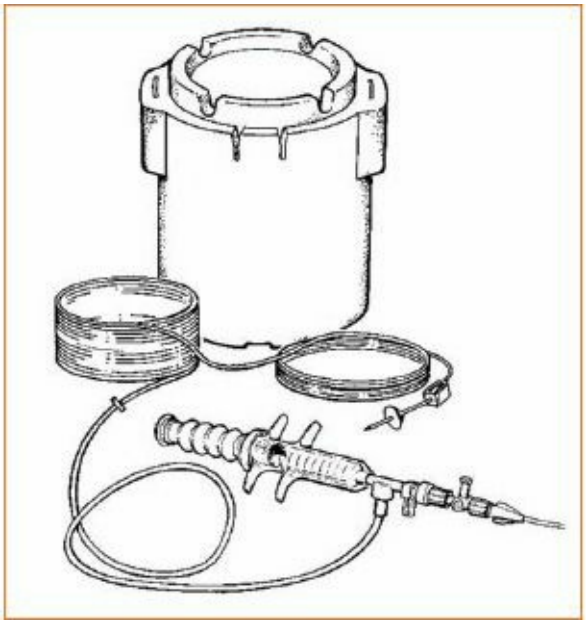

Figure 14-17 A thermodilution cardiac output set. Courtesy of Edwards Lifesciences. Used with permission.

11. Once the vein has been entered and the IV position of the needle has been confirmed, pass a Seldinger wire (included in introducer insertion supplies) through the needle.
12. Remove the needle.
13. Widen the skin opening using a scalpel.
14. Using a dilator, pass the PAC introducer over the wire into the vein. Remove and discard the wire.
15. Aspirate and flush the side port of the introducer with sterile saline.
16. Secure the introducer to the skin with suture(s).
17. Prepare the PAC by flushing the ports. Connect to the transducer(s) and slide the sterile sleeve over the catheter.
18. Test the PAC balloon and distal port to ensure that the waveform appears on the monitor.
19. Advance the PAC through the introducer.
20. Inflate the balloon once the PAC is past the distal end of the introducer (usually 15 cm).
21. Advance the PAC to the wedge position by observing waveforms on the monitor through the right atrium, right ventricle, and pulmonary artery.
22. If arrhythmias occur while the PAC is in the right ventricle, quickly advance the PAC into the pulmonary artery.
23. Once the pulmonary artery wedge tracing is observed, deflate the balloon to check for return of the pulmonary artery pressure waveform.
24. With the balloon deflated, pull back the catheter 1 to 2 cm and recheck wedge function.
25. Wedging the catheter should require 1 to 1.5 mL of air. If the catheter wedges with less than 1 mL of air, it has been inserted too far and will need to be pulled back slightly.
26. Secure the sterile sheath to the introducer and attach the PAC to the patient to prevent accidental dislodgement.
27. Obtain an anterior-posterior chest radiograph to check for pneumothorax and proper catheter position.

Invasive Pressure Measurements

A later section in this chapter will discuss how to take invasive hemodynamic measurements. Before moving on to the practical aspects of taking measurements, we will discuss the various measurements and their clinical significance.

By placing invasive catheters into the vasculature, hemodynamic parameters are continually monitored, and more advanced pressures can be assessed. Pressure for hemodynamic monitoring is measured in millimeters of mercury or, outside of the United States, in torr and kilopascals.

Common hemodynamic parameters are given in the following list. The line from which the measurement is obtained is shown in parentheses after each item, and the values that are calculated by a provider rather than obtained from the device are also noted.

- Central venous pressure (central line or PAC)
- Systemic blood pressure (arterial line)
- DBP (arterial line)
- MAP (arterial line, calculated or computed)
- Pulse pressure (arterial line, calculated)

- Pulmonary artery pressure (systolic, diastolic, and mean) (PAC)
- PCWP (PAC)
- CO (PAC)
- Pulmonary vascular resistance (PAC, calculated)
- SVR (PAC, calculated)
- Stroke volume (PAC, calculated)
- Mixed venous oxygen saturation (PAC)
- Total body surface area
- Cardiac index (PAC, calculated)

Normal ranges and values for invasive and noninvasive measurements are given in **Table 14-2**.

Cardiovascular Physiology

Cardiac Output

Critical care generally focuses on improving perfusion (the ability to deliver oxygen and nutrients to tissues). Hemodynamic monitoring assesses the effects of perfusion, and PACs look specifically at CO and its constituents: preload, afterload, and contractility of the heart. The CO is the product of stroke volume (SV) and heart rate (CO = SV × Heart Rate). The SV, or the amount of blood ejected with each ventricular contraction, is determined by preload, afterload, and contractility of the heart. Because SV results from three combined influences, heart rate has a far greater contribution and more immediate effect on CO than any one component of SV. When confronted with a low CO, a CCTP should investigate heart rate before evaluating constituents of SV.

TABLE 14-2 Normal Ranges and Values for Hemodynamic Measurements

Assessment Parameter	Normal Range/Value
CVP, mm Hg	2 to 6
SBP, mm Hg	100 to 120
DBP, mm Hg	60 to 80
MAP, mm Hg	70 to 105
Pulse pressure, mm Hg	40 to 60
Heart rate, mm Hg	60 to 100
Pulmonary artery pressure, systemic	15 to 30
Pulmonary artery pressure, diastolic	8 to 15
PCWP	4 to 12
CO, L/min	4 to 8
Pulmonary vascular resistance, dyne-sec/cm^{-5}	100 to 250
SVR, dyne-sec/cm^{-5}	800 to 1,200
SV, mL/beat	60 to 100

Sv_{O_2}, %	60 to 80
Scv_{O_2}, %	≥ 70
Cardiac index, L/min/m^2	2.5 to 4.2
Stroke volume index, mL/beat/m^2	30 to 50

Abbreviations: CO, cardiac output; CVP, central venous pressure; DBP, diastolic blood pressure; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; SBP, systolic blood pressure; Scv_{O_2}, mixed central venous oxygen saturation; SV, stroke volume; Sv_{O_2}, mixed venous oxygen saturation; SVR, systemic vascular resistance.

To account for differences in body size, some hemodynamic values are indexed. Indexing divides a hemodynamic parameter by the patient's total body surface area (BSA), which is stated in terms of meters squared. The BSA can be derived from a paper-and-pencil BSA chart but is most commonly calculated by hemodynamic monitoring software using the patient height and weight values entered by the clinician. For example, a **cardiac index** (average 2.5 to 4.2 L/min/m^2) is the patient's CO divided by his or her total BSA:

$$\text{Cardiac Index} = \frac{\text{CO}}{\text{BSA}}$$

A CO of 4.5 L/min may be perfectly adequate for a 17-year-old girl involved in a multivehicle crash, but not for a 325-lb professional athlete who crashed his motorcycle. The indexing of various hemodynamic parameters is often applied to ventricular work values, SVs, and calculations of oxygen consumption.

Preload

Preload is the degree of myocardial fiber stretch induced by volume in the ventricle at the end of diastole. Preload is synonymous with end-diastolic volume and end-diastolic pressure. Preload is determined by total blood volume, blood volume distribution, and atrial kick. States of hypovolemia result in decreased preload and may result from hemorrhage, diaphoresis, protracted vomiting or diarrhea, dehydration, burns, and gastric suction, among other causes. Hypervolemia, which typically results from fluid overload as a result of overzealous or runaway IV fluid administration or renal failure, is reflected in increased preload. Third-space losses create a relative hypovolemia reflected in decreased preload.

The distribution of blood volume also influences preload. Venodilation, as might result from drugs, fever, exercise, or distributive shock states such as neurogenic shock or sepsis, reflects decreased preload. Vasoconstrictive states induced by pressors, hypothermia, or cardiogenic shock states reflect increased preload. Intrathoracic pressure changes that decrease venous return, such as mechanical ventilation, positive end-expiratory pressure (PEEP), or pneumothorax, cause decreased preload. Intrapericardial pressure changes resulting from tamponade, pericarditis, or effusions affect the ability of the heart to fill and, hence, decrease preload.

Atrial kick, or atrial-ventricular synchrony, reported variously to be responsible for 10% to 20% of CO, is a preload-enhancing cardiac function. The small injection of blood from the atria into the ventricles just before ventricular systole boosts CO. Loss of atrial-ventricular synchrony decreases preload.

Preload is measured in several ways. Right ventricular preload is measured by CVP, which is closely synonymous with RA pressure. Left ventricular preload is measured by PCWP or, in some patients, by pulmonary artery diastolic pressure. During cardiac surgery, a left atrial pressure monitoring

catheter is sometimes placed to continually monitor left ventricular preload.

Afterload

Afterload is the resistance the ventricles must overcome to eject blood. Three factors typically determine afterload: outflow obstructions, vascular tone, and blood viscosity. Outflow obstructions, such as aortic valvular stenosis, hypertension, and atherosclerosis, produce greater resistance and, hence, increase afterload. Aortic aneurysms, in which blood flows through a false lumen rather than the inner lumen of the aorta, represent decreased afterload. As discussed with preload, vasoconstriction and vasodilation also affect afterload: vasodilation reduces afterload, and vasoconstriction increases afterload. Blood viscosity directly affects afterload. Increased afterload results from polycythemia because very viscous blood does not flow as readily as less viscous or very thin blood. This concept is important and explains why lowered hemoglobin levels are often tolerated and, in fact, sometimes considered beneficial in critically ill patients. Presuming that there is adequate hemoglobin to carry oxygen, values below those considered normal may well improve CO by decreasing afterload.

Left ventricular afterload is measured by SVR, and right ventricular afterload is measured by PVR. In clinical practice, left ventricular afterload is more often evaluated when addressing issues with CO because manipulations of SVR affect systemic circulation. Two instances when clinicians are interested in right ventricular afterload are when assessing a correlation between pulmonary artery diastolic pressure and PCWP, and when evaluating a patient for heart transplantation to determine if significant PVR is reversible. Patients with end-stage heart failure with elevated PVR that is not reversible will require heart and lung transplantation because a transplanted heart would fail when faced with significant right-sided resistance.

Contractility

Contractility is the inotropic state of the heart or the force with which the heart muscle contracts. Contractility is not directly measurable using conventional hemodynamic monitoring technology but can be assessed with the newer Doppler and ultrasound devices increasingly being used for evaluation of critically ill patients. Six factors influence contractility: myocardial muscle health, autonomic nervous system, metabolic states, ion environment, pharmacologic agents, and heart rate.

Myocardial muscle injury or ischemia can decrease contractility temporarily or permanently, although conditioning seems able to improve contractility following injury. The parasympathetic and sympathetic arms of the autonomic nervous system responsible for increasing and decreasing heart rate simultaneously affect contractility. Metabolic states such as acidosis, hypoxemia, and sepsis decrease contractility. Three ions have significant influence on contractility: calcium, sodium, and potassium. Hypocalcemia, hyponatremia, and hyperkalemia all decrease contractility, although opposite changes in these ion levels do not seem to boost contractility above normal.

Multiple pharmacologic agents influence myocardial contractility. Agents that increase contractility are referred to as positive inotropic agents and include digoxin, dopamine, dobutamine, milrinone, calcium, epinephrine, and glucagon. Negative inotropic agents, or those that decrease contractility, include beta-blockers, quinidine, procainamide, and calcium-channel blockers. Finally, heart rate can influence contractility by its effect on diastolic filling time and coronary artery perfusion. Slower heart rates have a greater diastolic time than faster heart rates, allowing more time for coronary artery filling compared with very rapid heart rates. Less diastolic time seen with rapid heart rates potentially diminishes coronary artery perfusion and may lower myocardial perfusion below that needed for adequate contractility.

Contractility is inferred from the values for **stroke volume index, left ventricular stroke work index**, and **right ventricular stroke work index**.

Measurements From a Central Venous Line

Central Venous Pressure

Central venous pressure (CVP) is a measure of the vena caval and RA pressures. It measures the RA filling pressures and is, therefore, indicative of the patient's fluid volume status and right-sided heart performance. The CVP can be measured by using a central line or the proximal port of a PAC. Changes in the CVP generally correlate with changes in left ventricular filling pressure in healthy people. This correlation may not exist in patients with hypovolemic shock or significant pulmonary disease.

Even though a CVP waveform tracing has systolic and diastolic values, only the mean value is used in clinical practice because the numbers are extremely low **Figure 14-18**.

The normal range for the CVP is 2 to 6 mm Hg. As fluid is administered to a patient, a rise in the CVP is expected. Elevated CVP readings can result from positive pressure ventilation, increased PVR, hypervolemia, right-sided heart failure, cardiac tamponade, tricuspid insufficiency, significant vasoconstriction, pulmonary embolus, or obstructive pulmonary disease; they can also be a late sign of left ventricular failure. Lower CVP values can indicate hypovolemia or significant vasodilation. Typically, a value between 5 and 8 mm Hg is considered the cutoff between low and normal preload. Fluids are often administered to patients with CVP values below this range to increase their preload.

Measurements From an Arterial Line

Arterial Blood Pressure

Direct blood pressure measurement using an arterial line provides continuous assessment of arterial (or systemic) pressure. Because hemodynamic status can change by the minute, continual blood pressure monitoring can help CCTPs more closely observe patients during transport. An arterial line connected to the transport monitor provides constantly updated SBP, DBP, and MAP values and an arterial waveform **Figure 14-19**. Components of the arterial waveform include the **dicrotic notch**, mean pressure, systole, diastole, systolic pulse pressure, and diastolic pulse pressure. The dicrotic notch represents the brief increase in aortic pressure reflected in a notching of the wave. It is caused by the sudden closure and spring back of the aortic valve leaflets and signals the start of diastole.

Blood pressure readings from an invasive arterial catheter, when properly obtained, have less potential for inaccuracies in measurement that are often associated with BP cuff measurements, such as operator error, inappropriate size or placement, and effects of low flow or high SVR (shock) states.

Mean Arterial Pressure

An important calculation, sometimes done by CCTPs and sometimes by the machine, is **mean arterial pressure (MAP)**, a function of the SBP and DBP. The MAP represents the average (ie, constant) pressure the arterial vasculature feels from the pulsatile nature of the heartbeat. The MAP is calculated by the transport monitor software measuring the mean area under the arterial pulse pressure waveform. A reverse of this calculation is used by electronic blood pressure (NIBP) software to derive the SBP and DBP for display. If precisely one third of the cardiac cycle was spent in systole and two thirds was spent in diastole, the MAP could be calculated by using the following formula:

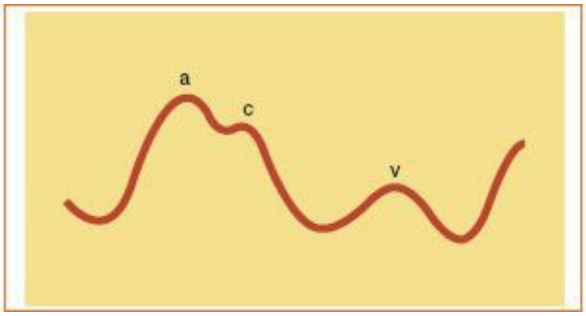

Figure 14-18 A central venous pressure waveform.

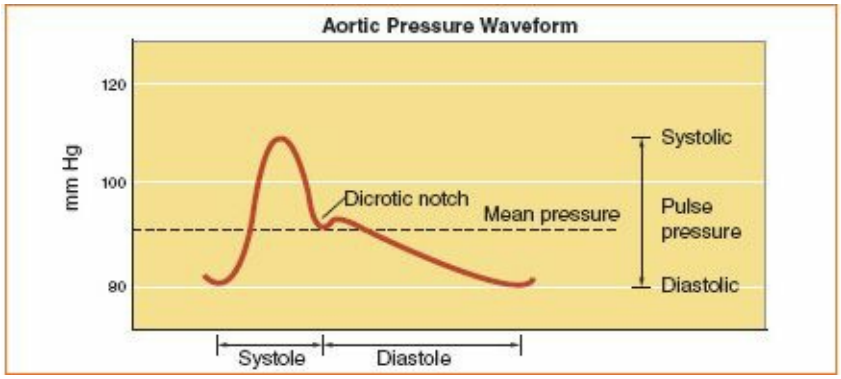

Figure 14-19 A blood pressure waveform from an arterial line.

$$MAP = DBP + \frac{1}{3}(SBP - DBP)$$

Because a heart rate of 70 beats/min is typically required, the formula is relatively useless in practice. The MAP measured by a transport monitor connected to an arterial line or by an NIPB is, however, the most precise of the pressure measurements available to CCTPs. Placement of an arterial line significantly affects the SBP. The further out from the heart that an arterial line is placed, the more pressure will be needed to flow blood and, therefore, the higher the SBP will be. The MAP, however, is unaffected by location of line placement and is the best parameter to use when making treatment decisions. Usually, a person needs an MAP between 70 and 105 mm Hg to satisfactorily perfuse the tissues. The most sensitive organs to hypotension are the kidneys, which typically require an MAP of 60 mm Hg or above and are likely to sustain irreversible injury when faced with an MAP below 60 mm Hg for more than 20 minutes. For that reason, most medical orders for blood pressure parameters require titration of drugs or administration of fluids to maintain an MAP of 70 mm Hg or greater.

Pulse Pressure

Pulse pressure is another value calculated by using the SBP and DBP. It is the mathematical difference between the SBP and DBP. Normal values of 40 to 60 mm Hg are seen in healthy people but may be altered in critically ill patients. The SV and vascular compliance affect the pulse pressure. An elevated pulse pressure can be indicative of high SV states (such as hypovolemia) or low vascular compliance (such as arteriosclerosis). In these states, there is a rise in SBP. If there is not a concomitant rise in DBP, elevated pulse pressure develops. Bradycardia can also cause an elevated pulse pressure. In this instance, lower DBP develops because of an extended diastole, which can lead to diastolic runoff. Low SV states (such as hypovolemia) and high vascular compliance (such as shock) will cause a decrease in SBP and, therefore, a decrease in pulse pressure (barring a proportional decrease in DBP). Tachycardia may cause a decreased pulse pressure by the reverse of the bradycardia mechanism.

Measurements From a Pulmonary Artery Catheter

Right Ventricular Pressure

Although not routinely monitored or measured, the **right ventricular pressure** is important during insertion and use of a PAC. The right ventricular pressure has three components **Figure 14-20**:

1. Systolic pressure, usually 20 to 30 mm Hg
2. Diastolic pressure, usually 0 to 5 mm Hg

3. Mean pressure, usually 10 to 20 mm Hg

Ventricular ectopy is common when the PAC is in the right ventricle; hence, it is important for CCTPs to be able to recognize a right ventricular waveform and its characteristic low diastolic pressure, which distinguishes it from a pulmonary artery pressure waveform.

Pulmonary Artery Pressure

Like the arterial BP waveform, the **pulmonary artery pressure** has three components **Figure 14-21**:

1. Systolic pressure, usually 15 to 30 mm Hg
2. Diastolic pressure, usually 8 to 15 mm Hg
3. Mean pulmonary artery pressure, usually 10 to 20 mm Hg

The respective pulmonary artery pulse pressure can also be calculated.

Pulmonary artery pressures are a function of right ventricular health and the vascular resistance of the pulmonary circuit. Although patients with significant heart failure or pulmonary obstructive disease can have chronically elevated pulmonary artery pressures or pulmonary hypertension, acute elevations in pulmonary artery pressures are unlikely to result from causes other than hypoxemia or hypercarbia. An astute CCTP who observes a sudden elevation in pulmonary artery pressures will immediately assess and correct any issues with oxygen saturation or ventilation (as reflected by end-tidal carbon dioxide readings).

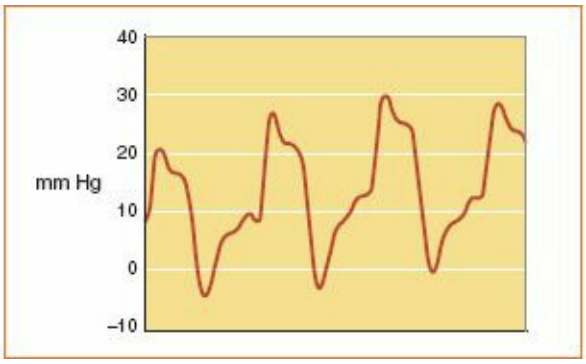

Figure 14-20 A right ventricular pressure waveform has a systolic pressure comparable to the pulmonary artery systolic pressure.

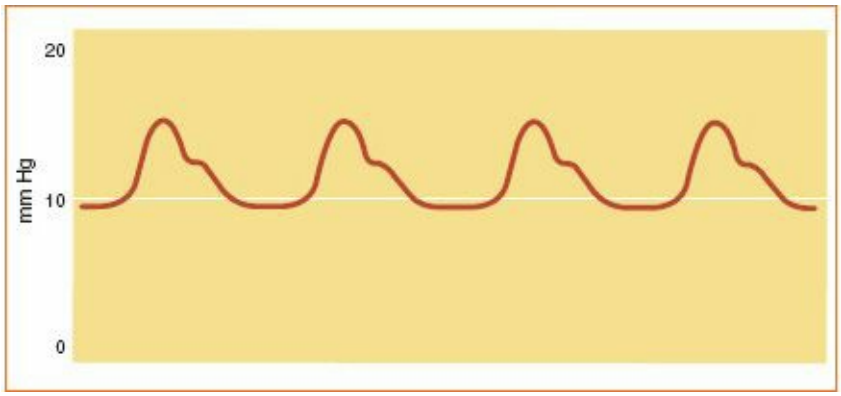

Figure 14-21 A pulmonary artery pressure waveform, which is similar to the arterial pressure waveform (ie, systolic, dicrotic notch, and diastolic components).

Elevations in the pulmonary artery pressure can result from conditions that increase pulmonary blood flow, such as atrial and ventricular septal defects or hypervolemia. Elevations in the pulmonary artery

diastolic pressure can result from tachycardia (usually >120 beats/min in adults) or pulmonary emboli. Decreased pulmonary artery diastolic pressure is seen with hypovolemia.

If pulmonary artery diastolic pressures suddenly drop, the catheter position should be reevaluated to determine if the PAC has migrated into the right ventricle (see Right Ventricular Pressure earlier in the chapter).

Pulmonary Capillary Wedge Pressure

The **pulmonary capillary wedge pressure (PCWP)** reflects preload to the left ventricle and is considered the gold standard for preload assessment. This measurement is also called pulmonary artery occlusion pressure and pulmonary artery wedge pressure. Also a function of a PAC, PCWP is an intermittent assessment performed by inflating a small balloon on the distal tip of the PAC, which causes the PAC to shift forward to "wedge" against the opening of the proximal branch of the pulmonary artery. This occludes the pulmonary artery from any antegrade blood flow. With the tip inflated, the transducer reads a pressure that is equivalent to the left atrial pressure. The left atrial pressure is closely related to and often parallels the **left ventricular end-diastolic pressure**, which is indicative of left ventricular health. The normal range for the PCWP is 4 to 12 mm Hg. A properly obtained PCWP will normally be slightly less than the pulmonary artery diastolic pressure (≤4 mm Hg). A PCWP of 10 to 12 mm Hg is normally used to differentiate hypovolemia from euvolemia in clinical practice. Patients with PCWP values below this level are often given fluids to optimize their preload.

The CCTP needs to understand how to read the PCWP waveform **Figure 14-22**. Hemodynamic waveforms often show variations in baseline as a result of respiratory-induced intrathoracic pressure fluctuations. Atmospheric and pleural pressures are most closely approximated at end expiration. To eliminate the effects of intrathoracic pressure on PCWP values, they are measured at end expiration.

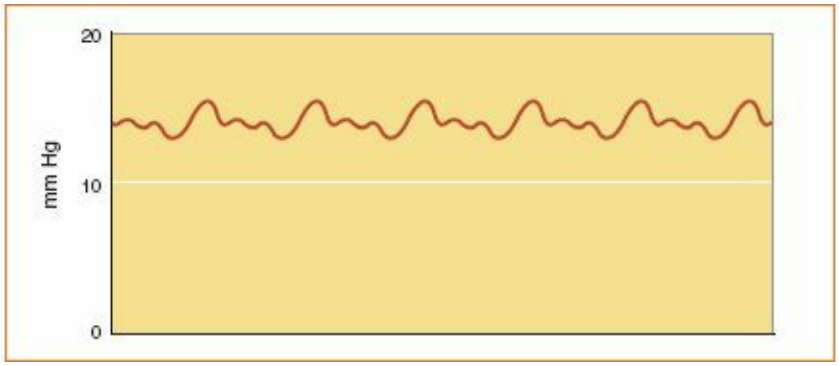

Figure 14-22 The waveform of a normal pulmonary capillary wedge pressure.

Depending on whether the patient is mechanically ventilated or spontaneously breathing, end expiration will be observed in different locations on the PCWP baseline. In mechanically ventilated patients, positive pressure inspiration elevates intrathoracic pressure and results in a positive fluctuation in the PCWP tracing baseline. Expiration is passive; end expiration is found at the lowest point in the waveform baseline. In spontaneously breathing patients, inspiration is induced by negative pressure. Expiration produces an increase in the waveform baseline; end expiration can be found at the highest point.

When measuring PCWP, a helpful tool to recall where to locate end expiration on the waveform baseline is "patient—peak; ventilator—valley." End expiration in spontaneously breathing patients is found at the peak of the waveform baseline. In mechanically ventilated patients, end expiration is found in the valley of the waveform baseline.

Once the proper position on the waveform is located, measurement of the PCWP waveform is done by locating two sequential positive deflections on the waveform immediately before the point where the

baseline changes. In spontaneously breathing patients, this would be immediately before the baseline begins to fall; in mechanically ventilated patients, this would be immediately before the baseline starts to rise.

The two sequential deflections are averaged to determine the mean pressure, as shown in **Figure 14-23**.

The PAC balloon typically holds up to 2 mL of air. Syringes included with the PAC normally allow the operator to inject only 1.5 mL of air to inflate the balloon. Regardless of the balloon's ability to hold up to 2 mL of air, it is recommended to only inflate the balloon with 1.5 mL, as overinflation may result in rupture of the pulmonary artery or damage to the balloon. This injection should be done slowly, over 2 to 3 seconds. Once a PCWP waveform is observed, the tracing can be "frozen" on the monitor screen, and the balloon should be allowed to passively deflate. Maximum inflation times should not exceed 10 to 15 seconds. If less than 1 mL of air is needed to produce a PCWP tracing, the PAC is likely inserted too far into the patient and is at risk for spontaneously wedging. Prolonged inflation or spontaneous wedging can result in pulmonary infarction. Manual flushing of a wedged catheter may cause pulmonary artery perforation.

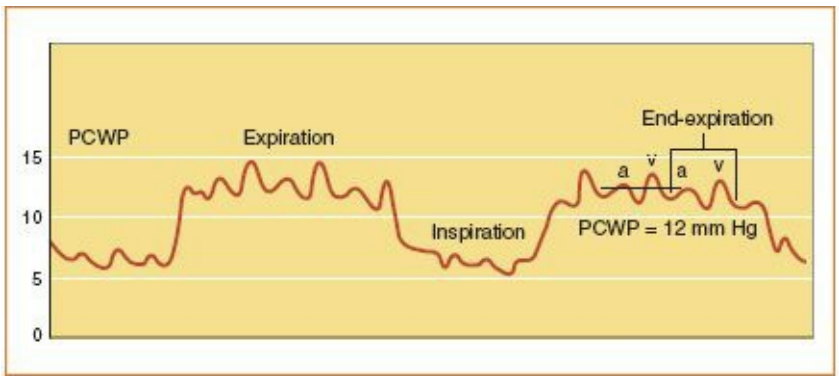

Figure 14-23 Respiratory variation in the pulmonary capillary wedge pressure waveform.

Causes of elevated PCWP are numerous and difficult to resolve definitively. Often, elevated PCWP results from the left ventricle not being able to clear the antegrade blood flow. If the left ventricle cannot clear increased flow from the right side of the heart (as in hypervolemia), an elevated PCWP will result. Left-sided heart dysfunction (as in left ventricular failure and mitral valve disease) will cause retrograde blood accumulation within the pulmonary vasculature and thereby show an increased PCWP. A PCWP level greater than 18 mm Hg often identifies a potential for pulmonary edema, especially with a normal colloidal osmotic pressure (ie, normal serum albumin level). High levels of PEEP used with mechanical ventilation can also cause an elevated PCWP. When PEEP levels above 10 cm H_2O are used, correction of measured PCWP may be requested. This is done by subtracting 1.5 mm Hg from the measured PCWP for every 5 cm H_2O of PEEP. For example, if the PEEP is 15 cm H_2O and the measured PCWP is 22 mm Hg, the corrected PCWP is 17.5 mm Hg.

If a patient has pulmonary edema, CCTPs may use the PCWP to aid in differentiating the cause. If pulmonary edema is the result of left-sided heart failure (cardiogenic), the PCWP will often be elevated. In cases in which pulmonary edema is the result of increased pulmonary capillary permeability (as in pneumonia or acute respiratory distress syndrome), the PCWP most likely will not be elevated. Care must be exercised with patients diagnosed as having acute respiratory distress syndrome because they often have elevated mean airway pressure levels and elevated PEEP, so the PCWP reading may be elevated as well.

Between the transducer on the tip of the PAC and the left ventricle lie three major anatomic components that may interfere with an accurate PCWP reading: the mitral valve, the left atrium, and the

pulmonary venous vasculature. Furthermore, the PCWP is a pressure trying to indicate a volume. This relationship generally holds unless the distensibility of the left ventricle has been affected (such as in a left ventricular myocardial infarction). In this case, the relationship fails.

The Frank-Starling Law

The **Frank-Starling law** states that there is a relationship between the distention of the ventricular myocardium and the force of the contraction. As the ventricular preload increases, the force of contraction of the myocardium also increases. This is the result of the increased stretch of the myocardial fibers. This relationship of increasing contraction with increases in the stretch of the myocardium immediately before systole continues until a point is reached and the force of contraction actually begins to fall off with subsequent detrimental increases in preload. The PCWP reflects preload in the left ventricle; the CVP reflects preload in the right ventricle. The Frank-Starling law describes how judicious administration of fluids results in improved CO up to a certain point, which varies between individual patients. Additional fluids given beyond the preload at which optimal CO is achieved result in worsened CO and the patient is said to have "fallen off the end of the Starling curve."

Cardiac Output

Cardiac output (CO) measurement rounds out the basic assessments performed by a PAC. Like the PCWP, CO is an intermittent assessment that involves some action by CCTPs. Typical CO assessment using a PAC uses the thermodilution method. This method involves injecting 5% dextrose in water (D_5W) at a known temperature (iced or room temperature) into the proximal port (usually the CVP port) of the PAC. Note that D_5W is the solution that is supposed to be injected; other solutions should not be used (other solutions, such as normal saline, introduce a low error level of approximately 2%). As the cold injectant moves past the thermistor on the distal end of the catheter, the temperature is recorded by the monitoring system and a curve is plotted comparing the temperature change over time between the injectant sensor and the distal end of the catheter. The monitor then calculates the CO. This procedure is repeated several times (three to six depending on local protocol), and the mean of these results is used to interpret the patient's CO. Curves that suggest erroneous injection technique or faulty temperature measurement are not included in the averaging strategy. Most transport monitors will not have the capability of performing thermodilution CO measurements during transport.

Normal CO ranges between 4 and 8 L/min. Investigation of low or higher than normal CO requires a stepwise approach considering each of the elements that compose the CO formula (CO = Heart Rate × SV).

The Fick Principle

The CO can also be calculated or estimated by using the **Fick principle**. First described by Adolph Fick in 1870, this method divides oxygen consumption by the difference between oxygen content of arterial and venous blood. The formula uses assumed values for oxygen consumption derived from basal metabolic studies on healthy subjects, which may or may not be valid in critically ill patients. Nevertheless, the Fick principle is commonly used in cardiac catheterization laboratories and critical care units. The formula is as follows:

$$CO = \frac{\text{Oxygen Consumption}}{\text{Arteriovenous Oxygen Content Difference}}$$

Data needed for calculating CO with this equation include the following:

1. BSA

2. Hemoglobin level
3. Arterial oxygen saturation (from a blood gas measurement or oxygen saturation as measured by pulse oximetry [Spo_2] from a pulse oximeter reading)
4. Mixed venous oxygen saturation (Spo_2) (from a blood gas sample drawn from the pulmonary artery port of a PAC or Svo_2 display reading from a fiberoptic PAC)

The BSA is expressed in square meters, and oxygen saturations are expressed as a decimal (eg, 98% would be expressed as 0.98).

Calculation of the estimated Fick CO is done as follows:

1. Calculate the oxygen consumption based on presumed 125 mL of oxygen consumed per square meter of BSA (ie, 125 × BSA).
2. Calculate the arteriovenous oxygen content difference. Each gram of hemoglobin can carry 1.36 mL of oxygen. Hence, the difference is expressed as follows: 1.36 × Hemoglobin × (Arterial Saturation — Venous Saturation) × 10.
3. Divide the calculated oxygen consumption by the calculated arteriovenous oxygen content difference to produce the estimated CO in liters per minute.

Assuming the following values, here is an example of the calculation:

- BSA = 1.33 m^2
- Hemoglobin = 12 g/dL
- Spo_2 (pulse oximeter) = 0.98 (98%)
- Svo_2 (saturation of blood gas sample drawn from pulmonary artery port) = 0.70 (70%)

$$CO = \frac{125 \times BSA\ 1.33}{Hgb\ 12 \times 1.36 \times (0.98 - 0.70) \times 10}$$

$$CO = \frac{166.25}{16.32 \times (0.28) \times 10}$$

$$CO = \frac{166.25}{45.696} = 3.64\ Liters/min$$

A simplified version of the formula can be used. This version calculates the constants (here, 125 has already been divided by 1.36 and 10), so that there are fewer calculations needed overall:

$$CO = \frac{9.19 \times BSA\ 1.33}{Hgb\ 12 \times (0.98 - 0.70)}$$

Pulmonary Vascular Resistance

Pulmonary vascular resistance (PVR) is calculated with the following equation:

$$PVR = \frac{(Mean\ Pulmonary\ Artery\ Pressure - PCWP)}{CO} \times 80$$

The PVR represents the resistance of the pulmonary vascular circuit that opposes flow out of the right ventricle and pulmonary artery, commonly referred to as right-sided heart afterload. The normal value is 100 to 250 dyne-sec/cm^{-5}. The CCTP may see an elevated PVR in patients with pulmonary hypertension or mitral valve stenosis.

Systemic Vascular Resistance

If a patient's MAP, CVP, and CO are known, the CO computer will calculate the **systemic vascular resistance (SVR)** by using the following equation:

$$SVR = \frac{(MAP - CVP)}{CO} \times 80$$

In a manner similar to PVR, a patient's SVR represents the total impedance to blood flow felt by the left ventricle, commonly referred to as afterload. Calculation of the SVR—with a normal range of 800 to 1,200 dyne-sec/cm^{-5}—is extremely useful in helping to differentiate the cause of shock. If the SVR is elevated, the patient has vasoconstriction, suggesting hypovolemia or pump failure. If the SVR is low, a distributive shock state such as neurogenic or septic shock is likely. Obviously the effects of vasodilating or vasoconstricting agents can affect SVR values. Also, SVR is a calculated, not a measured, value. As such, changes or errors in measuring any of the components included in the calculation could alter the results and lead to decisions based on inaccurate information.

The ideal SVR is thought to be just below 1,000 dyne-sec/cm^{-5}, and when a PAC is used to titrate vasodilator therapy (usually angiotensin converting enzyme inhibitor agents) in patients with heart failure, the goal is to achieve an SVR of 900 to 1,000 dyne-sec/cm^{-5}.

Stroke Volume

The amount of blood ejected in each stroke of a ventricle is measured in milliliters and recorded as the **stroke volume (SV)**. A normal SV is 60 to 100 mL/beat. The familiar equation that relates SV to CO and heart rate is as follows:

$$SV = \frac{CO}{\text{Heart Rate}}$$

As explained previously, ventricular performance is affected by the contractility (health) of the heart muscle and the preload and afterload to the respective ventricle. Any pathophysiologic factor that affects one of the performance determinants will augment or depress the SV.

The stroke volume index is calculated by dividing the SV by the BSA:

$$\text{Stroke Volume Index} = \frac{SV}{BSA}$$

The normal stroke volume index is between 33 and 47 mL/beat/m^2.

An estimation of contractility can be made by calculating left and right ventricular stroke work indexes as follows:

$$\text{Left Ventricular Stroke Work Index} = \text{Stroke Volume Index } (MAP - PCWP) \times 0.0136$$
$$\text{Right Ventricular Stroke Work Index} = \text{Stroke Volume Index } (\text{Mean Pulmonary Artery Pressure} - CVP) \times 0.0136$$

The normal left ventricular stroke work index is 40 to 75 gm-m/m^2/beat. (Note: gm-m represents grams per meter.) The normal right ventricular stroke work index is 5 to 10 gm-m/m^2/beat.

Mixed Venous Oxygen Saturation

If a fiberoptic oxygen saturation probe is attached to the distal end of the PAC, a **mixed venous oxygen saturation (SvO_2)** measurement can be recorded. This measurement is constant and requires no action by the clinician once the catheter is placed. In PACs without fiberoptic oximetry capability, a blood gas specimen can be obtained from the distal (pulmonary artery) port of the catheter to determine the mixed venous oxygen saturation. In effect, SvO_2 reflects the global balance between oxygen delivery and

consumption. The measurement is performed at the distal end of the PAC because the pulmonary artery is the most appropriate place to sample a mixture of all blood returning from the body. There are four factors that affect Svo_2; three pertain to oxygen delivery and one to oxygen consumption in the body. Oxygen delivery is affected by total hemoglobin levels, arterial oxygen saturation, and CO. Increases or decreases in any of these can affect the Svo_2. Changes in oxygen consumption (also called oxygen demand) can also affect the Svo_2. Oxygen consumption is increased with conditions that increase metabolic rate or muscle activity, such as fever, seizures, shivering, and increased work of breathing. Oxygen consumption may decrease when there is maldistribution of blood, which most commonly occurs in sepsis as a result of microcapillary obstruction leading to arterial blood being shunted past the capillaries into the venous blood. Normally, when oxygen demand increases and threatens to exceed oxygen supply, the body compensates by increasing CO and/or increasing oxygen extraction. When evaluating an Svo_2 value outside the normal range (0.60 to 0.80 [60% to 80%]), CCTPs should consider each of the four components that contribute to this parameter: total hemoglobin level, arterial oxygen saturation, CO, and oxygen consumption.

A measurement similar to mixed venous oxygen saturation is the **mixed central venous oxygen saturation ($Scvo_2$)**. Like mixed venous oxygen saturation, the $Scvo_2$ reflects the balance between oxygen supply and delivery. Measurements of $Scvo_2$ are obtained from a central venous catheter by drawing a blood gas specimen or from a fiberoptic oximetric tip connected to a specially designed monitor that displays the oxygen saturation. Because the location of the central venous line is more proximal than the pulmonary artery, blood sampled from a central venous line reflects extraction by the brain and upper body rather than global extraction; therefore, the $Scvo_2$ values are approximately 8% to 10% higher than the Svo_2 values. A normal $Scvo_2$ value is considered to be above 0.70 (70%).

Obtaining Invasive Hemodynamic Measurements

Once the central venous line, arterial line, or PAC is placed, it is connected to a pressure-monitoring transducer by using rigid pressure-monitoring tubing. The tubing is filled with an isotonic solution, usually normal saline. In the past, heparinized saline was often used, but lack of demonstrated benefit and the potential for harm to patients have all but eliminated its use as a flush solution. The difference between pressure-monitoring tubing and IV extension tubing is important because use of the latter will absorb much of the pressure waveform generated by the patient before it reaches the transducer. Transducers are biomedical devices designed to convert a physical or pressure waveform signal into an electrical signal. The electrical output of the transducer is connected by a proprietary electrical cable to the transport monitor.

To maintain patency of the pressure-monitoring line and fluid-filled system, a continuous flush solution system is used. Most often, this is done by placing the flush solution used to fill the monitoring system into a disposable pressure bag. Once the monitoring system is connected to the patient, free of bubbles, and functioning properly, the pressure bag is inflated to 300 mm Hg, or above the patient's BP. Whenever the pressure in the monitoring system exceeds the patient's BP, each transducer will flow 3 mL/h of flush solution into the patient. This continuous flush system maintains catheter patency and prevents blood backflow into the catheter and monitoring system. In cases in which less than 3 mL/h of flow through each transducer is necessary (such as in a neonate), the flush solution can be delivered to the transducer(s) by using an infusion pump.

If the transfer will involve air medical transport, all of the air left in the fluid bag, placed inside of the pressure bag, should be expelled to prevent expansion during flight. As mentioned earlier, the

pressure bag itself must remain at 300 mm Hg and may have a pressure indicator that will display the color green when inflated above 300 mm Hg. After the pressure bag is properly inflated, air should be turned off to prevent deflation **Figure 14-24**. The pressure bag should be periodically checked during transport to verify that it remains inflated.

Before moving a patient with hemodynamic monitoring equipment already in place, CCTPs should examine the equipment, note the values currently being displayed, and trace the tubing from each transducer to the pressure-monitoring catheter it is connected to. The catheter site should be examined and documented to be visibly clean, dry, and covered by an occlusive dressing. CCTPs should be familiar with operation of the stopcocks and catheters in use or should ask the clinician at the bedside for a review of its proper use.

Figure 14-24 An inflated pressure bag with proper inflation.

A CCTP may elect to transfer a patient to the transport stretcher before connecting transducers to the transport monitor or may make the connections to the transport monitor before moving the patient. In either case, one pressure cable is moved at a time to the transport monitor, ensuring that waveforms and values similar to those displayed on the hospital monitor appear on the transport equipment before transferring additional lines and pressure channels. Proceeding in a deliberate, stepwise manner avoids periods in which the patient is not connected to any monitoring equipment when changes may not be readily detected.

Extra caution is needed when moving a patient with hemodynamic monitoring equipment in place because catheters can easily become dislodged or pulled out when they are not adequately secured. Agency or service policy for securing monitoring lines and catheters during transport should be followed. The most reliable hemodynamic waveforms and pressure readings will be obtained from tubing less than 4′ (48″) from transducer to invasive catheter, with no more than one stopcock between the transducer and invasive catheter.

The best protection against accidental dislodgement or dislocation of invasive monitoring catheters is carefully set monitoring alarms. The transport environment is no exception to the need for monitoring alarm parameters designed to alert CCTPs if hemodynamic parameters exceed reasonable thresholds. Disconnected catheters will invariably register less than physiologic levels that can be readily detected when alarms are properly set by CCTPs.

Leveling and Zeroing the Pressure Transducer

The most common cause of error in obtaining direct hemodynamic pressure measurements is incorrect leveling of the transducer. Fluid used to fill the rigid pressure tubing that connects the monitoring catheter between the patient and the transducer will interfere with pressure readings if the pressure transducer is lower or higher than mid-heart level, commonly located at the patient's right atrium. The location of this

reference point is referred to as the **phlebostatic axis** and is located at the fourth intercostal space, mid-chest position **Figure 14-25**. **Referencing** is the process of ensuring that the hemodynamic pressure transducer is at the level of the left atrium. The transducer must be releveled with every position change of the patient; therefore, this point is often marked on the patient's skin. The simplest way to ensure proper placement during transport is to secure the transducer at the phlebostatic axis, although this is not always practical in the critical care setting or transport environment.

The phlebostatic axis moves with the patient and can be adjusted to obtain accurate readings in virtually any sitting or lying position. Transducers must be releveled with any change in patient position. For each inch that a transducer is leveled above the phlebostatic axis, readings will be 1.86 mm Hg less than actual pressures in the patient. For each inch that a transducer is leveled lower than the phlebostatic axis, values obtained will be 1.86 mm Hg greater than actual. Inches of error in leveling can have significant implications if treatment decisions are based on erroneously obtained values. For this reason, all leveling should be performed with a carpenter's level or leveling tool designed for hemodynamic monitoring applications.

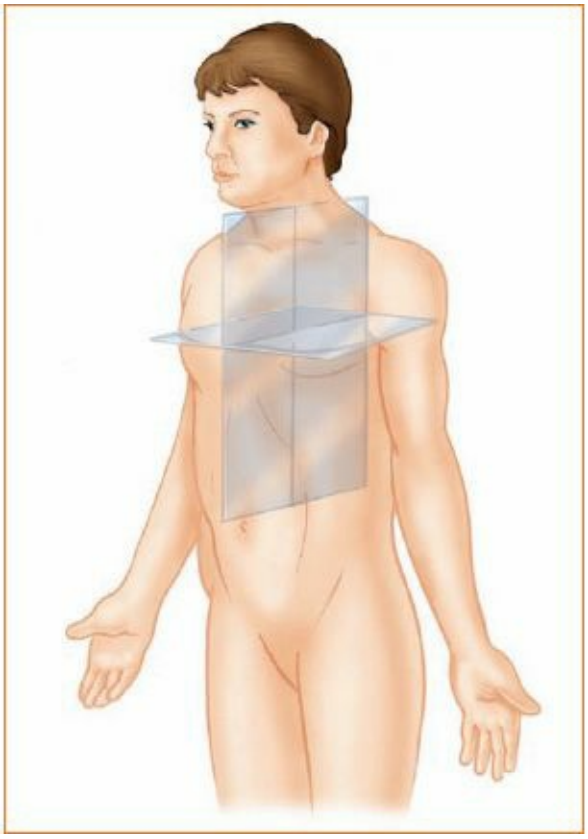

Figure 14-25 The phlebostatic axis.

In addition, any pressure transducer must be "zeroed" to eliminate the effects of atmospheric pressure on the measurements obtained. **Zeroing** is the process in which a transducer connected to the transport monitor is opened to atmospheric air to obtain a baseline reading of pressure in the environment. Once opened to air, the monitor is zeroed to eliminate the effects of atmospheric pressure on the transducer **Figure 14-26**. The procedure is as follows to zero the transducer: ensure that the cable is connected (or reconnected) to the monitor, close the stopcock to the patient, open the stopcock to air, and press the zero button on the monitor. Confirm that the monitor has accepted the zero value and actually indicates zero on the pressure and waveform displays.

Zeroing should be performed:

- Immediately after connecting the transducer to the transport monitor

- With any significant change of elevation greater than 1 atm
- Whenever displayed values are in question

Figure 14-26 Zeroing the transducer.

Depending on flight patterns and altitudes, zeroing is often conducted at the initial connection of the transducer to the transport monitor, at cruising altitude, and again on arrival at the destination.

Respiratory Variation

Changes in intrathoracic pressure result in variable direct pressure measurements. To accurately obtain invasive pressure measurements, it is important to take readings at end expiration. Only at end expiration are the pressures inside the thorax equalized to atmospheric pressure outside the body. Respiratory variations produce a rise and fall of the baseline observed on hemodynamic pressure waveforms. In mechanically ventilated patients (positive-pressure ventilation), end expiration occurs in the lower portions, or valleys, of the rise-and-fall pattern. End expiration in spontaneously breathing patients (negative-pressure ventilation) correlates to the peaks of the rise-and-fall pattern. Making certain to read CVP and PCWP in the proper location based on whether the patient is mechanically ventilated (valley) or spontaneously breathing (peak) will ensure that the values are obtained during end expiration and not falsely affected by intrathoracic pressure changes.

Transducers and Cables

There are several transducer brands on the market, each with its own fast-flush system. The two most common types are the squeezable style and the pull style. The squeezable-style device has two pieces of plastic on either side of the transducer that, when squeezed, will fast flush the closed fluid-filled system **Figure 14-27A**. The pull-style (or pigtail) device has a small piece of rubber that resembles a pigtail **Figure 14-27B**. To flush the system, the CCTP pulls the tail straight out (away from the transducer).

Fast flushing overrides the normal delivery of 3 mL/h of flush solution through the transducer into the patient and allows free flow of pressurized flush solution through the system for as long as the fast flush assembly is activated. Fast flushing is useful as an initial technique to troubleshoot a **dampened waveform** or absent waveform in a system that had previously been functioning normally.

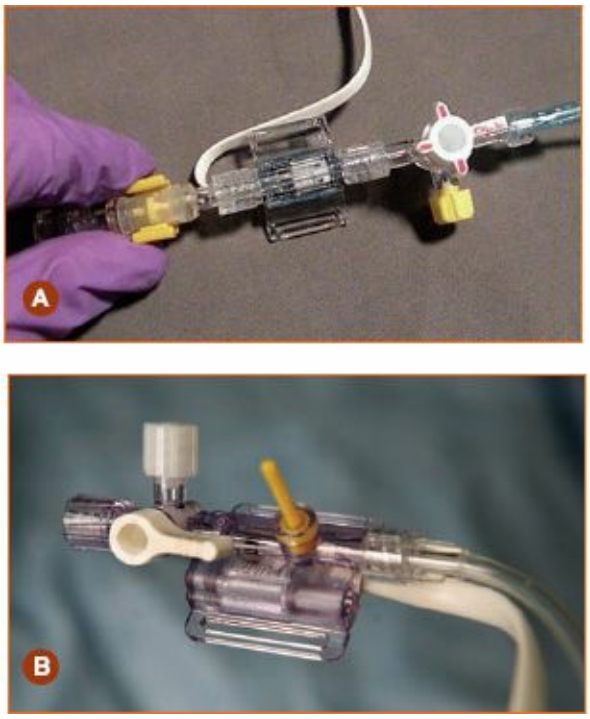

Figure 14-27 The two most common transducer flush system devices. **A.** Squeezable. **B.** Pull style.

CCTPs should become familiar with transport monitors and the cables needed to connect to pressure-monitoring equipment and transducers. Transport monitors are often limited to monitoring two pressure channels; it may be necessary to decide which pressures will be observed during transport. Any patient with a PAC must have the distal port (pulmonary artery) continuously monitored in case the PAC spontaneously wedges. Unmonitored or undetected spontaneous wedging can result in pulmonary infarction.

The cables that connect patient transducers to the monitor that an agency uses must be compatible with the equipment in use at the referring and receiving hospitals. There are two main cable types on the market. The most common has an end that attaches to the transducer that resembles a phone line connection; the other is best described as a half-moon connection **Figure 14-28**. It is best to carry at least two sets of each cable type to ensure accommodation of various transport monitors and transducers.

Potential Complications During Transport

Many complications can occur during transport of patients with central lines, arterial lines, or PACs. Probably the most common is accidental dislodgement or removal of the line or catheter. Meticulous attention to securing catheters, lines, and attached tubing before moving a patient to the transport stretcher with repeated checks for security and stability of these devices will help avoid loss of these important monitoring or access devices. Nevertheless, sudden patient movements or snags during movement happen, and lines sometimes become dislodged. Should an invasive line come completely out of a patient, the CCTP should immediately apply direct pressure to the insertion site and hold until bleeding stops. Central line and PAC insertion sites will usually stop bleeding with 3 to 5 minutes of direct pressure. Arterial lines can take considerably longer, depending on the size of the catheter and the clotting status of the patient. When holding pressure on an arterial line insertion site, CCTPs need to be certain that they are actually compressing the artery. Failure to apply pressure directly over the artery will allow continued bleeding into the tissue around the insertion site and can result in significant hematomas. Once bleeding is controlled, an occlusive dressing is applied to the site and the site is inspected frequently for continued bleeding.

Figure 14-28 Two types of cables that connect the transducer to the monitor are a phone line–type connection and a half-moon connection. A half-moon connection is shown here.

No attempt should be made to replace a catheter that dislodges but does not come completely out of the patient. Patency should be assessed by attempting to aspirate blood from each lumen to determine if each remains in a blood vessel. Options for continued use should be discussed with medical control. A catheter that needs to be removed is gently withdrawn from the patient and steps are followed as outlined previously to control bleeding at the insertion site.

Central venous access can have many of the same complications as peripheral venous access. Some of the complications include blood clotting from inadequate flow, breaking off of an embolism, catheter extravasation from improper placement, and catheter migration, which can cause inadvertent cannulation and pericardial tamponade. Other common problems encountered during invasive hemodynamic monitoring and actions to resolve them are listed in **Table 14-3**.

TABLE 14-3 Common Problems Encountered During Hemodynamic Monitoring

Problem	Actions to Resolve the Problem
Absence of a waveform tracing	Activate the fast-flush feature of the transducer for 1 to 2 seconds. Check the connections of the monitor cable. Ensure that the fluid-filled system is patent. Check that the stopcock is in the correct position and that the pressure bag is properly inflated. Aspirate blood from the stopcock. Notify the sending physician.
Damping of a waveform	Ensure that the flush solution container is not empty. Ensure that the pressure bag is properly inflated. Check the tubing for air bubbles or clots. Assess the catheter and insertion site for kinks.
Abnormally high or low readings	Verify that the transducer is properly leveled at the phlebostatic axis. Ensure that the pressure bag is properly inflated. Check that the fluid-filled system is patent.

	Rezero the transducer. Consider the possibility of actual hypertension or hypotension. Assess pressure with an alternative means to confirm values.
Air bubbles within the fluid-filled system	Ensure that the circuit is filled slowly to avoid air bubbles. Verify that the fluid chamber is not upside down and that the stopcocks are closed to air. Aspirate blood to the stopcock. Slowly flush fluid from the pressure bag to clear the line. Avoid pressurizing the system until it is connected to the patient and fully functional.
Confusing the arterial with the venous line	Clearly label arterial line tubing as "ARTERIAL" to avoid mistaking as the line for venous access.
Hemorrhage from an accidental disconnection	Set monitor alarms. Check tubing and connectors for tightness.
Unable to wedge	If the balloon inflates but cannot be withdrawn, suspect rupture: label the balloon port as follows: "Ruptured—DO NOT WEDGE." If the balloon functions normally, the catheter may need to be advanced: notify the receiving facility on arrival.
Continuous PCWP waveform	Verify that the balloon tip has not been left inflated. Have the patient cough or change position to free the catheter tip. Fast flush the PAC to free the catheter tip from the wall of the pulmonary artery. Notify the sending physician.
Blood in the line	Confirm that the flush solution container is not empty. Check that the stopcocks are in the correct position and that the tubing is securely connected. Verify that the patient's blood pressure has not exceeded that in the pressure bag (the pressure bag is properly inflated).
Pulmonary artery waveform now appears to be a right ventricular waveform	Observe for cardiac irritability. If ectopy is compromising hemodynamic status, pull back the catheter into the right atrium (15- to 20-cm marking at the introducer). Inflate the balloon to float the tip of the PAC back into the pulmonary artery. Notify the sending physician.
Loss of circulation distal to the arterial line site	Notify medical control. May need to remove the arterial line.

Clotted	Do not attempt to forcefully flush a clotted central venous or arterial line. Cap the line. Label the line as "clotted."

Abbreviations: PAC, pulmonary artery catheter; PCWP, pulmonary capillary wedge pressure.

TABLE 14-4 Relationship Between Shock Type and Invasive Hemodynamic Measurements

	Shock Type		
Measurement	Hypovolemic	Cardiogenic	Distributive
Preload (CVP, PCWP)	Decreased	Increased	Decreased
Afterload (SVR, PVR)	Increased	Increased	Decreased
Cardiac output	Decreased	Decreased	Increased
Svo_2 or $Scvo_2$	Decreased	Decreased	Increased
Blood pressure (MAP)	Decreased	Increased	Decreased

Abbreviations: CVP, central venous pressure; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; PVR, pulmonary vascular resistance; $Scvo_2$, mixed central venous oxygen saturation; Svo_2, mixed venous oxygen saturation; SVR, systemic vascular resistance.

Recognition of Shock

Shock is a common cause of morbidity in the critical care setting. Hemodynamic monitoring can help CCTPs to differentiate between various types of shock and assess the effectiveness of treatment during transport. There are three recognized shock states: hypovolemic, cardiogenic, and distributive. Hypovolemic shock includes volume loss from acute or chronic hemorrhage, excessive diuresis, third-space losses, and any other condition that depletes intravascular volume. Cardiogenic shock causes are diverse and include myocardial depression from ischemia and/or infarcts, cardiomyopathies, stunning following cardiac surgery, arrhythmias that decrease flow, mechanical abnormalities leading to pump failure, and obstructive conditions such as massive pulmonary embolism, tension pneumothorax, and pericardial tamponade. Distributive shock states include sepsis, systemic inflammatory response syndrome, toxic shock syndrome, anaphylaxis, poisonings, neurogenic conditions such as spinal cord injury, and other vasodilatory etiologies. Each has classic hemodynamic findings that help distinguish among them. Because shock is characterized by reduced systemic tissue perfusion, the end result is decreased tissue perfusion. Prompt recognition and reversal of shock avoids a rapidly irreversible sequence of cell death, end-organ damage, lactic acidosis resulting from anaerobic metabolism, multisystem organ failure, and death.

Two hemodynamic parameters distinguish the different types of shock: CO and SVR. In hypovolemic shock, preload is decreased as a consequence of depleted intravascular volume. Decreased preload leads to a decline in SV, which results in decreased CO. To maintain end-organ perfusion, SVR increases to compensate for the declining CO. Cardiogenic shock involves a complex cascade of events resulting from pump failure leading to decreased CO. The SVR typically increases in an effort to maintain CO, which further exacerbates pump failure and leads to increased preload and a relative total hypervolemic condition. In distributive shock, vasodilation is often the primary culprit and is observed by a significantly decreased SVR. When afterload declines dramatically, CO increases. **Table 14-4** summarizes the findings expected with each of the three shock states.

Flight Considerations

Concerns pertaining to flight physiology include the hypoxic effects of altitude and gas expansion. Even in pressurized cabins, oxygen saturation in healthy people declines by a mean of 5.5%, and the saturation often approaches 0.90 (90%). Patients with reduced oxygen saturation on the ground can be expected to experience further declines. Close monitoring of oxygen saturation will enable CCTPs to respond to changes in a patient's condition and maintain sufficient levels of inspired oxygen to ensure adequate saturation.

Physiologic changes that may be evident to CCTPs in response to lowered oxygen levels at high altitude include a chemoreceptor-induced increase in tidal volume and, if respiratory compensation is inadequate, an increased CO achieved mainly through an increased heart rate. Hypoxia and increased sympathetic nervous system tone predispose patients to arrhythmias.

Gas expansion in flight occurs in accordance with Boyle's law (the volume to which a given quantity of gas is compressed is inversely proportional to the surrounding atmospheric pressure). Pneumothoraces may become tension pneumothoraces with significant hemodynamic compromise. Air should be removed from IV bags because it will expand, potentially increasing infusion rates. Pumps should be used for medication infusions. Zeroing of transducers is recommended when cruising altitude is reached and with changes of altitude of 1,000′ or more.

Summary

Hemodynamic monitoring provides CCTPs with multiple measures of the cardiovascular status of their patients. Proper use of these clues to guide patient management requires technical skill in the correct use of the equipment and an understanding of the meaning of these data. Experienced CCTPs will use multiple methods (such as physical assessment findings and lab test results) to confirm that the hemodynamic measurements obtained reflect perfusion. Hemodynamic monitoring provides one piece of the clinical picture needed to form an overall impression and diagnosis. The most important tool for hemodynamic monitoring will always be the CCTP's own knowledge and experience.

Case Study

A 68-YEAR-OLD MAN WITH PULMONARY EDEMA was brought to the emergency department of a community hospital by EMS. Paramedics found him with acute shortness of breath and intubated him in the field when he failed to respond to nitroglycerin, furosemide, and morphine. He is presently in the community hospital ICU awaiting your arrival for ground transport to a heart failure program at a tertiary center 2 hours away. The referring hospital personnel advise that an arterial line and PAC have been placed and that they are attempting to lower the patient's BP while they await your arrival. There is no evidence of an acute myocardial infarction. A chest radiograph revealed diffuse interstitial edema consistent with pulmonary edema. The results of lab work, including cardiac markers, electrolytes, and renal function tests, were normal.

On arrival, you confirm the information previously reported. You note the patient ventilating well on a fraction of inspired oxygen of 0.4, a tidal volume of 7 mL/kg, a respiratory rate of 14 breaths/min in the synchronized intermittent mandatory ventilation (SIMV) mode, and a PEEP of 5 cm H_2O. Continuous infusions of propofol, fentanyl, and nitroglycerin are running. The nitroglycerin is infusing at 200 μg/min. The registered nurse reports that escalating doses of furosemide have not resulted in any increased urine output. The following hemodynamic readings were taken 5 minutes before your arrival at the bedside:

- Pulse rate: 100 beats/min

- Blood pressure (SBP/DBP/mean): 220/110/135 mm Hg
- Pulmonary artery pressure (S/D/M [systolic/diastolic/mean]): 57/34/40 mm Hg
- PCWP: 28 mm Hg
- CVP: 20 mm Hg
- CO: 3.9 L/min
- Cardiac index: 1.7 L/min/m^2
- SVR: 2,359 dyne/s/cm^{-5}

1. What are the implications of these hemodynamic values?
2. What interventions would help stabilize this patient's condition for transport?
3. Are there other hemodynamic data that would be helpful?

Analysis

Familiarity with hemodynamic findings associated with various forms of shock would immediately point to cardiogenic shock in this patient. An initial decline in myocardial pumping efficiency from a yet undetermined cause triggered a cascade of events beginning with vasoconstriction and progressing to hypervolemia that ultimately resulted in pulmonary edema. Vasoconstriction is seen in the elevated afterload (SVR) and hypertension; hypervolemia is evidenced by elevated preload values (CVP and PCWP). The CO is likely low because the heart is unable to pump against the incredibly high afterload. Urine output is likely compromised by renal retention of sodium and water in response to the low CO. The values seen in this case example are, in fact, classic values seen in patients with cardiogenic shock. As their condition deteriorates, they will ultimately become hypotensive and acidotic and will die if untreated.

The first intervention suggested by the values obtained with the PAC is use of an agent to reduce the high afterload state. Staff reported attempting to lower the patient's blood pressure with nitroglycerin, but current dosing is generally considered maximal. Nitroglycerin is primarily a venodilating agent with minimal arterial dilating properties except at extremely high doses. Given the patient's degree of hypertension, which persists even with the nitroglycerin infusion, significant afterload reduction will require an agent with more potent arterial vasodilating properties. The transport crew consulted with providers caring for the patient and decided to initiate an infusion of sodium nitroprusside. Nitroprusside has venous and arterial dilating properties and is a potent antihypertensive agent. Following initiation of a nitroprusside drip, gradually titrated up to 3 μg/kg/min, the patient's MAP declined to 95 mm Hg, CVP to 14 mm Hg, and PCWP to 24 mm Hg. The CO doubled to 7.8 L/min. The calculated SVR was then 831 dyne/s/cm^{-5}. With the improved CO, the patient's urine output immediately increased. Had CO remained low once afterload reduction was achieved, the transport crew would likely have sought to initiate an inotropic infusion. Dobutamine is the inotropic agent of choice for first-line treatment of low CO associated with heart failure.

Not all hemodynamic parameters discussed in this chapter were used in evaluating this patient. Patient problems and potential treatment options under consideration guide the hemodynamic measurements and calculations used. With the data used by the CCTPs receiving this patient, a clear picture of pump failure with low CO emerges. One question not apparent from these data is whether the perfusion needs of the patient are being met by the present CO. If oxygen demands exceed supply, the patient's condition will deteriorate and most likely will do so with the additional stress of transport.

Clearly, the patient's CO is low. Mixed venous oxygen saturation would indicate whether the present CO is meeting the perfusion needs of the patient. As described, some PACs have a fiberoptic oximetric

tip that continuously displays the mixed venous oxygen saturation. Because this PAC did not, the transport crew requested that the hospital staff send a blood specimen from the pulmonary artery port of the PAC for blood gas analysis. The results showed a mixed venous oxygen saturation of 0.49 (49%), well below the normal range of 0.60 to 0.80 (60% to 80%). The result for a repeated specimen drawn after hemodynamics appeared more stable following initiation of the nitroprusside infusion was 0.64 (64%), a dramatic improvement reflecting adequate tissue perfusion.

Prep Kit

Ready for Review

- Invasive hemodynamic monitoring is used to assess the heart, vascular network, and fluid volume status. It is used in conjunction with, not as a replacement for, physical assessment techniques such as capillary refill, skin color, skin turgor, body temperature, heart and lung sounds, and mental status.
- Invasive hemodynamic measurements are obtained via a closed catheter system, which is typically placed in the patient by a physician. Catheter placement is usually outside the scope of CCTPs. Measurements are read on a monitor that is connected to a transducer on the catheter.
- Asepsis is critical in the care of patients with central lines and hemodynamic monitoring equipment. Five key practices decrease the incidence of catheter-related bloodstream infections: hand hygiene, maximal barrier precautions during insertion, chlorhexidine skin antisepsis, optimal catheter site selection, and prompt removal of unnecessary lines.
- Blood pressure is measured directly through the use of an arterial line or indirectly through the use of a device that senses pulsatile flow such as a sphygmomanometer, which measures systolic and diastolic pressures. Indirect measurements assess flow, and direct monitoring devices measure pressure. Pressure and flow are different parameters, so readings obtained using indirect and direct methods cannot be expected to correlate exactly.
- Systolic blood pressure is the measure of pressure on the arterial walls during systole; diastolic blood pressure is the measure of pressure on the walls of the arteries during diastole. The formula for blood pressure is cardiac output multiplied by systemic vascular resistance (BP = CO × SVR).
- To avoid errors when using indirect monitoring devices to measure blood pressure, CCTPs should be careful to use the correct blood pressure cuff size for the patient and to position the patient's extremity in which blood pressure is measured at mid-heart level.
- Transport monitors often include noninvasive blood pressure (NIBP) units, which automatically measure indirect blood pressure at predetermined intervals. The NIBP units measure heart rate and mean arterial pressure (MAP) only. Computer software then calculates systolic and diastolic blood pressures.
- CCTPs should evaluate the heart rate obtained from the NIBP unit against the actual patient pulse, the heart rate displayed on a pulse oximeter, or an ECG heart rate display to determine the accuracy of the NIBP measurements. If the NIBP heart rate differs significantly from the actual patient heart rate, the calculated systolic and diastolic blood pressures should be considered unreliable.
- Because the MAP is actually measured by the NIBP unit, this value is often used in making patient care and treatment decisions.
- Heart rate is a key sign of hemodynamic instability in the emergency or critical care patient. A heart rate obtained from a pulse oximeter is more reliable than manual assessment by the CCTP, particularly

in the noisy environment of an ICU or a CCTP vehicle.

- The Allen test is used to assess extremity perfusion and test ulnar artery function.
- Central venous lines provide access to the core vessels of the body. The right internal jugular vein is the easiest site to access. Other common insertion sites are the subclavian, brachial, and femoral veins. Subclavian sites have the lowest infection risk; femoral sites have the highest risk for infection, and their use is strongly discouraged in adults.
- Central venous pressure (CVP) monitoring is used to determine right ventricular preload and intravascular volume status and to assess right-sided heart function. The normal range for the CVP is 2 to 6 mm Hg. To ensure accuracy, CVP measurement should be obtained during end expiration.
- Central venous lines often include outlet ports, which are used for rapid fluid replacement, medication administration, rapid access to central circulation, and invasive monitoring.
- Contraindications for central venous access are few. They include significant coagulopathy, local trauma to the site of insertion, and infection at the site of insertion.
- The most common complication associated with the insertion of a central line is pneumothorax or hemothorax from an unsuccessful attempt at subclavian line insertion. Other complications range from bleeding, to infection, and to blood withdrawal problems.
- The triple-lumen catheter is the most commonly used central line. The lumens can be used for fluid and drug administration and for CVP monitoring. For some patients, one port may be reserved for total parenteral nutrition; that port should not be used during transport.
- Some central venous catheters have one or two access ports, and some are installed under the skin (tunneled). Consult the receiving facility and local protocols for direction in using tunneled central lines.
- CCTPs should be familiar with placement; use; maintenance required for different types of catheters, including the HICKMAN® catheter, the GROSHONG® catheter, the port-a-cath, and the peripherally inserted central catheter (PICC); and the possible complications and advantages and disadvantages of each catheter. All complications should be reported to the receiving facility as soon as possible.
- Although central venous lines are rarely placed by CCTPs, knowledge of how they are placed will help CCTPs care for patients who have a central venous line.
- The Seldinger technique is the most common technique used for line insertion. Specific procedures are used for femoral, internal jugular, and subclavian vein insertion.
- Common problems that occur when inserting a central venous line include sluggish infusion, inability to withdraw blood, and catheter damage.
- Direct blood pressure measurement using an arterial line is indicated for patients who require constant blood pressure measurement, particularly patients who are in shock and are not responding to therapy. Arterial lines are also used for patients receiving vasoactive or antihypertensive infusions.
- Contraindications for the use of an arterial line include ischemia of the extremity, infection at the puncture site, Raynaud disease, and prior vascular surgery in the area of the insertion site.
- CCTPs generally do not place arterial lines, but they may need to assist in the procedure; therefore, they should be familiar with the insertion procedure.
- A pulmonary artery catheter (PAC), also known as a Swan-Ganz catheter or “swan,” is inserted into the venous system of a patient. Although CCTPs do not insert PACs, knowledge of the procedure is useful in providing care.

- PACs have multiple lumens that terminate at different points along the catheter and correspond to different locations in the heart. PACs are marked at 10-cm intervals beginning at the distal tip of the catheter. CCTPs should note the centimeter measurement of the PAC at the introducer when initially assessing a patient. This information will help to determine if the catheter moves into or out of the patient during transport.
- The PAC measures right atrial (RA) and pulmonary artery pressure. The RA pressures are displayed as mean pressures; pulmonary artery pressures are displayed as systolic, diastolic, and mean values. Inflation of the PAC balloon blocks blood flow from the right ventricle behind the balloon tip and results in the appearance of a pulmonary capillary wedge pressure (PCWP) waveform on the monitor. The PCWP waveform is measured as a mean value.
- Complications of PAC insertion are nearly the same as those of central line insertion. Probably the greatest potential complication of PAC use is misinterpretation of the data by clinicians, resulting in inappropriate therapy and potentially worsening outcomes.
- A thermistor is connected to the distal end of the PAC. The thermistor measures thermodilution cardiac output and provides a continuous reading of the pulmonary artery temperature, which is considered the gold standard for core body temperature measurement.
- Indications for the use of PACs are based on clinician experience, not outcome studies. Clinicians are advised to consider the risks and benefits for critically ill patients on an individual basis.
- Contraindications to the use of a PAC include significant coagulopathy, local trauma to the site of insertion, infection at the site of insertion, and inability to float the PAC into the pulmonary artery.
- CCTPs should be familiar with normal hemodynamic ranges and values and the lines from which the measurements are obtained.
- Cardiac output (CO) is the product of stroke volume (SV) and heart rate: (CO = SV × Heart Rate). The SV is determined by preload, afterload, and contractility of the heart. Because the SV is determined by three components, heart rate contributes more to and has a more immediate effect on CO than any one component of SV. When confronted with low CO, CCTPs should investigate heart rate before evaluating the components of SV.
- Some hemodynamic values are indexed to account for differences in body size; for example, a cardiac index is the patient's cardiac output divided by his or her total body surface area.
- Preload is the degree of myocardial fiber stretch induced by volume in the ventricle at the end of diastole. Hypovolemia, venodilation, intrathoracic pressure changes, and intrapericardial pressure changes result in decreased preload. Hypervolemia and vasoconstriction result in increased preload.
- Right ventricular preload is measured by central venous pressure. Left ventricular preload is measured by pulmonary capillary wedge pressure or pulmonary artery diastolic pressure.
- Afterload is the resistance the ventricles must overcome to eject blood. Three factors typically determine afterload: outflow obstructions, vascular tone, and blood viscosity. Outflow obstructions, vasoconstriction, and polycythemia increase afterload. Vasodilation reduces afterload. Lowered hemoglobin levels are often tolerated in critically ill patients because cardiac output may be improved by decreasing afterload.
- Contractility is the inotropic state of the heart or the force with which the heart muscle contracts. Contractility is assessed with newer Doppler and ultrasound devices. Six factors influence contractility: myocardial muscle health, autonomic nervous system, metabolic states, ion environment, pharmacologic agents, and heart rate.

- Central venous pressure (CVP) is a measure of the vena caval and right atrial pressures. It is measured from a central venous line or pulmonary artery catheter. A CVP waveform tracing has systolic and diastolic values, but only the mean is used in clinical practice because the numbers are extremely low.
- The normal range for CVP is 2 to 6 mm Hg. Fluids are often administered to patients with CVP values below 5 to 8 mm Hg to increase their preload.
- Continuous blood pressure monitoring through an arterial line provides CCTPs with constantly updated systolic and diastolic blood pressure and mean arterial pressure values and an arterial waveform. Components of the arterial waveform include the dicrotic notch, mean pressure, systole, diastole, systolic pulse pressure, and diastolic pulse pressure.
- Mean arterial pressure (MAP) is a function of the systolic blood pressure and diastolic blood pressure. It is calculated by the transport monitor software or the CCTP. An MAP between 70 and 105 mm Hg is needed to satisfactorily perfuse the body's tissues; most medical orders require titration of drugs or administration of fluids to maintain an MAP of 70 mm Hg or greater.
- Pulse pressure is another value calculated using systolic and diastolic blood pressures. It is the mathematical difference between these values. Normal values are 40 to 60 mm Hg.
- Pulmonary artery catheter measurements include right ventricular pressure, pulmonary artery pressure, pulmonary capillary wedge pressure, and cardiac output. CCTPs should know the normal values for each of these measurements and how to evaluate each of the measurements.
- CCTPs should be able to recognize a right ventricular waveform and its characteristic low diastolic pressure, which distinguishes it from a pulmonary artery pressure waveform.
- A CCTP who observes a sudden elevation in pulmonary artery pressures should immediately assess and correct any issues with oxygen saturation or ventilation. If pulmonary artery diastolic pressures suddenly drop, the catheter position should be reevaluated to determine if the PAC has migrated into the right ventricle.
- CCTPs should also know how to read a pulmonary capillary wedge pressure (PCWP) waveform. When a PCWP waveform is observed, the tracing can be frozen on the monitor screen, and the balloon should be allowed to passively deflate.
- The Frank-Starling law states that there is a relationship between the distention of the ventricular myocardium and the force of the contraction. As the ventricular preload increases, the force of contraction of the myocardium also increases due to the increased stretch of the myocardial fibers. The law describes how administration of fluids can improve cardiac output to a certain point, which varies among individual patients. Additional fluids given beyond that point worsen cardiac output.
- The thermodilution method is typically used to assess cardiac output with a pulmonary artery catheter. Most transport monitors are not capable of performing thermodilution cardiac output measurements during transport.
- Cardiac output can be calculated or estimated by using the Fick principle. The formula used is as follows:

$$CO = \frac{\text{Oxygen Consumption}}{\text{Arteriovenous Oxygen Content Difference}}$$

- Pulmonary vascular resistance (PVR) is the resistance of the pulmonary vascular circuit that opposes flow out of the right ventricle and pulmonary artery. It is commonly referred to as right-sided heart afterload. The PVR may be elevated in patients with pulmonary hypertension or mitral valve stenosis.
- Systemic vascular resistance (SVR) is the total impedance to blood flow felt by the left ventricle, commonly referred to as afterload. Calculation of the SVR is helpful in determining the cause of shock.

- The amount of blood ejected in each stroke of a ventricle is measured in milliliters and recorded as the stroke volume (SV). A normal SV is 60 to 100 mL/beat.
- Mixed venous oxygen saturation (SvO_2) reflects the global balance between oxygen delivery and consumption. It is measured at the distal end of the PAC because the pulmonary artery is the most appropriate place to sample a mixture of all the blood returning from the body. Four components contribute to SvO_2: total hemoglobin level, arterial oxygen saturation, cardiac output, and oxygen consumption.
- Mixed central venous oxygen saturation ($ScvO_2$) reflects the balance between oxygen supply and delivery in the brain and upper body.
- Before moving a patient with hemodynamic monitoring equipment in place, CCTPs should examine the equipment in use, note the values displayed, and trace the tubing from each transducer to the pressure-monitoring catheter. The catheter site should be examined to ensure that it is visibly clean, dry, and covered by an occlusive dressing and its condition documented. A CCTP who is unfamiliar with the operation of the stopcocks and catheters in use should ask the clinician at the bedside to explain their operation.
- The patient can be transferred to a stretcher before or after transducers are connected to the transport monitor. A deliberate, orderly manner is needed when moving connections from the hospital monitor to the transport monitor to avoid periods when the patient is not connected to any monitor. Agency or service policy should be followed for securing monitoring lines and catheters during transport. Monitoring alarms need to be set to protect against accidental dislodgement or dislocation of invasive monitoring catheters.
- The most common cause of error in obtaining direct hemodynamic pressure measurements is incorrect leveling of the transducer. To ensure accurate pressure readings, the transducer must be at mid-heart level. The transducer must be releveled with each position change of the patient. Because errors in leveling can significantly impact treatment decisions, all leveling should be performed using a carpenter's level or a leveling tool designed for hemodynamic monitoring applications.
- Pressure transducers must be "zeroed" to eliminate the effects of atmospheric pressure on the measurements obtained. Depending on flight patterns and altitudes, transducers may be zeroed at initial connection to the transport monitor, at cruising altitude, and at the destination.
- Direct pressure measurements are affected by changes in intrathoracic pressure. To obtain accurate measurements, readings should be taken at end expiration (the lower portions, or valleys, of the rise-and-fall pattern for mechanically ventilated patients; and the peaks of the rise-and-fall pattern for spontaneously breathing patients).
- CCTPs should become familiar with transport monitors, cables, and transducers. Cables must be compatible with the equipment used at the referring and receiving hospitals.
- CCTPs should be familiar with common problems encountered during hemodynamic monitoring and actions to resolve them. The most common complication during transport of a patient with a central line, an arterial line, or a PAC is accidental dislodgement or removal of the line or catheter. If an invasive line is completely removed from a patient, direct pressure is immediately applied to the insertion site and held until the bleeding stops. If a catheter dislodges but does not come completely out of the patient, replacement should not be attempted. An attempt should be made to aspirate blood from each lumen to determine if each one remains in a blood vessel. Options should be discussed with medical control. A catheter that must be removed is gently withdrawn from the patient and bleeding is controlled at the insertion site.

- Prompt recognition and reversal of shock avoid a rapidly irreversible sequence that can result in the patient's death. Understanding the relationship between hemodynamic measurements and the different types of shock can help CCTPs recognize the type of shock and assess the effectiveness of treatment during transport.
- Oxygen saturation and gas expansion are concerns during flight. CCTPs should closely monitor the patient's oxygen saturation level to respond to changes in the patient's condition and maintain sufficient levels of inspired oxygen. Gas expansion should be addressed by removing air from IV bags, using pumps for medication infusions, and zeroing transducers.

Vital Vocabulary

afterload The tension or stress that develops in the ventricles during systole; measured by pulmonary and systemic vascular resistance.

Allen test A technique in which the patient's hand is initially held above the head while the fist is clenched and the radial and ulnar arteries are compressed; the hand is then lowered and the fist is opened, ulnar pressure is released, and radial pressure is maintained; after ulnar pressure is released, color should return to the hand within 6 seconds.

arterial lines Catheters inserted into the patient's arterial vascular system for the purpose of producing a waveform with pressure measurements; also called an A-line.

cardiac index A hemodynamic value that adjusts a patient's cardiac output to take into account his or her total body surface area.

cardiac output (CO) The amount of blood pumped out of the heart in 1 minute; the product of the stroke volume (average 70 mL) and the heart rate (average 60 to 100 beats/min).

central venous lines IV access catheters that terminate in central circulation, usually just proximal to the right atrium.

central venous pressure (CVP) The pressure in the superior vena cava (average 2 to 6 cm H_2O); reflects the pressure in the venous system when the blood is returned to the right atrium; indicative of a patient's fluid volume status and right-sided heart performance.

dampened waveform A hemodynamic pressure waveform that appears to have lost crisp deflections.

diastolic blood pressure (DBP) The trough or resting pressure in the arterial system that occurs during ventricular diastole.

dicrotic notch The brief increase in aortic pressure reflected in a notching of the wave; caused by the sudden closure and spring back of the aortic valve leaflets; signals the start of diastole.

Fick principle A method of indirectly determining cardiac output, in which the amount of oxygen uptake of blood as it passes through the lungs is equal to the oxygen concentration difference between mixed venous and arterial blood; the formula uses assumed values for oxygen consumption derived from basal metabolic studies on healthy subjects, which may or may not be valid in critically ill patients.

Frank-Starling law A law of physiology that states that the greater the myocardium is stretched, the greater the force of contraction.

invasive hemodynamic monitoring A term describing methods for assessing the physiologic condition of the three principle components of the cardiovascular system: heart, vascular network, and fluid volume; mainly assesses the capability of a patient's heart to pump the requisite amount of blood to the

body, but also can assess compliance, tone, resistance of the vascular network, and fluid status; includes a variety of pressure values and other measurements.

left ventricular end-diastolic pressure The pressure exerted on the left ventricle at the end of diastole; the normal value is 4 to 12 mm Hg and is measured by using a pulmonary artery catheter.

left ventricular stroke work index A calculation of the contractility of the left ventricle indexed to the patient's body surface area; same as stroke volume index.

mean arterial pressure (MAP) Represents the average (that is, constant) pressure in the arterial vasculature; a function of systolic and diastolic blood pressures.

mixed central venous oxygen saturation ($Scvo_2$) The percentage of oxygen bound to hemoglobin in blood returning to the right side of the heart from the head and upper body, representative of oxygen extraction by the head and upper extremities.

mixed venous oxygen saturation (Svo_2) The percentage of oxygen bound to hemoglobin in blood returning to the right side of the heart, representative of global oxygen extraction.

phlebostatic axis An imaginary point located at the fourth intercostal space, mid-chest level, which serves as an external landmark for the right atrium.

preload The end-diastolic stretch of the muscle fibers of the ventricle; measured by right atrial pressure or central venous pressure and wedge pressure.

pulmonary artery catheter (PAC) A catheter with a balloon near its tip that is passed through a vein into the right side of the heart, through the right ventricle, and into the pulmonary artery; records the pressure transmitted back from the left atrium; also referred to as a Swan-Ganz catheter.

pulmonary artery pressure The pressure measured in the pulmonary artery, usually displayed with a pressure waveform and digital systolic, diastolic, and mean values.

pulmonary capillary wedge pressure (PCWP) The mean pressure measured while occluding the pulmonary artery with a balloon-tipped catheter proximal to the site of measurement; reflects left atrial pressure (also called pulmonary artery wedge pressure and pulmonary artery occlusion pressure).

pulmonary vascular resistance (PVR) The resistance or impedance to ejection of the right ventricle of the heart.

pulse pressure The difference between systolic and diastolic blood pressures.

referencing The process of ensuring that the hemodynamic pressure transducer is at the level of the left atrium.

right ventricular pressure The pressure in the right ventricle that consists of systolic, diastolic, and mean pressures; important during insertion and use of a PAC.

right ventricular stroke work index A calculation of contractility of the right ventricle indexed to the patient's body surface area.

Seldinger technique The most common technique for inserting a central venous line; involves inserting a needle with a syringe, then inserting a guide wire into the needle. Once the guide wire is in place, the needle is removed, an incision is made, and a catheter is inserted over the guide wire; the guide wire is then removed.

stroke volume (SV) The amount of blood ejected by the ventricles during each contraction; varies between 60 and 130 mL/beat, with the average being 70 mL.

stroke volume index A calculation of contractility of the left ventricle indexed to the patient's body

surface area; same as the left ventricular stroke work index.

systemic vascular resistance (SVR) The resistance or impedance to ejection of the left ventricle of the heart.

systolic blood pressure (SBP) Peak pressure in the arterial system that occurs during ventricular ejection or systole.

thermistor The apparatus used for quickly determining very small changes in temperature.

triple-lumen catheter A type of catheter consisting of three distinct continuous tubes that allow for pressure monitoring, blood sampling, and fluid and drug administration.

zeroing A process of calibrating a pressure transducer to eliminate extraneous atmospheric and hydrostatic pressures from the data being measured.

Intra-aortic Balloon Pump Therapy

Authors

Phillip L. Coule, MD

Mike McEvoy, PhD, RN, CCRN, REMT-P, CIC

Susan Spadoni, RN, BSN

Objectives

1. List the five phases of the cardiac cycle and describe the associated events that affect:
   - Blood volume in the heart chambers
   - Coronary perfusion as it relates to the cardiac cycle
   - Myocardial oxygen demand
   - The arterial pressure waveform
   - The physiologic effects of heart failure (p 600–601)
2. Generally describe the setup and operation of an intra-aortic balloon pump (IABP) (p 598).
3. Describe the mechanics of the IABP, including the following:
   - Basic design and functions of the IABP
   - Catheter structure and function
   - Balloon structure and function (p 603)
4. List indications for IABP therapy (p 609).
5. List contraindications to IABP therapy (p 611).
6. Describe methods and locations of insertion (p 613).
7. Discuss complications from IABP insertion (p 617–619).
8. Discuss timing of balloon inflation and deflation (p 608–609).
9. Explain modes of IABP timing (p 605–606).
10. Define these primary physiologic effects achieved by inflation and deflation of the intra-aortic balloon:
    - Diastolic augmentation
    - Systolic afterload reduction
    - Improved coronary flow (p 603–604)
11. Identify improper balloon inflation timing and discuss the hemodynamic effects and corrective action during each of the following stages:
    - Early inflation
    - Early deflation
    - Late inflation
    - Late deflation (p 608–609)
12. Discuss transport considerations and potential complications of IABP therapy.
    - Altitude changes
    - Cardiac arrest during transport Depletion of helium

- Console failure
- Balloon rupture
- Limb ischemia
- Insertion site bleeding (p 612–621)

13. Discuss cardiac-assist devices, including:
    - Extracorporeal membrane oxygenation (ECMO)
    - Implanted left ventricular-assist device (LVAD), right ventricular-assist device (RVAD), and biventricular-assist device (BiVAD) (p 619–621)

Introduction

As described in the preceding chapters, intensive cardiac care requires special technical knowledge and skills, especially for the transport of patients receiving **intra-aortic balloon pump (IABP) therapy**, in which a balloon connected to a pump via a catheter has been inserted into the aorta to provide temporary assistance to a failing heart. Although the transport of the patient during IABP therapy is a daunting task for trained transport professionals, with proper study and education, CCTPs can obtain the knowledge and skill necessary to feel more comfortable in this situation. It is important to note, however, that IABP therapy is a highly advanced skill. This chapter discusses maintaining IABP therapy, recognizing and correcting problems, and performing emergency procedures for IABP failure and is not intended to be all inclusive in regard to IABP therapy.

Previous chapters dealt primarily with the electrical components of the cardiac cycle. This chapter addresses a therapy for compromised mechanical (pumping) function of the heart: the IABP. Electrical and mechanical functions of the heart are interdependent, thus failure of one will quickly lead to failure of the other.

IABP therapy begins with the insertion (by a trained and credentialed physician or surgeon) of a balloon, typically via the femoral artery, into the descending thoracic aorta. The tip of the balloon catheter is located just distal (approximately 2 cm below) the takeoff of the left subclavian artery. Once in place, the balloon is connected to a console to shuttle helium gas, inflating the balloon at the onset of diastole and deflating just before systole (ventricular ejection). Inflation and deflation are timed to the cardiac cycle, resulting in significant augmentation of flow to the coronary and renal arteries during diastole (increased supply) and substantially reduced afterload during systole (decreased demand). The **timing** of inflation and deflation is crucial; if inflation and deflation do not occur at the proper time in the cardiac cycle, the device will not only fail to yield the desired results, but also could harm the patient. One of the CCTP's main roles in transporting a patient undergoing IABP therapy is to ensure that timing occurs at the proper points in the cardiac cycle. Proper timing is ensured by reading the patient's electrocardiographic (ECG) and pressure waveforms and continuously monitoring the patient's condition and all devices. If necessary, the CCTP modifies the timing. Other CCTP responsibilities include securing the patient to prevent movement of the balloon (which can create significant problems or injuries) and ensuring that all equipment has the necessary power supply to continue operating during transport **Figure 15-1**.

Figure 15-1 An important CCTP responsibility when transporting a patient with an intra-aortic balloon is to secure the patient to prevent balloon movement.

To provide proper care to a patient undergoing IABP therapy, it is necessary to have a basic understanding of normal heart anatomy and physiology, the pathophysiology of heart failure, and the benefits that IABP therapy offers. After mastering an understanding of these basic principles, CCTPs may apply them to the use of any model or brand of IABP, with some education specific to each model.

History

Intra-aortic balloon pumping, or counterpulsation, was first used for patients in cardiogenic shock in the late 1960s. Since that time, the number of indications for the intra-aortic balloon (IAB) has steadily increased. Today, IABP counterpulsation is the therapy most frequently used worldwide to assist patients with left ventricular (LV) failure. Original IABP units were crude in design with manual timing of inflation and deflation, requiring great skill and constant monitoring to ensure correct timing of inflation and deflation. With improvements in technology, today's IABP units are computer equipped to determine correct inflation and deflation timing and have benefited from miniaturization so that some IABP models will fit easily into a helicopter for transport. The IAB catheters have also become smaller, with multilumen designs allowing for arterial pressure monitoring and IAB inflation and deflation and, in some models, fiberoptic sensors. With these newer consoles, it is possible to initiate IABP therapy in the community hospital setting and transport the patient in a more stable condition to a larger facility for further diagnosis and treatment.

Cardiovascular Anatomy and Physiology

To understand the mechanics of IABP therapy and the benefits it can offer to a patient with compromised cardiovascular status, it is helpful to review some basic concepts of cardiovascular anatomy and physiology.

The heart lies in the thoracic cavity beneath the sternum; approximately two thirds of it is left of the

midsternal line. The **atrioventricular (AV) valves** (mitral and tricuspid) lie between the atria and the ventricles, and the **semilunar valves** (aortic and pulmonic) are the exits from the ventricles **Figure 15-2**. The AV valves have **chordae tendineae**, which attach the edge of the valve to the **papillary muscles** attached to the endocardium. The chordae tendineae hold the AV valves in place in their closed position and prevent them from prolapsing into the atria during systole, or ventricular contraction. In contrast, the semilunar valves do not have chordae tendineae but are attached to their respective vessels at their outer edges. The valve action depends on the valve leaflets (the thin leaflike cusps or flaps that compose the valves) being pushed together by the force of the blood trying to flow back into the heart, which keeps them in a closed position, much like a parachute opening. The opening and closing of the semilunar valves is related to the pressure changes that occur in the heart, aorta, and pulmonary artery.

The purpose of each of the cardiac valves is to prevent the backward flow of blood in the heart. If a valve is structurally defective, a backward flow of blood through the valve is referred to as valvular regurgitation or insufficiency. A valve scarred so severely that its lumen is reduced while in the open position is referred to as valvular stenosis.

The coronary arteries supply the heart muscle with oxygen. The ostea (openings) to the coronary arteries are located at the base of the aorta, just **caudal** to the attachment points of the aortic valve leaflets **Figure 15-3**. This anatomy is extremely important because their location means that the ostea are obstructed when the valve is in the open position. Therefore, although this is the time that the heart is ejecting blood, virtually none of it can get into the coronary arteries. In addition, because the coronary arteries are embedded in the myocardium, resistance in these vessels increases greatly during systole. As a result of these two factors, *virtually all coronary perfusion occurs during diastole.*

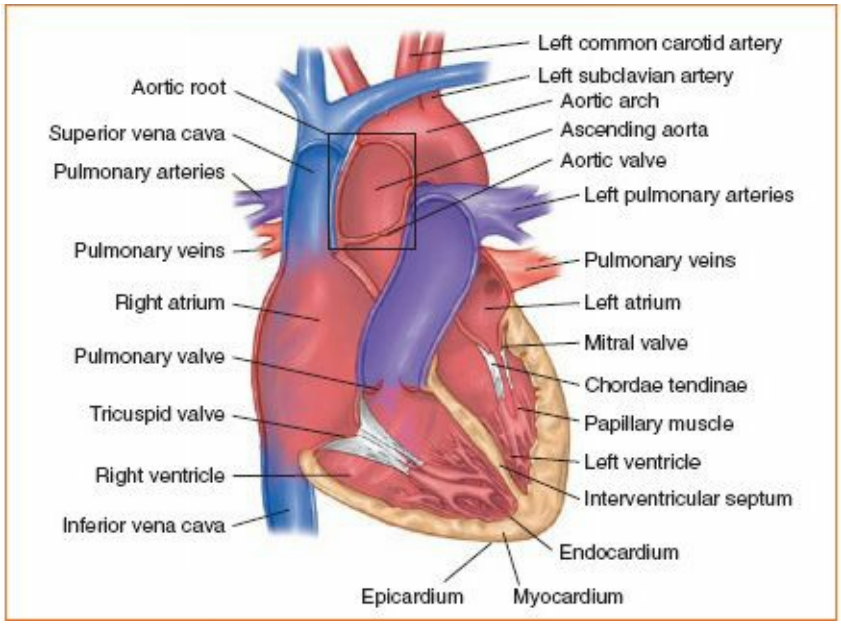

Figure 15-2 Anatomy of the heart.

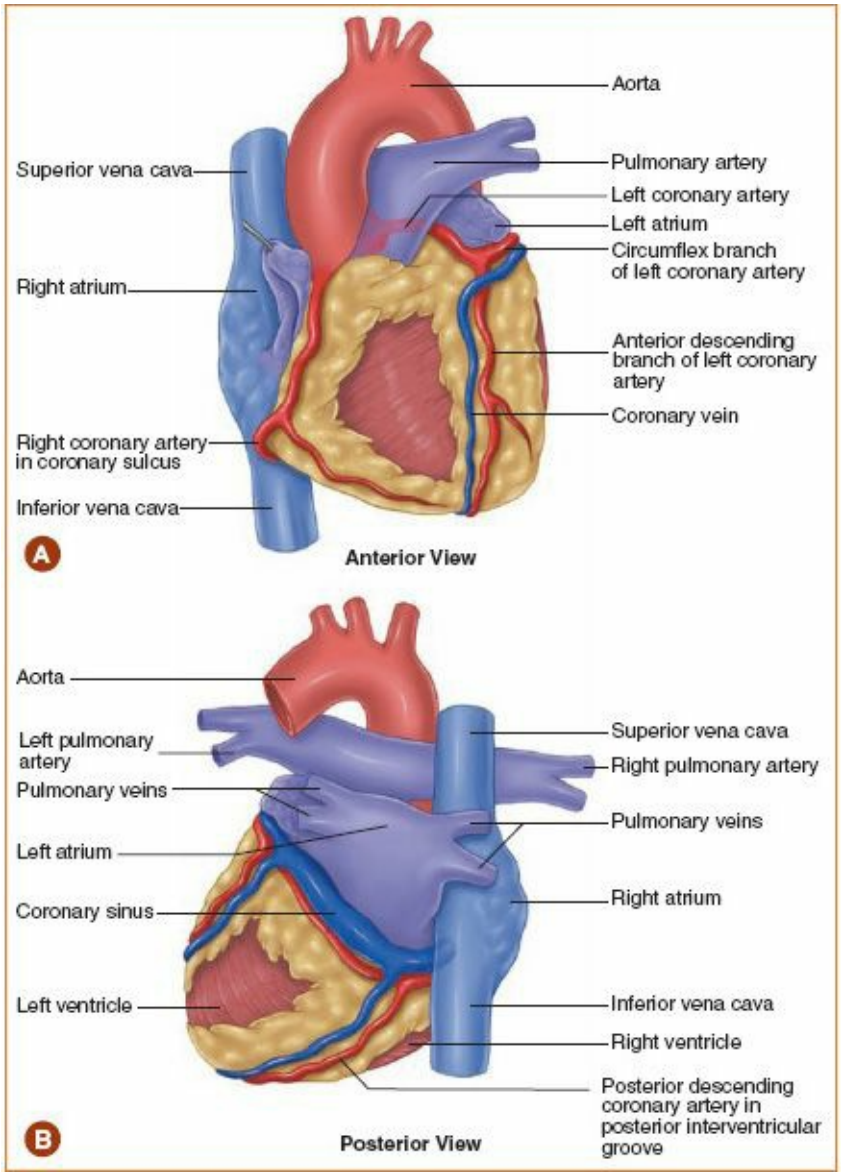

Figure 15-3 Coronary arteries. **A.** Anterior view, showing takeoff point of left and right main coronary arteries from the aorta. **B.** View from below and behind, showing the coronary sinus.

Cardiac Cycle

The cardiac cycle consists of two main stages: **systole**, the period of work or the contraction phase of the heart cycle, and **diastole**, the period of rest or the relaxation phase of the heart cycle. Systole and diastole can be further divided into five phases: atrial systole, isovolumetric contraction, ventricular ejection, isovolumetric relaxation, and ventricular filling **Figure 15-4**.

Atrial Systole

Atrial systole begins in response to an electrical impulse from the sinoatrial (SA) node, indicated as the P wave on an ECG. As the electrical impulse conducts through the atrial myocardium and internodal pathways, the atrium depolarizes and contracts. The mitral and tricuspid valves are open before atrial systole with blood already flowing passively from the atria into the ventricles. The contraction of the atria ejects additional blood into the ventricles and accounts for 20% to 30% of the ventricular filling volume (preload). This “atrial kick” raises ventricular volume and pressure and is important to the effective contraction of the ventricle because of the relationship between the stretching of the myocardium and the force of contraction of the ventricles. This relationship is known as the Frank-Starling curve. Its importance to heart failure will be discussed later.

Isovolumetric Contraction

During **isovolumetric contraction**, the electrical impulse from the atria conducts through the AV node to the ventricular conduction system, causing the ventricles to depolarize and contract. Immediately after ventricular contraction begins, ventricular pressure rises abruptly, closing the AV valves. The volume of blood in the ventricles just before these valves close is the ventricular **preload**. As mentioned, ventricular preload is important to cardiac function because of the relationship between ventricular preload and contractility. This relationship is described as the **Frank-Starling curve**.

During isovolumetric contraction, the pressure in the aorta and pulmonary arteries is higher than the pressure in the ventricles, and, therefore, the semilunar valves remain closed. The pressure in the ventricles continues to rise during ventricular contraction but, because all of the cardiac valves are closed, there is no change in ventricular blood volume. (*Isovolumetric* means "same volume.")

Ventricular Systole

Once the pressure in the pulmonary artery is equaled by the pressure in the right ventricle, the pulmonary valve opens and the right ventricle begins to eject blood into the pulmonary artery. The pulmonary valve opens slightly before the aortic valve because the pressure gradient is less for the pulmonary circulation. As the pressure in the left ventricle exceeds the pressure in the aortic root (the section of the base of the aorta that is attached to the heart, including the leaflets of the aortic valve and the openings where the coronary arteries attach), the valve leaflets open and allow the left ventricle to eject the blood into the aorta. During ventricular ejection, the aortic valve leaflets are forced against the wall of the aorta (their open position). As mentioned earlier, no coronary perfusion occurs at this stage because when the aortic valve leaflets are open, they block the coronary arteries.

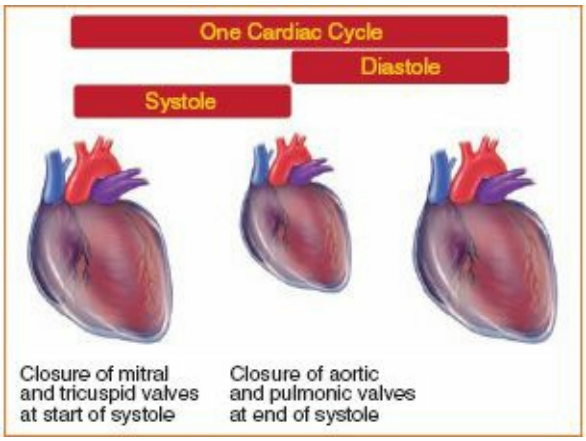

Figure 15-4 Systole and diastole.

Isovolumetric Relaxation

Near the end of ventricular ejection, the ventricles begin to relax as ventricular tissue starts to repolarize. As the ventricles relax, pressure in the ventricles drops below the arterial pressure, and the semilunar (aortic and pulmonary) valves close. The valves close because of the attempt of blood to flow backward into the heart. During this **isovolumetric relaxation** phase, the AV valves have not yet opened. Continued ventricular relaxation leads to the decrease in ventricular pressure that will soon allow the AV valves to open as atrial pressure increases.

Ventricular Filling

When pressure in the ventricles drops below the pressure in the atria, the mitral and tricuspid valves open and ventricular filling begins. Blood flows passively from the atria through the AV valves into the ventricles. When the SA node produces an electrical impulse that initiates atrial systole, the cardiac cycle

begins again.

The five phases of the cardiac cycle are summarized in **Table 15-1**.

Pressure Waveforms

Because an understanding of the pressure changes in the aorta is vitally important to IABP therapy, the following discussion of pressure waveforms focuses on the left side of the heart and the aorta. Pressure changes in the left ventricle during the stages of the cardiac cycle are described as follows:

TABLE 15-1 Summary of the Cardiac Cycle

Phase	Events
Atrial systole	The sinoatrial node gives impulse. Atrium depolarizes. Atria contract, forcing blood into ventricles. Ventricular volume and pressure are increasing.
Isovolumetric contraction	Impulse travels through the atrioventricular node. Ventricles depolarize. Mitral and tricuspid valves close. Ventricular pressure rises abruptly.
Ventricular ejection (systole)	Pressure in the pulmonary artery equals pressure in the right ventricle. Pulmonary valve opens; right ventricle ejects. Pressure in the left ventricle exceeds pressure in the aortic root. Aortic valve opens; left ventricle ejects.
Isovolumetric relaxation	Ventricles relax and repolarize. Pressure in ventricles drops to less than arterial pressure. Aortic and pulmonary valves close owing to blood attempting to flow backward.
Ventricular filling (diastole)	Ventricular pressure drops below pressure in the atria. Mitral and tricuspid valves open. Blood flows through the atria and into the ventricles. Cycle begins again.

1. At the beginning of the cardiac cycle, aortic pressure is at its lowest (ie, diastolic) level. The elastic state and vascular resistance of the arteries determine this pressure. During diastole, the AV valves are open and blood flows passively from the atria into the ventricles. The pressures in the ventricles and atria are nearly equal and significantly lower than the pressure in the aorta.
2. The SA node depolarizes, causing the atria to contract. This contraction causes the pressure in the atria and ventricles to rise. As the impulse is conducted through the ventricles, the pressure rises sharply.
3. When the pressure in the left ventricle exceeds that of the left atrium, the mitral valve snaps closed.

The pressure continues to rise until the pressure in the aorta is exceeded, causing the aortic valve to open. As the aortic valve opens and blood enters the aorta, the pressure will rise to the peak systolic level and then begin to fall as ventricular ejection tapers.

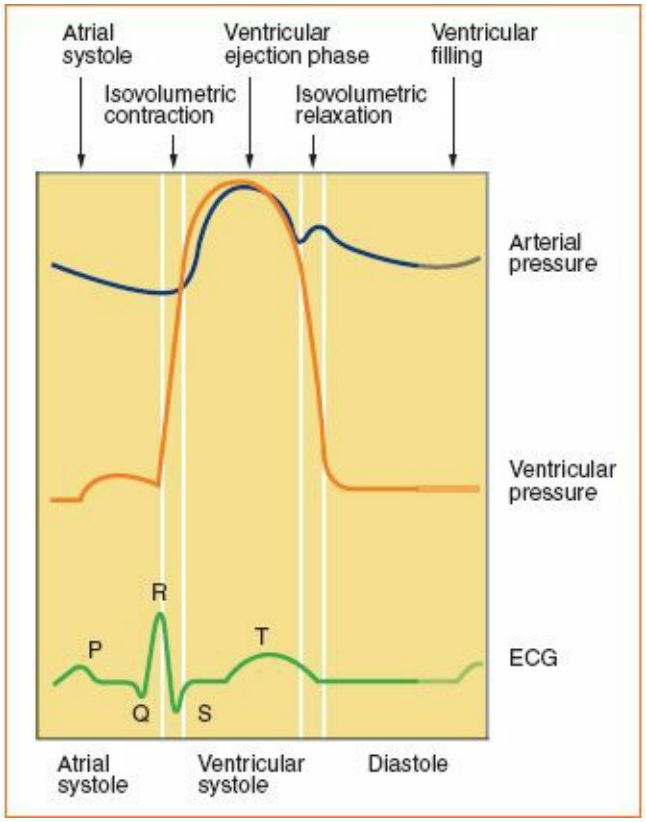

Figure 15-5 Arterial pressure waveform. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

4. The aortic pressure begins to decrease. As the pressure in the left ventricle drops, the pressure in the aorta becomes greater than that in the left ventricle. This change in pressure causes a slight backward flow of blood into the ventricle, and the backward flow causes the valve leaflets to be forced outward and into their closed position, much like that of a parachute opening.
5. As the aortic valve leaflets are forced outward into place, the pressure gradient across the valve increases significantly because the ventricle continues isovolumetric relaxation. The valves "bulge" slightly under the pressure of the blood from the aorta and then spring back slightly. This springing back causes a slight "bump" in the aortic pressure waveform, referred to as the **dicrotic notch**, signaling the onset of diastole. With the valve closed and the ventricles continuing to relax, the ventricular pressure decreases rapidly **Figure 15-5**.
6. When the pressure in the ventricle is less than the pressure in the atrium, the mitral valve opens and blood begins to flow passively into the ventricle from the atrium.

Myocardial Oxygen Supply and Demand

Myocardial oxygen supply must balance myocardial oxygen demand (**myocardial oxygen consumption [MVO_2]**) to meet myocardial metabolic requirements or ischemia will result. Factors that can affect myocardial oxygen supply include coronary artery anatomy, diastolic pressure, diastolic time, and oxygen extraction. Because the majority of blood flow to the coronary arteries occurs during diastole when the ventricle is at rest, diastolic pressure and time spent in diastole (diastolic time) profoundly affect the blood flow to the coronary arteries and, thus, myocardial oxygen supply. Because the time required to

complete systole is fixed, any increases in heart rate (HR) must result from decreased diastolic time and, therefore, less time to perfuse the coronary arteries.

The MVO_2 varies with HR, preload, afterload, and contractility; any increase in these factors increases oxygen demand.

Heart failure is a cyclic phenomenon. Injury to the myocardium, as might occur with an acute myocardial infarction (MI), results in a series of physiologic and hemodynamic changes that can affect the balance between oxygen supply and demand. The injury (from whatever cause) decreases pumping efficiency, cardiac output (CO), and arterial pressure. CO is composed of stroke volume (SV) × HR (CO = SV × HR). In this equation, for CO to remain the same, a decrease in SV or HR must be compensated by an increase in the other. Therefore, if the ability of the heart to pump effectively were impaired (such as might occur with an MI), causing a drop in the SV, the HR must increase for CO to remain the same. As discussed previously, coronary perfusion occurs only during diastole, and any increase in HR results in less diastolic time and, thus, less time for coronary perfusion. Because the HR is increased, the MVO_2 also increases, worsening the mismatch of oxygen supply and demand. The decreased coronary perfusion, coupled with the increased MVO_2, leads to worsened ischemia. Ischemia causes the heart to pump less effectively, leading to a greater decrease in SV. The HR increases to maintain CO, and the cycle of heart failure continues **Figure 15-6**.

The treatment of cardiac failure is aimed at restoring normal cardiac function and the balance between myocardial oxygen supply and oxygen demand. If initial intervention fails to restore the balance, the IABP offers a mechanical means of rebalancing them.

The Intra-aortic Balloon Pump

The IABP is a device that helps increase the blood flow to the heart muscle, thereby decreasing the heart's workload. It contains a small balloon ranging from about 25 to 50 mL of gas capacity for adults (sizes vary by manufacturer). The proper size of IABP catheter is determined according to patient height as indicated in the manufacturer's instructions. Typically, the IABP catheter is threaded into the descending aorta through the femoral artery. Insertion can be accomplished through a sheath (a large-diameter catheter placed into a vessel to allow smaller catheters or devices to be inserted through the catheter lumen into the vessel) or by using a catheter designed for sheathless insertion. When access to the femoral artery has already been obtained using a sheath (such as in a cardiac catheterization laboratory), a practitioner inserting an IABP catheter may decide to insert the device through the existing sheath rather than making a separate puncture. When IABP placement is elective or planned or when significant concerns about leg ischemia exist, sheathless insertion offers the advantage of an overall smaller diameter device in the access vessel. Sheathless insertion, then, may reduce complications of limb ischemia by reducing the size of the obstruction in the femoral artery. As mentioned, IABP therapy is also called counterpulsation because the balloon deflates during systole and inflates during diastole. An ECG machine determines when the balloon should be inflated and deflated.

Mechanics of IABP Function

Balloon Structure and Position

The IAB catheter consists of a long, narrow balloon mounted on a thin catheter. Typical catheters have two lumens: a central lumen and a gas lumen. The **central lumen** is used to guide catheter insertion into the femoral artery and through the arterial system, positioning the IAB tip in the descending thoracic aorta just below the origin of the left subclavian artery **Figure 15-7**. Alternative placement strategies for IAB

catheters include access through the axillary artery and, occasionally, transthoracic placement, which is typically reserved for critically ill patients unable to be weaned from cardiopulmonary bypass following cardiac surgery in whom femoral access is not possible or is contraindicated. Once the catheter is in place, the central lumen also allows monitoring of aortic blood pressure through a setup much like a standard arterial line. The **gas lumen** carries helium gas from the pump console to the IAB to control balloon inflation. Evolving technologies also incorporate a fiberoptic catheter lumen used to measure aortic pressure and (in some models) aortic oximetry.

Counterpulsation Sequence

Following placement of the catheter, it is connected to the IABP console. The IABP console pump inflates and deflates the balloon with helium in conjunction with the mechanical cardiac cycle. Helium is used because of its low molecular weight, which allows it to be pumped rapidly without much turbulence from the flow of the gas. Helium also adds safety because it is less likely to cause an air embolus if the balloon ruptures. Correct IABP timing inflates the balloon during diastole when the left ventricle is relaxed and the coronary arteries are filling with oxygenated blood **Figure 15-8**.

Physiologic Effects of IABP Therapy

For patients in cardiogenic shock, IABP therapy lowers systolic blood pressure as the balloon deflates at the onset of systole and raises diastolic pressure when the balloon inflates during diastole. Mean arterial pressure (MAP) will also rise as a result of the **diastolic augmentation**. Diastolic augmentation may be best thought of as a "second systole" because it occurs *during* diastole, but the rapid inflation of the balloon augments the diastolic pressure and effectively creates a second pressure wave to perfuse the heart and tissues. This sudden increase in pressure improves the flow to the coronary arteries and systemic circulation.

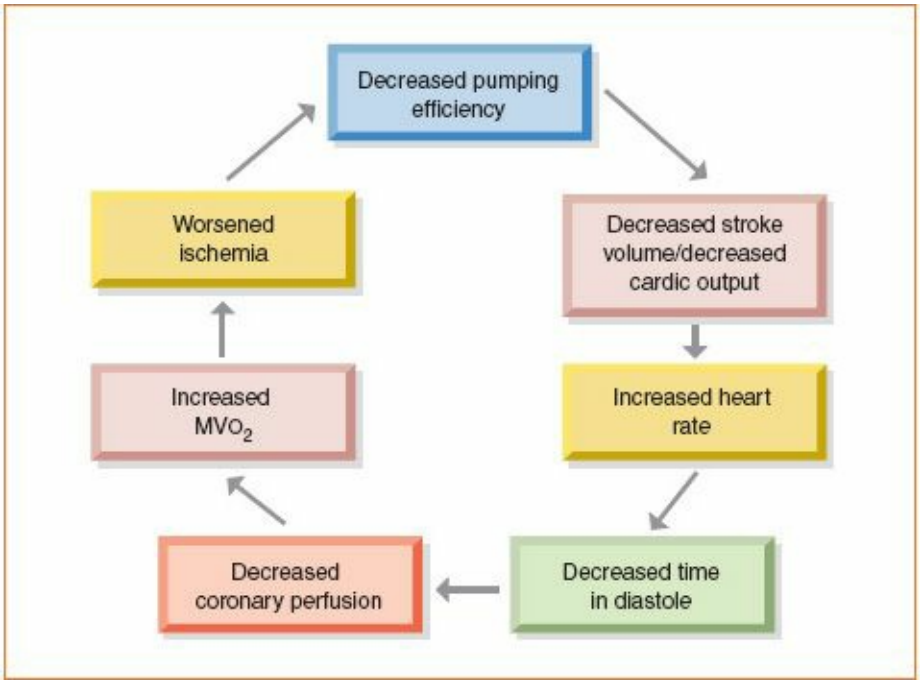

Figure 15-6 The cycle of heart failure.

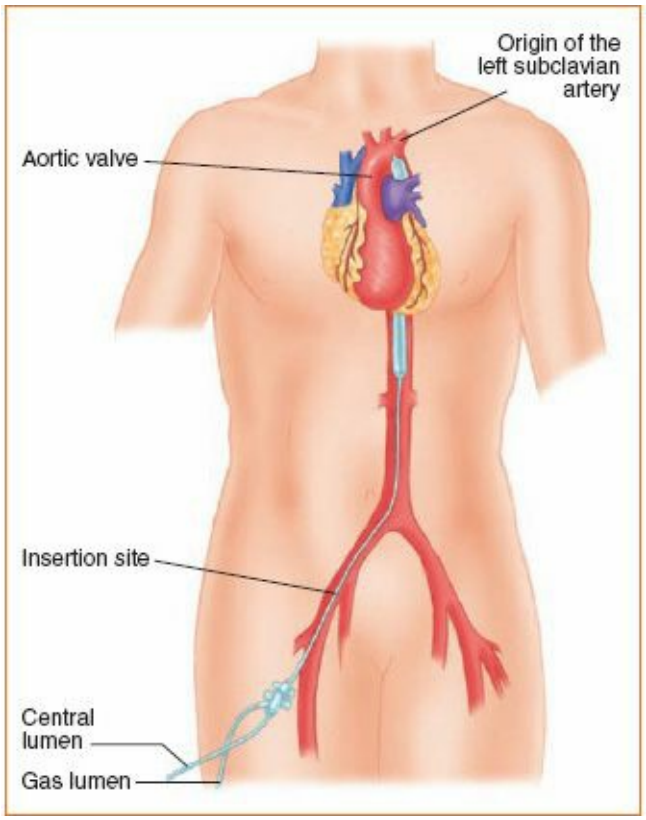

Figure 15-7 Intra-aortic balloon placement. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

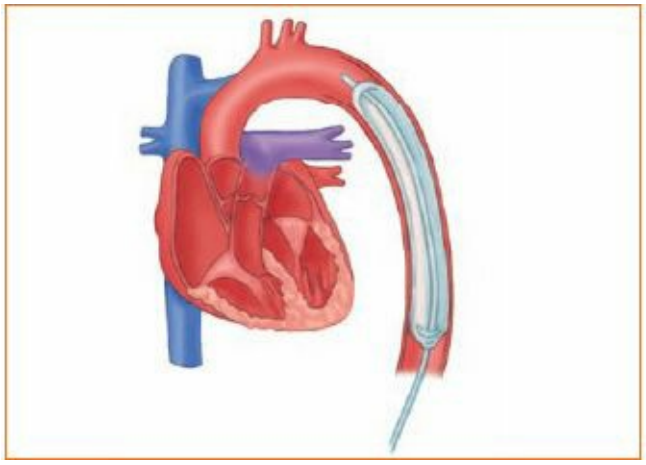

Figure 15-8 Intra-aortic balloon inflation. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

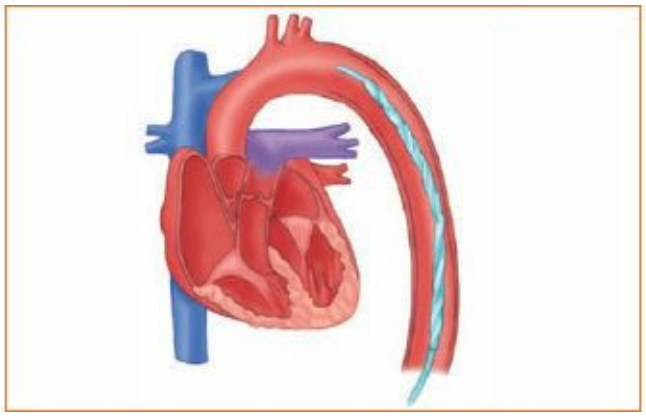

Figure 15-9 Intra-aortic balloon deflation. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

The balloon deflates at the end of diastole, just before the next ventricular ejection **Figure 15-9**. The sudden deflation of the balloon causes a drop in aortic pressure because the space that was occupied by the balloon is suddenly gone. This dramatic drop in pressure reduces the resistance against which the ventricle has to work to open the aortic valve and eject blood. To review from previous discussion, the ejection from the left ventricle begins when the pressure in the left ventricle is greater than that in the aorta. The sudden deflation of the IAB results in a lower pressure that must be overcome for the valve to open and the ejection of blood to begin. Because the majority of the myocardial oxygen demand is expended in overcoming this pressure, the result is a dramatic decrease in MVO_2. In addition, because less pressure must be overcome, the SV is also maximized. Because CO = SV × HR, an increase in SV allows the HR to decrease while still maintaining CO. A decrease in HR leads to increased diastolic time and, therefore, longer coronary perfusion time. The improvement in CO, with a lower MVO_2, effectively interrupts the cycle of heart failure and allows the heart to "rest" and recover from the insult that started the cycle. The increase in CO results in increased renal and peripheral perfusion and, therefore, may also improve metabolic derangements that may have developed as a result of the shock state during the period of decreased CO.

Balloon Volume or Augmentation

Each IABP console allows the operator to control the volume of gas shuttled back and forth to the balloon with each counterpulsation cycle. This control is variously referred to as augmentation or balloon volume. Typically, when IABP therapy is initiated immediately after the IABP catheter is inserted, software in the console begins shuttling gas at the lowest volume possible, gradually increasing the volume during several inflation-deflation cycles to allow the balloon to unfurl from the compressed condition in which it is packaged. There is little reason during routine use or during transport that the balloon volume or augmentation should be adjusted at less than maximal or full volume. This control is used with nonstandard balloon catheters as might be inserted in pediatric patients or, in some settings, to wean the patient from IABP therapy before removing the balloon. Given that a fully inflated balloon rarely occupies more than half the total diameter of the average aorta, weaning is more efficiently accomplished by reducing the assist ratio or frequency (discussed later in this chapter) rather than the inflation volume.

Waveform Changes and Triggers

As mentioned, proper IABP timing is essential to providing the full benefit of IABP therapy. The console constantly monitors the arterial pressure waveform, the patient's ECG, and the balloon gas pressure waveform during pumping to evaluate the timing and effectiveness of the therapy. The arterial pressure waveform that the IABP console monitors may come from the central lumen of the IAB catheter, from the fiberoptic catheter, or from a peripheral arterial catheter **Figure 15-10**. IAB inflation and deflation can be set to trigger from the ECG, from pressure changes, from a pacemaker, from an internally preprogrammed rate, or from combinations of these. The most reliable is the ECG. Triggering the IABP from the ECG provides the most optimal timing for inflation and deflation while still permitting the IAB to immediately deflate if the console senses an increase in pressure indicating ventricular ejection (such as with a premature ventricular or atrial contraction), a paced beat, or another signal that systole has begun. Most modern IABP console computers are able to track irregular arrhythmias and tachyarrhythmias (such as atrial fibrillation) and adjust timing as needed to protect the patient. The provider caring for the patient chooses the trigger best suited to the patient's condition.

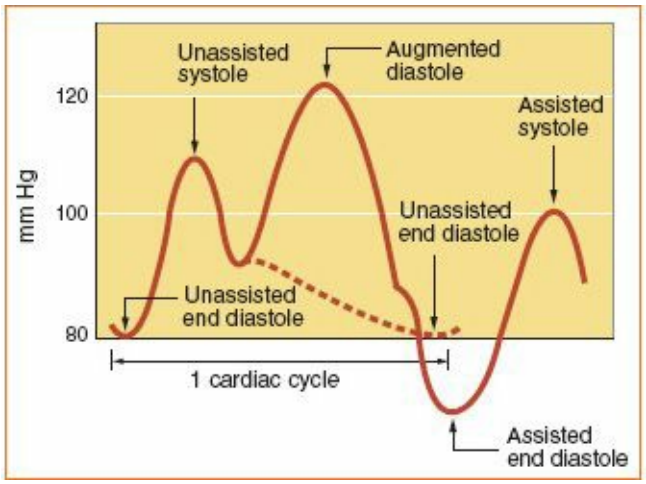

Figure 15-10 Arterial pressure waveform during intra-aortic balloon pump therapy. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

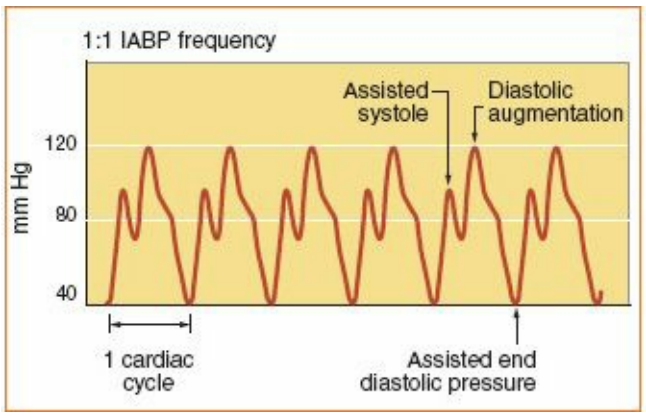

Figure 15-11 Diastolic augmentation. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

Proper IABP Timing

The timing of IABP therapy can be selected from a variety of triggers. Early IABP machines had only manual timing, requiring great skill on the part of the operator to adjust the pump for proper timing with every change in the HR of more than 10 beats/min. The newer generation IABP consoles have sophisticated software capable of adjusting balloon inflation and deflation through a variety of changes and arrhythmias. However, computers are not infallible, and the IABP operator must constantly monitor the IABP to ensure correct operation and timing. Incorrect timing can be detrimental to the patient, not only because it does not maximize the therapy, but also because errors in timing, such as late deflation of the balloon, can worsen heart failure. Likewise, early inflation can damage the aortic valve.

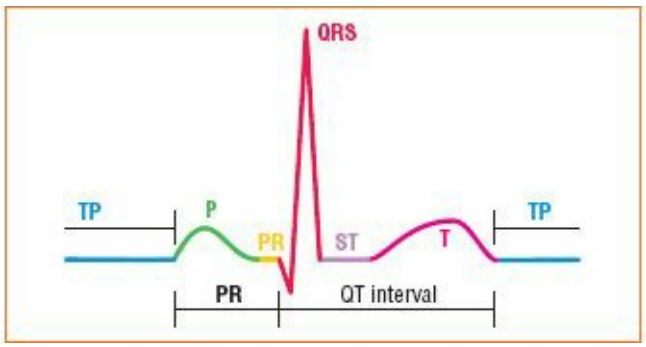

Figure 15-12 The components of an electrocardiographic strip.

Trigger Selection

Trigger signals available to initiate balloon inflation and deflation vary by manufacturer, although all IABP consoles usually default to using the QRS complex from the ECG to locate each cardiac cycle **Figure 15-12**. Early model IABP consoles triggered inflation from the midpoint of the T wave and deflation from the R wave on the ECG. The operator then manually adjusted the inflation and deflation to optimize timing. This so-called conventional timing worked fairly well as long as the R-R intervals remained consistent. Changes in HR, arrhythmias, or ectopic beats, or any other change in diastolic time posed problems for older IABP consoles and required manual correction of timing. Present-generation IABP consoles have sophisticated computer software capable not only of recognizing changes in HR, balloon pressures, patient blood pressures, tubing dead space, and console pneumatic rate of response, but also instantly making changes in timing to inflate and maintain balloon inflation throughout diastole. Modern-day or "real" timing using sophisticated computer software offers greater afterload reduction and improved MAP by extending the inflation period into the early isovolumetric contraction period.

The safest and, usually, the default trigger on most IABP consoles is the ECG, which allows the pump to trigger from the R wave on the patient's ECG for deflation. Pacer spikes are ignored in most consoles when using the ECG as the trigger source. Some manufacturers offer more than one ECG trigger mode, depending on HR and morphologic features of the ECG complexes. During ECG triggering, deflation will also occur if the IABP console senses an increase in systolic blood pressure indicative of the onset of systole, regardless of whether an R wave appears on the ECG.

Pressure can also be selected as a trigger source. The systolic upstroke of the patient's arterial pressure waveform is used as the trigger source. Using pressure is not as desirable as using the ECG as the trigger because it delays deflation until systolic ejection has already begun, reducing the beneficial effects of deflation simultaneous with ventricular ejection. With pressure selected as the trigger, most IABP consoles ignore the ECG signal. Pressure is the preferred trigger mode during CPR because it works synchronously with compressions to improve diastolic perfusion. This mode can be useful when the ECG signal is unavailable, excessive artifact exists, or ECG voltage is too low to produce a recognizable R wave. Excessive movement of ECG wires, very active patients, and procedures such as surgery that involve considerable staff contact with ECG lead areas may make pressure a desirable trigger mode.

A pacemaker trigger is also available on most IABP consoles and is usually further divided into atrial- and ventricular-paced rhythms. The only time that pacemaker triggers are useful is when the patient rhythm is 100% paced and the QRS complex has such poor morphologic features that the IABP console cannot use it in the ECG trigger mode. For patients with an AV-paced rhythm, the ventricular-paced trigger should be selected if pacer triggering is required. Most IABP consoles also offer an internal trigger mode that works completely asynchronously with the patient's ECG and arterial pressure. The internal trigger mode should never be used in any patient with cardiac output, including patients undergoing CPR. Situations when internal triggering may be used are generally limited to cardiac surgical procedures with no available ECG and external circulatory support. Internal triggering can prevent thrombus formation on the IABP catheter in such cases.

Evaluation of an IABP Waveform

The IABP device has the option to pump in several modes called assist ratios or IABP frequency. These modes are as follows:

- 1:1 assist ratio, in which the pump inflates with each heartbeat
- 1:2 assist ratio, in which the pump inflates with every other heartbeat
- 1:3 assist ratio, in which the pump inflates with every third heartbeat

- 1:4 assist ratio, in which the pump inflates with every fourth heartbeat
- 1:8 assist ratio, in which the pump inflates with every eighth heartbeat

CCTPs should assess several parameters of the waveform. The evaluation of the IABP waveform is most easily accomplished by placing the IABP into the 1:2 **assist ratio**. This ratio allows comparison of pressure waves of the unassisted cycle with the assisted one. In this mode, every other contraction is augmented by the IABP. In a strip of 1:2 augmentation waveforms, the peaks created by the inflation of the IAB are easily identified because they should be the highest pressure peaks **Figure 15-13**. Because the IAB inflates during diastole, these pressure waveforms are referred to as the **diastolic augmentation waveforms**. The pressure waveform that follows the diastolic augmentation peak (IAB inflation) is referred to as the **assisted systole** waveform because the deflation of the IAB assists the ventricle in ejecting blood, thereby reducing the ventricular **afterload** (the resistance that must be overcome to eject the blood from the ventricles). The third pressure waveform is referred to as **unassisted systole** because the balloon pump is not moving and the waveform reflects what would normally occur without IABP intervention. To evaluate for correct IABP timing, the pressure peaks, slopes, and inflation and deflation points of each of these pressure waveforms must be evaluated in a systematic manner. The parameters of the IABP waveform that should be evaluated are as follows:

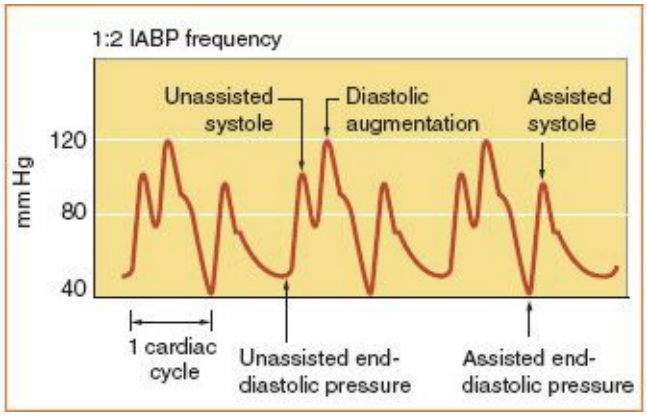

Figure 15-13 Pressure waveform augmented 1:2. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

1. Systole and diastole of each pressure waveform. Although it may seem confusing at first, it is critical to identify systole and diastole in the pressure waveforms. This balloon inflation gives an appearance of systole as the pressure peaks are high; however, it is important to remember that the heart is in diastole. It may help to think of balloon inflation as a second systole that occurs in diastole.
2. Diastolic augmentation, assisted systole, and unassisted systole. When looking at a 1:2 augmentation strip, this can be done easily by identifying the balloon inflation. This pressure waveform will be the diastolic augmentation. Immediately before this waveform is the unassisted systole. The pressure waveform that occurs immediately after the diastolic augmentation is the assisted systole.
3. The point of inflation. Inflation should occur at the dicrotic notch, as this signals the closure of the aortic valve **Figure 15-14A**. To find the dicrotic notch, the IAB inflation point is manually moved to a later time in the cardiac cycle. Once the dicrotic notch is located, the console inflation should be adjusted to an earlier time until the notch created by the inflation of the balloon on the dicrotic notch forms a crisp "V" **Figure 15-14B**. The balloon inflation point should be reflected on the pressure waveform as a sudden increase in pressure during diastole. A crisp V with no evidence of the dicrotic notch reflects inflation of the balloon immediately at the onset of diastole. Note: If the

dicrotic notch is visible, inflation is occurring too late. If inflation occurs too early, the V will open slightly as the slope of the diastolic augmentation decreases slightly (less steep slope).

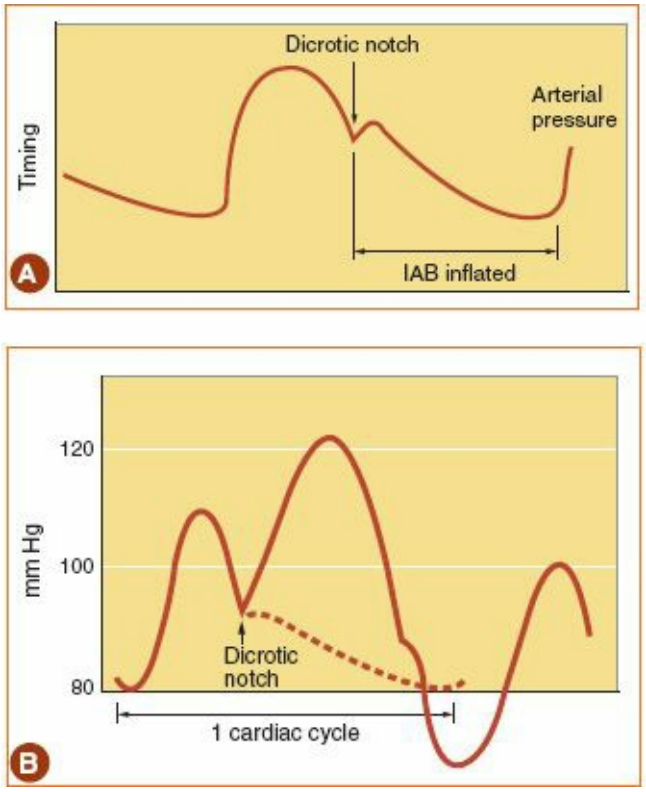

Figure 15-14 Pressure waveform showing the point of inflation. **A.** Dicrotic notch. **B.** A crisp V after adjusting the console for inflation to occur earlier. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

4. End-diastolic dip in pressure created by balloon deflation. The end-diastolic dip should dip below the baseline end-diastolic pressure occurring with unassisted systole. This dip should be followed by a straight-line slope to the next systolic peak. If a diastolic dip is created, followed by a plateau and then the beginning of the systolic peak, deflation is occurring too early. If there is no end-diastolic dip, but rather an end-diastolic pressure that is above the baseline of the unassisted systole and a straight slope up to the next systolic peak, deflation is occurring late. Ideally, CCTPs should optimize deflation by adjusting it to an earlier or a later time to obtain the lowest possible assisted end-diastolic pressure while not reducing diastolic augmentation. It is helpful to be familiar with the expected waveforms, but deflation is best optimized to achieve the most favorable pressures indicative of reduction in after-load (assisted end-diastolic pressure) without impinging on ventricular ejection (reduced diastolic augmentation).

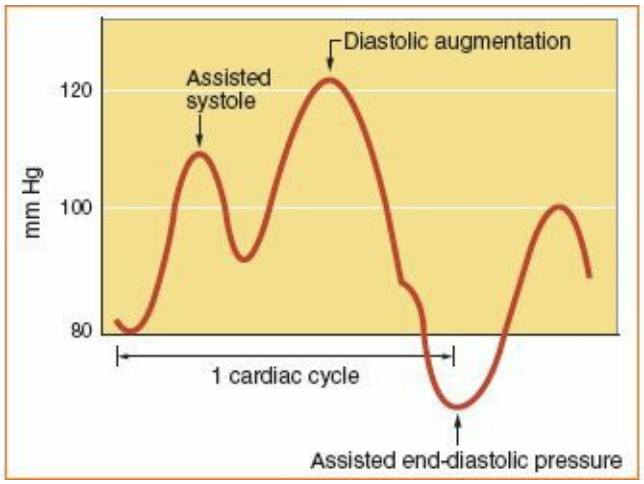

Figure 15-15 Pressure waveform with slopes of diastolic augmentation and assisted systole marked. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

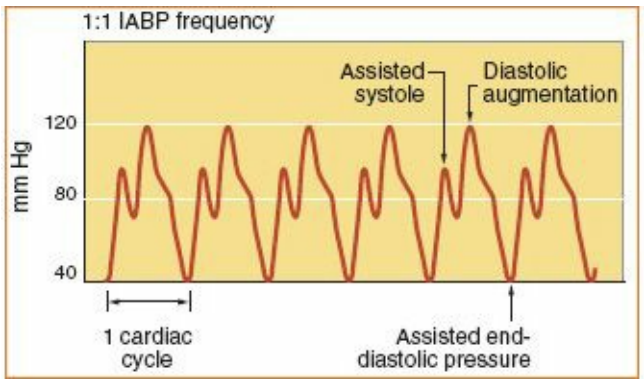

Figure 15-16 Pressure waveform showing peak pressures of assisted systole and unassisted systole. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

5. Slope of diastolic augmentation pressure and slope of assisted systole **Figure 15-15**. The slopes of the diastolic augmentation peak (balloon inflation) and the slope from the end-diastolic dip to the assisted systolic peak should be straight lines and nearly parallel.
6. Diastolic augmentation peak pressure. If effective IABP therapy is being achieved, the diastolic augmentation peak pressure should be higher than (or at least equal to) the systolic pressures.
7. Comparison of the peak pressure of assisted systole with the peak pressure of unassisted systole **Figure 15-16**. If effective IABP therapy is being accomplished, the peak pressure of assisted systole should be lower than the systolic peak of unassisted systole, which reflects that the IABP is reducing the peak pressures and, thus, decreasing the workload of the heart and reducing MVO_2.

TABLE 15-2 IABP Timing Errors

Error	Definition	Waveform Characteristics	Physiologic Effects
Early inflation	Inflation of the IAB before aortic valve closure	IAB inflation before the dicrotic notch; diastolic augmentation encroaches onto systole (may be unable to distinguish the two)	Possible premature aortic valve closure; possible increase in LV, EDV, and EDP, or in pulmonary capillary wedge pressure; increased LV wall stress (afterload); aortic regurgitation; increased MVo_2
Late inflation	IAB inflation markedly after aortic valve closure	IAB inflation after the dicrotic notch; absence of sharp V	Suboptimal coronary artery perfusion
Early deflation	Premature IAB deflation, during the diastolic phase	Sharp drop following diastolic augmentation Suboptimal diastolic augmentation Assisted aortic EDP may be equal to or less than unassisted aortic EDP Assisted systolic pressure may rise	Suboptimal coronary artery perfusion; potential for retrograde coronary and carotid blood flow; suboptimal afterload reduction; increased MVo_2
Late deflation	Balloon deflation late in the cardiac cycle	Assisted aortic EDP may be equal to unassisted aortic EDP; prolonged rate of rise of assisted systole; diastolic augmentation may appear widened	Afterload reduction essentially absent; increased MVo_2 because of prolonged isovolumetric contraction and greater resistance to LV ejection; increased afterload if IAB impinges on LV ejection

Abbreviations: EDP, end-diastolic pressure; EDV, end-diastolic volume; IAB, intra-aortic balloon; LV, left ventricular; MVO_2, myocardial oxygen consumption.

Timing Errors

Timing during IABP therapy is very important. **Table 15-2** summarizes timing errors, waveform characteristics, and physiologic effects, all of which are discussed in the next section. These errors result from incorrect timing by the IABP operator.

Early Inflation

The IAB should inflate at the dicrotic notch, which signals the closure of the aortic valves. Inflation that occurs too early is reflected on the waveform by a shortened normal pressure decrease that follows diastole. Because the aortic valves have not closed, this error in timing can be detrimental to the patient by decreasing pumping efficacy. On the pressure waveform, this is reflected as an "opened V" and with a lessened slope on the diastolic augmentation waveform. The pathophysiologic effect of early inflation is that the ejection of blood from the left ventricle is impaired by the sudden increase in aortic pressure while the aortic valve is open, forcing premature closure of the aortic valves and decreasing the SV **Figure 15-17**. It is also possible for early inflation to result in damage to the aortic valve.

Late Inflation

If the dicrotic notch is visible on the pressure waveform, inflation of the IAB is late. The late inflation of the IAB, although causing little harm, does not maximize the benefits of IABP therapy because the pressure in the aorta has decreased before the IAB inflates, and, therefore, the profound increase in diastolic pressure that maximizes coronary and systemic circulation is not realized **Figure 15-18**.

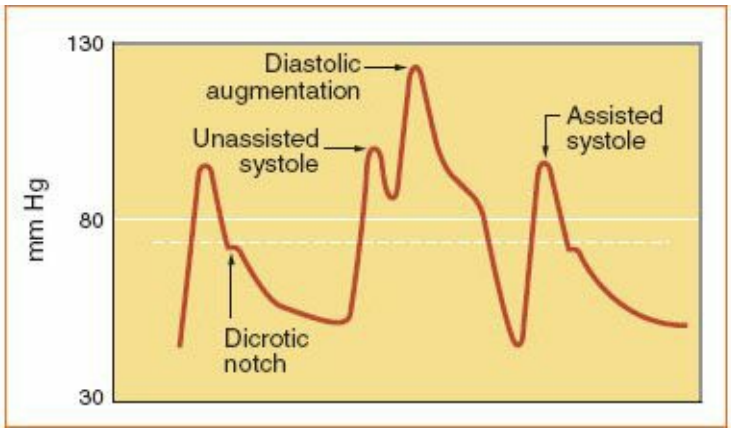

Figure 15-17 Early inflation. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

Early Deflation

The timing for deflation of the IAB should be the R wave. Using this trigger for deflation is effective for preventing early deflation. This trigger allows for sudden deflation of the IAB, resulting in the end-diastolic dip that decreases the workload of the ventricles to overcome the aortic pressure and eject blood from the ventricles. If deflation occurs too early, the pressure in the aorta will equalize and rise slightly to plateau before systole, meaning that a higher end-diastolic pressure must be overcome for the ventricles to eject blood. The waveform will exhibit a sharp drop from diastolic augmentation with a characteristic prolongation of the assisted aortic end-diastolic period. This lack of inflation through to the end of diastole means not only that the benefits of IABP therapy are not realized by assisting the next systole, but also that the duration of increased pressure during diastole (which benefits the coronary arteries and system circulation) is also decreased **Figure 15-19**.

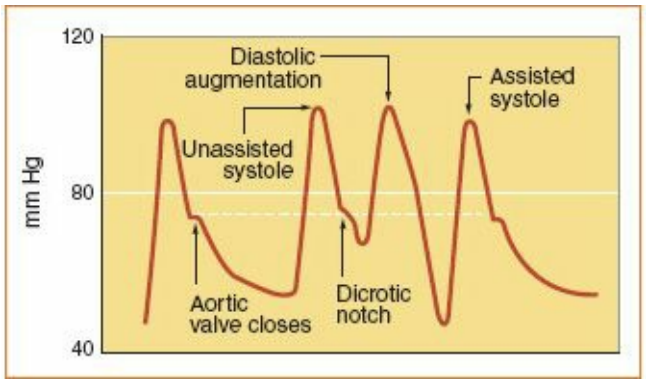

Figure 15-18 Late inflation. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

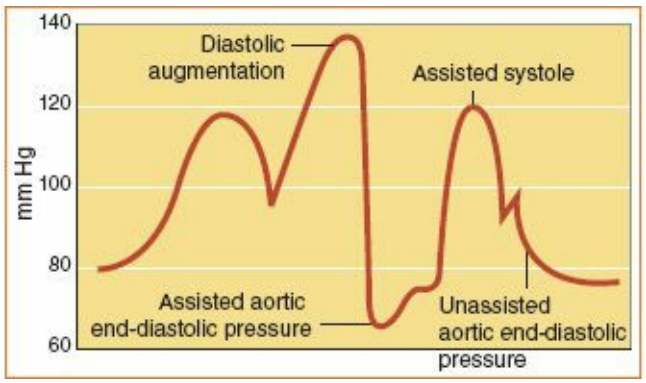

Figure 15-19 Early deflation. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

Late Deflation

As stated previously, the use of the R wave as the trigger is the most reliable to prevent errors in timing of IAB deflation. However, late IAB deflation can be extremely detrimental to the patient. Late deflation is characterized by a widened appearance of the diastolic augmentation waveform base and a prolonged rate of rise in the assisted systolic waveform **Figure 15-20**. Because the balloon is still inflated while the heart is trying to eject blood from the left ventricle, the pressure in the aorta never drops to the baseline or dips below it. This increased pressure at which the aortic valves can open and eject blood from the ventricles increases the afterload and significantly increases the MVO_2 of the left ventricle because the majority of MVO_2 is used to overcome the pressure in the aorta to eject the blood. Thus, late deflation of the balloon *worsens* myocardial ischemia and needs to be avoided.

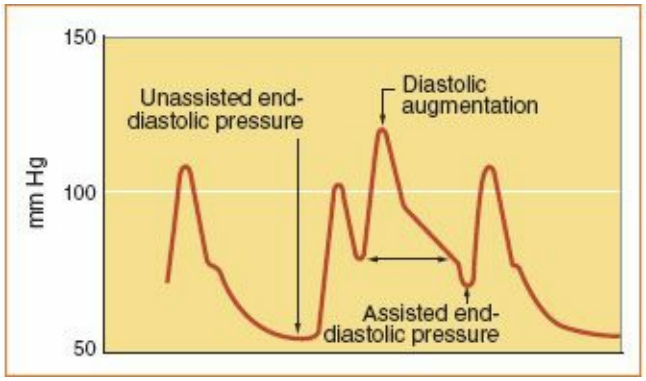

Figure 15-20 Late deflation. Illustration from source material by Datascope Corp. and Maquet Cardiovascular. Used with permission.

IAB Insertion

Indications

IABP therapy can be used effectively to treat a variety of conditions resulting in heart failure. Conditions or situations that benefit from IABP therapy are listed in **Table 15-3**. IABP therapy offers valuable benefits by reducing cardiac work and MVO_2 and improving peripheral perfusion in patients with a variety of conditions and undergoing cardiovascular and surgical procedures.

Indications for IABP therapy include the following:

- Refractory ventricular failure
- Cardiogenic shock
- Unstable refractory angina
- Impending infarction
- Mechanical complications due to acute MI (ie, ventricular-septal defect [a hole in the wall between the ventricles], mitral regurgitation, or papillary muscle rupture)
- Ischemia-related intractable ventricular arrhythmias
- Cardiac support during high-risk general surgical or coronary angiography or angioplasty procedures
- Septic shock
- Weaning from cardiopulmonary bypass

- Intraoperative pulsatile flow generation
- Support for failed angioplasty and valvuloplasty

TABLE 15-3 Conditions or Situations That Benefit from IABP Therapy
Chest pain from unstable angina
Severe arrhythmias
Cardiogenic shock
Septic shock
Heart failure
Myocardial ischemia from unstable angina
MI
Ventricular irritability
Ventricular-septal defect (before surgical intervention)
Papillary muscle dysfunction (before surgical intervention)
Papillary muscle rupture (before surgical intervention)
Impaired cardiac function (before surgical intervention)
Support during diagnostic and interventional procedures (ie, coronary angiography and angioplasty)
Weaning from cardiopulmonary bypass
Failed angioplasty (until patient undergoes surgical intervention)
Unsuccessful valvuloplasty (until patient undergoes surgical intervention)
During cardiopulmonary bypass
Cardiac support during noncardiac surgery
Prophylactic support while awaiting cardiac surgery
Myocardial contusion
Mechanical bridge to other assist devices or heart transplantation
Abbreviations: IABP, intra-aortic balloon pump; MI, myocardial infarction.

In myocardial ischemia and chest pain associated with unstable angina, impending infarction, and intractable ventricular arrhythmias related to ischemia, the IAB can be beneficial in maintaining adequate coronary artery perfusion, relieving myocardial ischemia, and decreasing myocardial oxygen demand. If cardiac catheterization and further interventions are necessary, the patient can undergo these procedures in a more hemodynamically stable condition. The IAB can also be used in conjunction with cardiopulmonary bypass pumps to provide pulsatile flow. For patients in septic shock, myocardial

function may be impaired, and the IABP may be used to increase CO to meet the increased metabolic demands.

Patients who experience severe chest pain accompanied by ECG changes or arrhythmias and who do not obtain relief from drug therapy are at great risk of developing an MI. Improving coronary blood flow and reducing LV work will minimize chest pain and ECG changes associated with the MI. IABP therapy is often considered when symptoms persist despite maximal medical therapy. If cardiac catheterization and further interventions are indicated, the IABP improves the patient's hemodynamic status before the procedures.

Depending on the area of an acute MI, mechanical complications can occur. Although these complications involve a small percentage of MIs, the resulting hemodynamic compromise can have lethal consequences, especially if not treated immediately. Ventricular-septal defects, papillary muscle dysfunction, and papillary muscle rupture usually require surgical intervention, often on an emergency basis. If the patient undergoes cardiac catheterization or surgical intervention in a hemodynamically compromised state, the potential for mortality and morbidity increases significantly. The IABP provides temporary support to achieve hemodynamic stability before undertaking definitive measures.

Ventricular irritability, a frequent complication of acute MI, can lead to severe arrhythmias and further hemodynamic compromise. In most patients, conventional drug therapy and supportive measures are sufficient to reverse the irritability and arrhythmias. However, lack of response to conventional medical therapy results in high risk for further myocardial damage and death. IABP therapy has proven effective in stabilizing the hemodynamic condition of patients with ventricular irritability or arrhythmias by increasing coronary artery perfusion, reducing ischemia, and maintaining adequate peripheral perfusion.

In the already compromised heart, a decrease in arterial pressure can reduce myocardial oxygen supply and cause a loss of functional myocardial tissue. Prevention of worsening failure and cardiogenic shock requires prompt treatment of any signs of hemodynamic instability. Treatment aims at relieving LV workload and restoring the balance between myocardial oxygen supply and demand, allowing the myocardium time to heal and recover maximal function. IABP therapy assists in this effort by decreasing LV workload and increasing coronary artery perfusion.

LV failure following an acute MI may progress to cardiogenic shock. As with LV failure, the objectives of cardiogenic shock treatment are decreased cardiac work, increased myocardial oxygen supply, and lowered MVO_2. The combined effects of IABP therapy—increased oxygen supply, decreased afterload, and improved systemic perfusion—allow the heart to rest and help halt the subsequent vicious cycle that often occurs in acute MI.

Patients with impaired cardiac function are considered high-risk candidates for general surgery. Anesthetic agents and the procedure itself can place increased oxygen demands on the weakened heart. IABP therapy provides hemodynamic stability by helping balance myocardial oxygen supply and demand preoperatively, intraoperatively, and during the critical postoperative period when demands on the heart are particularly high.

The IABP works in conjunction with coronary angiography and angioplasty to support and stabilize the conditions of high-risk patients undergoing these procedures. Overall, IABP therapy can provide increased coronary artery perfusion and a reduction in cardiac work, thus lowering the risk of hemodynamic compromise due to reduced coronary flow during IAB inflation or acute coronary occlusion.

Weaning a patient from cardiopulmonary bypass may be difficult when support of the heart and lungs on the cardiopulmonary bypass machine is prolonged, surgical revascularization (placement of bypass grafts around blocked coronary arteries) is partially achieved, or preexisting myocardial dysfunction is present. Termination of cardiopulmonary bypass may result in hypotension and a low CO, despite

administration of inotropic and vasoactive drugs. IABP therapy in this setting decreases LV resistance, improves CO, and increases coronary artery and systemic perfusion pressures, facilitating the patient's removal from the cardiopulmonary bypass machine.

IABP therapy can support and stabilize the conditions of patients with severe LV failure resulting from failed angioplasty (attempts to open an occluded coronary artery in an interventional cardiac catheterization laboratory). Overall, the IABP can provide increased coronary artery perfusion and decreased cardiac work, thus reducing the risk of hemodynamic compromise because of reduced coronary flow or acute coronary occlusion. Unsuccessful valvuloplasty, however, a procedure in which a balloon-tipped catheter is used to dilate a stenotic heart valve, may produce cardiac dysfunction. The IABP helps support cardiac function until the patient can undergo definitive valve repair or replacement.

Septic shock is the consequence of overwhelming infection that affects all organ systems and dramatically increases metabolic demands. Characterized by low blood pressure, impaired neurologic function, decreased CO, and fever, it can lead to cardiogenic shock. The increased metabolic demands of a patient in shock lead to a mismatch between oxygen supply and demand in the tissues. This deficiency causes cells to carry on anaerobic respiration, creating lactic acid. As the lactic acid builds up in the body, it impairs the contractility of the heart and leads to impaired heart function. As discussed previously, this begins a vicious cycle of heart failure leading to decreased perfusion that worsens heart failure. For patients with an inadequate response to other supportive measures, IABP therapy can increase coronary blood flow, reduce LV workload by lowering systolic pressure, and improve tissue perfusion by maintaining adequate MAP.

In short, IABP therapy can be used for a variety of indications. **Table 15-4** summarizes the potential benefits of IABP therapy. Whatever the indication for use, the IABP fulfills basic roles: reducing the workload of the myocardium, improving coronary and systemic flow, and restoring the balance between the metabolic demands of the heart and body and the supply of oxygen available.

TABLE 15-4 Benefits of Intra-aortic Balloon Pump Therapy

Improves coronary artery perfusion
Increases cardiac output
Maintains peripheral perfusion
Reduces myocardial ischemia
Decreases myocardial oxygen demand
Improves hemodynamic stability
Decreases afterload

Contraindications

Although CCTPs do not insert the IAB, they may arrive before or during consideration of IAB insertion. It is useful to understand the contraindications to IABP therapy, which include the following:

- Severe aortic valvular insufficiency
- Abdominal or aortic aneurysm
- Severe calcific aortic or iliac arterial disease or severe peripheral vascular disease

These contraindications are discussed individually in the following sections.

Severe Aortic Insufficiency

IABP therapy is contraindicated in patients with severe aortic valve insufficiency. For the benefits of IABP therapy to be realized, the aortic valve must be competent. Balloon inflation in the setting of aortic valve insufficiency would force blood from the aorta across the valve into the ventricle. This **aortic regurgitation**, in turn, would increase cardiac work by overloading the ventricle with additional blood volume. In essence, the ventricle would have to pump the same blood back and forth, paradoxically increasing the workload. An incompetent aortic valve is also more likely to sustain damage from an improperly inserted IAB or poorly timed IAB inflation and deflation.

Aortic Aneurysm or Dissection

Use of the IABP is contraindicated if the patient has an abdominal or thoracic aortic aneurysm or aortic dissection. During insertion, the IAB catheter could become misdirected into the aneurysm itself or tear the weakened wall of the aorta. The increased pressure generated with counterpulsation could worsen the aneurysm or dissection.

Aortoiliac or Severe Peripheral Vascular Disease

Severe, calcific arterial or peripheral vascular disease is also a contraindication to IABP therapy, although some view it as a **relative contraindication**. The physician must decide whether the benefits of IABP therapy outweigh the risk of further compromised arterial blood flow. Peripheral vascular disease may limit the ability to advance the catheter through the atherosclerotic vessel. In addition, the presence of the catheter could cause plaque rupture or vessel occlusion, resulting in leg ischemia. This information is important to the IABP operator (usually a CCTP) because blood flow to the extremity distal to insertion must be monitored for evidence of circulation compromise.

Insertion Site Factors

Using a catheter without a sheath, or sheathless insertion, is not recommended if the patient has any of the following:

- A large amount of fatty tissue at the insertion site over the common femoral artery because the excessive distance between the skin and the femoral artery is likely to trap the catheter in the subcutaneous tissue
- Extensive scarring or fibrosis at the insertion site
- Other contraindications to percutaneous insertion

Side Effects and Complications

Side effects and complications of IABP therapy include the following:

- Limb ischemia (compartment syndrome may develop after the IAB is removed)
- Excessive bleeding from the insertion site
- Thrombocytopenia (owing to platelet destruction)
- Immobility of the balloon catheter
- Balloon leak
- Infection
- Aortic dissection
- Thrombosis
- Altitude changes during air transport

Management of specific complications is discussed later in this chapter.

IABP Operation During Transport

As with pacemakers and implanted cardioverter defibrillators, operation of an IABP varies somewhat from model to model. The fundamentals apply to all IABPs, however, so the material studied to this point will be useful for training with a specific IABP device. If possible, CCTPs should study and practice with the device that will be used on transports to help familiarize themselves with the specifics of IABP operation and common problems and their solutions.

Most critical care transport programs require that a CCTP be accompanied by a certified perfusionist or critical care registered nurse knowledgeable about the IABP, so CCTPs are working with a colleague with additional training in this area on calls that involve a patient receiving IABP therapy.

Vehicle Requirements

Patients receiving IABP therapy are candidates for transport in ground ambulances or in fixed- or rotary-wing aircraft. Some issues to consider when using these vehicles include battery life and vehicle power supply, space and weight constraints, and loading, unloading, and securing the pump in the vehicle. Addressing these issues when developing an IABP transport program will resolve most potential problems before the first transport.

Power Supply

Transport vehicles often have an inverter capable of converting the DC voltage generated by the engine to AC voltage suitable for powering the IABP. In addition to AC power, some aircraft produce 24-V DC power. Many IABPs are capable of operating on 110- to 120-V of AC power or 24-V of DC power, although the latter may require an adapter cable. Most IABP systems also incorporate batteries for limited periods of portable operation **Figure 15-21**. Ensuring a match between IABP power requirements and the available power supply in the transport vehicle is a crucial planning step when establishing an IABP transport program. Careful attention to transport-related physical and logistic considerations—well in advance of actual transport—ensures the ability of CCTPs to focus on patient-specific needs during transport.

Figure 15-21 A portable intra-aortic balloon pump.

Space, Weight, and Equipment Attachment

It is also necessary to evaluate space and weight constraints of the transport vehicle before transport and

the logistics of loading and unloading the IABP and the patient. Ground ambulances generally have minimal restrictions on weight, and the system will usually fit easily into the vehicle. In a transport aircraft, space limitations may require reconfiguration of the pump and monitor module. The additional weight of the system may also be an issue in air operations, another important planning point during transport program development.

Once the IABP is in the transport vehicle, it is critical to secure the pump so that it remains stable for safe operation throughout transport. It may be necessary to work with the IABP manufacturer, Federal Aviation Administration representatives, and the aircraft mechanic to ensure that an adequate system is in place to secure the IABP against air turbulence.

Equipment

The following equipment should be gathered before working with an IABP during transport:

- IABP with transport module
- Appropriately sized balloon catheters with insertion kit Spare helium tank (200 psi) Operator's manual
- Stopcocks
- 60-mL syringe (Luer tip)
- Skin electrodes
- IABP extension tubing
- Doppler ultrasound device (to assess distal pulses)
- Extra ECG cables
- 2″ cloth tape to secure IABP ECG electrodes and catheter to patient
- Arterial pressure monitoring transducer and setup
- Pressure transducer cables
- Arterial flush solution (500 mL of normal saline with 1,000 U of heparin)
- Adapters to fit other brands of balloon catheters to the IABP console
- Knee splint Soft restraints

Steps for Using the IABP

Skill Drill 15-1 describes the steps performed when beginning a call involving a patient receiving IABP therapy. These steps are as follows:

1. When entering the facility to transport a patient receiving IABP therapy, visually assess the surroundings to ensure that hallways, elevators, and routes of travel will accommodate necessary equipment and personnel **Step 1**.
2. Obtain the patient report **Step 2**.
3. Ascertain current IABP settings and note typical pressures (console systolic, diastolic, augmentation, and mean arterial pressures) **Step 3**.
4. Determine IABP catheter model, size, and insertion depth (measurement at insertion site) **Step 4**.
5. Ascertain that the balloon tip location has been verified by chest radiograph **Step 5**.
6. Conduct an assessment **Step 6**. IABP focus includes inspection of the insertion site for active bleeding, peripheral pulses in both lower extremities (may require Doppler confirmation), and a

radial pulse in the left upper extremity (to ensure subclavian blood flow).

7. Attach new ECG leads and secure each lead over the electrode with 2″ cloth tape **Step 7**. This step will prevent lead disconnection and potential loss of trigger during transport.
8. Ensure that the IAB catheter is taped securely to the patient's leg **Step 8**.
9. Apply a knee immobilization splint to the leg in which the IAB was inserted to prevent leg flexion during transport **Step 9**.
10. Ensure that the appropriate connectors to attach the IABP to the transport console are available. Determine the console that will be used at the receiving facility, and be certain to take any necessary adapters or connectors (usually included in the IAB insertion kit).
11. Move the patient to the transport stretcher **Step 10**. Connect and secure all pumps, monitors, ventilators, and other equipment.
12. Transfer the IABP to the transport console at the bedside or in the transport vehicle (if the IABP console is mounted in the vehicle) **Step 11**.
13. Establish power to the transport IABP console **Step 12**.
14. Open the helium tank, and verify pressure **Step 13**.

Skill Drill 15-1

Operating the IABP During Transport

1 Visually assess the surroundings to ensure that hallways, elevators, and routes of travel will accommodate necessary equipment and personnel.

2 Obtain the patient report.

3 Ascertain current IABP settings and note typical pressures.

4 Determine IAB catheter model, size, and insertion depth.

5 Ascertain that the balloon tip location has been verified by chest radiograph.

6 Conduct an assessment.

7 Attach new ECG leads and secure each lead over the electrode with 2″ cloth tape.

8 Ensure that the IAB catheter is taped securely to the patient's leg.

9 Apply a knee immobilization splint to the leg in which the IAB was inserted to prevent leg flexion during transport. Ensure that the appropriate connectors to attach the IABP to the transport console are available. Take any adapters that will be necessary at the receiving facility.

10 Move the patient to the transport stretcher. Connect and secure all pumps, monitors, ventilators, and other equipment.

11 Transfer the IABP to the transport console at the bedside or in the transport vehicle (if the IABP console is mounted in the vehicle).

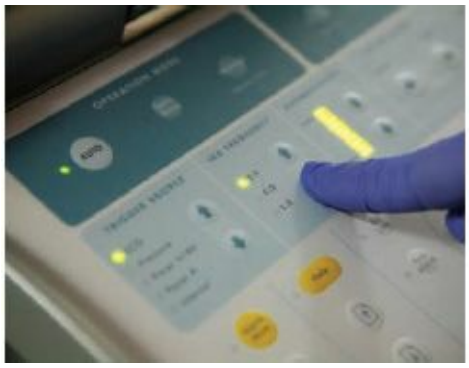
12 Establish power to the transport IABP console.

13 Open the helium tank and verify pressure.

14 Follow the IABP console instructions for start-up (on console help screens or in manufacturer-provided user manual):

- Establish ECG and
  pressure waveforms from the patient.
- Confirm initial pump settings.

- Set timing.
- Initiate IAB pumping.
- Set console alarms.
- Confirm all pump settings.



15 Optimize IABP timing in a 1:2 mode:
- Set inflation by adjusting inflation to a later time until the dicrotic notch becomes visible, then move inflation to an earlier time until a crisp V pattern appears at the dicrotic notch.
- Set deflation to achieve the lowest possible diastolic pressure while maintaining maximal augmentation.

16 Assess pressures every 5 minutes or with any changes in the patient's condition during transport. Check the insertion site and pulses every 15 minutes.

15. Follow the IABP console instructions for start-up (on console help screens or in manufacturer-provided user manual) **Step 14**:
- Establish ECG and pressure waveforms from the patient.
- Confirm initial pump settings.
- Set timing.
- Initiate IAB pumping.
- Set console alarms.
- Confirm all pump settings.

16. Optimize IABP timing in the 1:2 mode **Step 15**:
- Set inflation by adjusting inflation to a later time until the dicrotic notch becomes visible, then move inflation to an earlier time until a crisp V pattern appears at the dicrotic notch.
- Set deflation to achieve the lowest possible diastolic pressure while maintaining maximal augmentation.

17. Assess pressures every 5 minutes or with any changes in the patient's condition during transport. Check the insertion site and pulses every 15 minutes **Step 16**.

Special Populations

Always immobilize the knee of the IABP leg prior to transport. This helps avert sudden leg movement, which may lead to bleeding or dislodgement of the IABP catheter. This is especially relevant to the geriatric patient whose tissues are less elastic and therefore more prone to damage from sudden movement.

Altitude Changes

Barometric pressure, the pressure exerted by gases in the ambient air, decreases with increasing altitude. During air transport, atmospheric pressure changes alter the gas volume in the IAB catheter and may affect IAB performance. As an aircraft ascends and atmospheric pressure decreases, the structural strength of the IAB restricts the rise in gas volume, but gas pressure in the IAB increases. Atmospheric pressure increases as the aircraft descends, reducing the gas volume in the IAB, which can decrease the effectiveness of IAB inflation.

Some IABPs compensate for atmospheric pressure changes by automatically initiating a refill cycle to adapt gas volume in the IAB to the external change. Initiation of one of these cycles typically begins when external pressure changes reach a preprogrammed threshold. Called autofill mode, this mode automatically purges and fills the IAB when local atmospheric pressure decreases or increases by 25 or 50 mm Hg, respectively. These pressure changes occur approximately every 1,000′ of ascent or 2,000′ of descent, respectively. The autofill mode should be used during air transport. If using an older model of IABP, its ability to compensate for altitude changes should be verified. If it is not capable of compensating for altitude changes, the IABP operator can manipulate the extent to which the balloon inflates to make use safer. The manual fill must be performed at the same intervals that an autofill would occur.

The potentially most catastrophic consequence that could result from IABP operation at an altitude would be a rapid ascent to altitude with the IAB inflating to full capacity. Theoretically, the gas will expand as the ascent occurs and the same volume of gas will cause the IAB to expand more, in theory causing the IAB to rupture. To prevent this complication, when operating an IABP console that is not capable of altitude adjustments, the pilot should be asked to coordinate altitude changes with the patient care crew. Slow ascents and descents allow the opportunity to adjust the pump. For ascent, the extent to which the IAB inflates should be reduced. Most IABP consoles allow a reduced inflation assist. When cruising altitude has been reached, the IAB should be refilled at the new altitude. For descent, the balloon should be kept inflated at full-assist capacity, and the procedure (refilling the balloon at the new altitude) should be repeated when on the ground.

Patient Assessment

Of the patients who are admitted to a community hospital with an acute MI, cardiogenic shock develops in 5% to 10%. Because the IABP can be an effective means of support for patients in LV failure and cardiogenic shock, personnel in these facilities may initiate IABP therapy. Unfortunately, the hospitals may not be equipped with cardiac surgery or cardiac catheterization laboratories or have the ability to perform interventional cardiology procedures. When the choice is to transfer patients with such conditions to a tertiary facility for further evaluation and treatment, early insertion of an IAB may make

transport safer by promoting hemodynamic stability. Some IABP-related considerations need attention before transport.

Assessment of a patient receiving IABP therapy revolves around two questions: (1) Is the therapy effective for the patient? (2) Are there complications resulting from the therapy? Patient assessment parameters that are useful for evaluation of the effectiveness of IABP therapy are vital signs, oxygenation, urine output, peripheral perfusion, central nervous system (mentation), and overall general condition. For a patient receiving correctly administered IABP therapy, one would expect, except in the most severe cases, that the patient would experience an improvement of each of the aforementioned parameters. Improvement of the vital signs, oxygenation, urine output, peripheral perfusion, and mentation of the patient can be expected because of the increase in CO. Some patients are confused during IABP therapy, which may be attributed to alterations in cerebral circulation induced by IAB counterpulsation. In the transport environment, the CCTP should be prepared to restrain or sedate an agitated patient receiving IABP therapy for the safety of the patient and crew. The CCTP should assess and document these parameters at least every 15 minutes or whenever there is a change in the patient's condition. Note that although the IABP will measure arterial blood pressure, it may be useful to measure the patient's noninvasive blood pressure (on the patient's arm with a blood pressure cuff), for reference.

Complications that may result from IABP therapy are most often related to the insertion site of the device or impairment of circulation by the balloon or the extremity where it is inserted. When in proper position, the IAB lies in the thoracic aorta just distal to the takeoff of the left subclavian artery. If during transport the IABP were to migrate toward the patient's head (**cephalad**), the distal portion of the IAB could occlude the takeoff to the left subclavian artery, which may be exhibited as a dampening or absence of the pulse in the left arm. Therefore, the CCTP should palpate or, if necessary, use a handheld Doppler ultrasound device to assess the left radial pulse and compare it with the right radial pulse when performing vital signs or patient assessments. Placing a pulse oximeter probe on a finger of the left hand would also provide early warning of compromised circulation to the left subclavian artery. In addition, the IAB may migrate toward the feet, causing an impairment in renal function. The depth of insertion of the IAB should be monitored and documented. A sudden decrease in urine output may also signal this impairment in renal blood flow, and, therefore, urine output should be noted and documented.

Special Populations

Be certain to evaluate mental status and level of orientation prior to transport. IABP therapy may lead to confusion necessitating physical or chemical restraint during transport. In geriatric patients, it is important to determine whether confusion is normal behavior for the patient (such as with dementia) or the result of altered cerebral blood flow secondary to IABP counterpulsation.

As mentioned earlier, the majority of IABs are inserted via the percutaneous technique in the femoral artery. This site should be inspected for evidence of bleeding, externally or internally. Any hematomas that have developed should be noted and marked on the skin to allow the CCTP or other health care provider to assess progression of the hematoma. Care should be taken to inspect the buttocks and posterior hip area because bleeding in this area may be difficult to detect. If the femoral artery is used as the insertion site, the CCTP should assess and document the presence of the distal pulses and capillary refill time (CRT) in the extremity used and compare it with the distal pulses and CRT in the other leg. The CCTP should splint the knee of the leg in which the IAB was inserted to prevent excessive movement that might lead to bleeding at the site or impairment of distal circulation. The sudden loss of pulses or decrease in CRT could signal that the IAB is occluding the femoral artery and causing ischemia in the

limb. If this complication occurs, medical control should be notified immediately and consideration given to the removal of the device in a facility as soon as feasible. In addition, because circulation in the extremity may be impaired, the potential for compartment syndrome to develop is high while the catheter is in place and after it has been removed. Compartment syndrome is heralded by the five Ps: Pain (out of proportion to what is expected), Pallor, Paralysis, Pulselessness, and Paresthesia. Also, the extremity might feel cold to the touch.

Emergency Interventions

There are several potential situations to troubleshoot during IABP therapy that are discussed in the following sections.

Cardiac Arrest

If cardiac arrest occurs, the trigger selection should be set to "pressure" and CPR started. The IABP will continue to operate in synchrony with compressions, augmenting diastolic flow and improving coronary perfusion. Defibrillation should be provided as necessary. There is no need to disconnect the IABP or associated monitoring equipment when shocking the patient. Like standard ECG and hemodynamic monitoring, IABP consoles are electrically isolated to prevent damage from defibrillators. Compression depth can be readily adjusted according to the MAP displayed on the IABP console. A minimum MAP of 60 mm Hg is necessary to perfuse vital organs during resuscitation.

Signs and Symptoms

Cardiac Arrest During IABP Therapy

- Pulselessness
- Flattening of unassisted arterial pressure waveforms. (The IABP will continue to generate regular waveforms if set to the ECG trigger and electrical complexes are present. *Do not* mistake the IABP pressure waveforms for evidence of cardiac output!)

Transport Management

Cardiac Arrest During IABP Therapy

- Switch the IABP trigger to pressure.
- Initiate CPR.
- Provide standard ACLS and BCLS resuscitation, including defibrillation, if indicated.
- Once return of spontaneous circulation occurs, MAP is adequate, and the ECG rhythm is stable, return the IABP trigger to the ECG mode.
- Reassess timing.

Balloon Rupture or Leak

Perhaps the most catastrophic complications that can result from IABP therapy are balloon rupture and air embolus. Although they are extremely rare occurrences, most balloon ruptures follow repeated friction of too large a balloon or a properly sized balloon located low in the thoracic aorta where sharp calcific

plaques tend to be most prominent. The CCTP should inspect the IAB tubing often for the presence of blood in the air channel. Although the central canal of the catheter functions like an arterial line and, therefore, is expected to occasionally have blood in the tubing, the gas lumen and channel of the catheter should never contain blood. If a chlorhexidine 2% skin preparation was used before insertion of the IAB catheter, flecks of the prep solution on the tubing may appear at a quick glance to be blood inside the tubing, so caution is required to distinguish blood inside the tubing from preparation solution or another substance on the outside surface. If blood is noted in the gas lumen of the catheter, IABP therapy should be discontinued immediately. The catheter should be disconnected, and, if signs or symptoms of gas embolus are present, place the patient in a left lateral recumbent position **Figure 15-22**, administer high-flow oxygen, and transport to the nearest appropriate facility. Although helium gas can leak into the bloodstream if the balloon ruptures, it is highly unlikely for two reasons: (1) Most IAB ruptures are miniscule holes. (2) During inflation, the gas pressure within the balloon is considerably less than the pressure in the aorta. Instead, blood is more likely to leak backward into the balloon, and this happens during deflation. A leak in the catheter may be signaled by an "excessive gas loss" alarm from the IABP console. Causes of gas loss alarms include high fever and significant tachycardia, both of which accelerate normal loss of gas from the circuit, as do loose connections or pinholes in the IAB tubing. If a gas loss alarm is triggered, the patient and tubing should be carefully inspected to determine the cause of the alarm. If after acknowledging this alarm, a source of a leak cannot be determined, the CCTP should assume that an IAB leak is a possibility and follow the aforementioned procedures.

A sudden loss of augmentation on the arterial line waveform and blood in the IAB catheter may be noted. If this occurs, the console to the patient should be shut off and medical control notified.

Console Failure

If the IABP console becomes disabled, manual inflation and deflation should be performed as soon as possible. The balloon must not remain idle (ie, immobile) in a patient for more than 30 minutes.

Skill Drill 15-2 gives the steps to manually inflate and deflate the IAB catheter.

1. Disconnect the IAB from the male Luer end of the extension tubing **Step 1**.
2. Attach the three-way stopcock and 60-mL syringe to the IAB catheter's male Luer **Step 2**. *Warning: Never inject air into the central lumen (female Luer hub).*
3. Aspirate to ensure that blood is not returned through the extracorporeal tubing. *Warning: If blood is aspirated from male Luer fitting of the extracorporeal tubing, immediately remove the IAB catheter owing to damage to the IAB.*
4. Inflate the IAB with 40 mL of air or helium, and immediately aspirate **Step 3**. Repeat every 5 minutes while the IAB is inactive.

The purpose of inflating and deflating the balloon manually is not to replicate the physiologic effects of IABP therapy, but rather to keep the balloon from accumulating clots in the folds while idle or immobile in the aorta.

Figure 15-22 The left lateral recumbent position.

Depletion of Helium

The IABP console user screen includes an indicator of the pressure in the helium tank. Most consoles also include a conventional pressure gauge in the proximity of the helium tank for use when the console is not in operation. A full helium tank will usually allow many weeks of IABP therapy without need for replacement. Should the tank require replacement, the console will provide visual and audible alerts. If the console indicates an empty helium tank, the CCTP should first ascertain that the tank valve is opened. Helium tanks operate in the same manner as oxygen tanks and are connected to the IABP console through a yoke similar to those found on oxygen regulators. The pin-index system for helium tanks will seat only into a helium yoke.

Should a tank require replacement, the valve on the depleted helium cylinder must be closed and the tank replaced with a full one. As with oxygen, a washer is required to ensure a tight seal between the tank and the yoke. Although it is unlikely that a helium supply would be completely depleted during a transport, it is possible for bumps and movement during transport to loosen or dislodge a helium tank from the IABP console, resulting in depletion of the helium supply. A spare (full) helium tank should always be carried during transport.

Excessive Bleeding

If excessive bleeding is noted from the insertion site, the CCTP should apply direct pressure over the site to control the bleeding. The CCTP should also consult with medical control for consideration of discontinuing infusions of anticoagulant medications or, if the bleeding cannot be controlled, diverting to the closest appropriate facility.

Catheter Migration or Accidental Removal

The uncontrolled environment of the prehospital arena presents unique challenges. The movement of patients presents opportunities for lines and attached devices to be removed accidentally. Before moving a patient, note the location and insertion mark of the IABP catheter; and before the patient is transferred to the stretcher, apply a knee splint to the leg in which the IAB was inserted. Tape the IAB catheter securely to the patient's leg. To reduce the chance of dislodging the IAB, IAB tubing connectors should not be taped together; if they become caught or tangled during movement, it is far better to have them pull apart. IAB catheters have sterile sheaths that allow for adjustment of the insertion depth without contamination of the catheter. If the catheter has moved significantly but has not become dislodged or disconnected from the sterile sheath protector, the IABP should be placed in standby mode (pumping stopped) and the catheter reinserted to the appropriate depth. Significant accidental movement of more than a few centimeters should not be adjusted without consultation with medical control or the referring physician. If the movement of the catheter occurred at the referring facility, obtaining a chest radiograph before

transport would verify the location of the catheter. If significant movement of the catheter occurred before transport, the physician who inserted the catheter can be asked to evaluate its position or potentially replace it before transport. If significant movement or accidental removal of the balloon occurs during transport, consider discontinuing IABP therapy after consultation with medical control. Allowing IABP therapy to continue with a misplaced balloon could cause significant complications, such as impaired renal blood flow or significant limb ischemia.

Skill Drill 15-2

Manual Inflation/Deflation of an IAB

1 Disconnect the IAB from the male Luer end of the extension tubing.

2 Attach the three-way stopcock and 60-mL syringe to the IAB catheter's male Luer. *Never inject air into the central lumen*. Aspirate to ensure blood is not returned through the extracorporeal tubing. *Immediately remove the IAB catheter if blood is aspirated from the male Luer fitting of the extracorporeal tubing*.

3 Inflate the IAB with 40 mL of air or helium, and immediately aspirate. Repeat every 5 minutes while the IAB is inactive.

Transport Management

Excessive Bleeding at IAB Insertion Site

- Apply direct pressure.
- Be certain that pressure is applied over the arterial insertion site (not the external puncture site).
- If bleeding cannot be controlled, consult with medical control:
  - Consider discontinuing anticoagulant infusions (ie, heparin).
  - Consider diverting to the closest appropriate facility.

Special Populations

Control excessive bleeding with direct manual pressure to the IABP insertion site. This is particularly important in geriatric patients whose tissues are less elastic and therefore are more prone to injury and bleeding, for example as a result of sudden movement. Controlling excessive bleeding should not interfere with ongoing IABP therapy.

Cardiac-Assist Devices

In addition to the IABP, CCTPs may encounter a wide variety of cardiac- or circulatory-assist devices. Transport may be required for patients on **extracorporeal membrane oxygenation (ECMO)** or patients with a **ventricular-assist device (VAD)** (which can be an implanted right ventricular-assist device [RVAD], left ventricular-assist device [LVAD], or biventricular-assist device [BiVAD]). There are dozens of such devices presently in use worldwide, and newer, more sophisticated devices regularly appear on the market. The complexity of circulatory-assist technology precludes a complete review of every device, but there are some important considerations for the safe transport of these patients.

Figure 15-23 An extracorporeal membrane oxygenation circuit consists of a pump, a membrane oxygenator, and a heat exchanger, and is connected to the patient by an arterial or venous cannula.

ECMO is not therapy itself; it is an adjunct to oxygenation and ventilation and considered life support for a patient with cardiac and/or respiratory failure. ECMO ensures adequate oxygenation by

replacing the function of the lungs in gas exchange. An ECMO circuit is managed by a specially trained critical care registered nurse or by a perfusionist. The circuit includes an arterial or venous cannula that is connected to the patient and has a pump that directs bloodflow into the patient, a membrane oxygenator that adds oxygen and removes carbon dioxide, and a heat exchanger that replaces lost body heat **Figure 15-23**. Venous blood drains with gravity and the siphon effect of the pump. ECMO flow is nonpulsatile, meaning that ECMO pressure waveforms will be flat. Bleeding is the leading complication of ECMO because full-system anticoagulation is required to prevent thrombus formation. Other complications include pump failure, cannula dislodgement, cardiac arrest, or circuit problems such as an air embolus. Electrical and gas requirements need to be carefully assessed before transport to ensure an uninterrupted supply.

The most commonly encountered VAD is the LVAD, which can be fully implanted or externally delivered. Traditionally, LVADs have been a bridge-to-transplant option for patients with refractory end-stage heart failure. More recently, several VADs, including LVADs, RVADs, and BiVADs, have been approved as destination therapy, meaning they are an alternative to heart transplantation **Figure 15-24**. Temporary VADs are often used for patients with significant myocardial dysfunction as a consequence of infection, infarction, ischemia, or their inability to be weaned from cardiopulmonary bypass support following cardiac surgery. Criteria for placement of VADs require that patients be reasonable candidates for transplantation because it may not always be possible to wean a patient from VAD support.

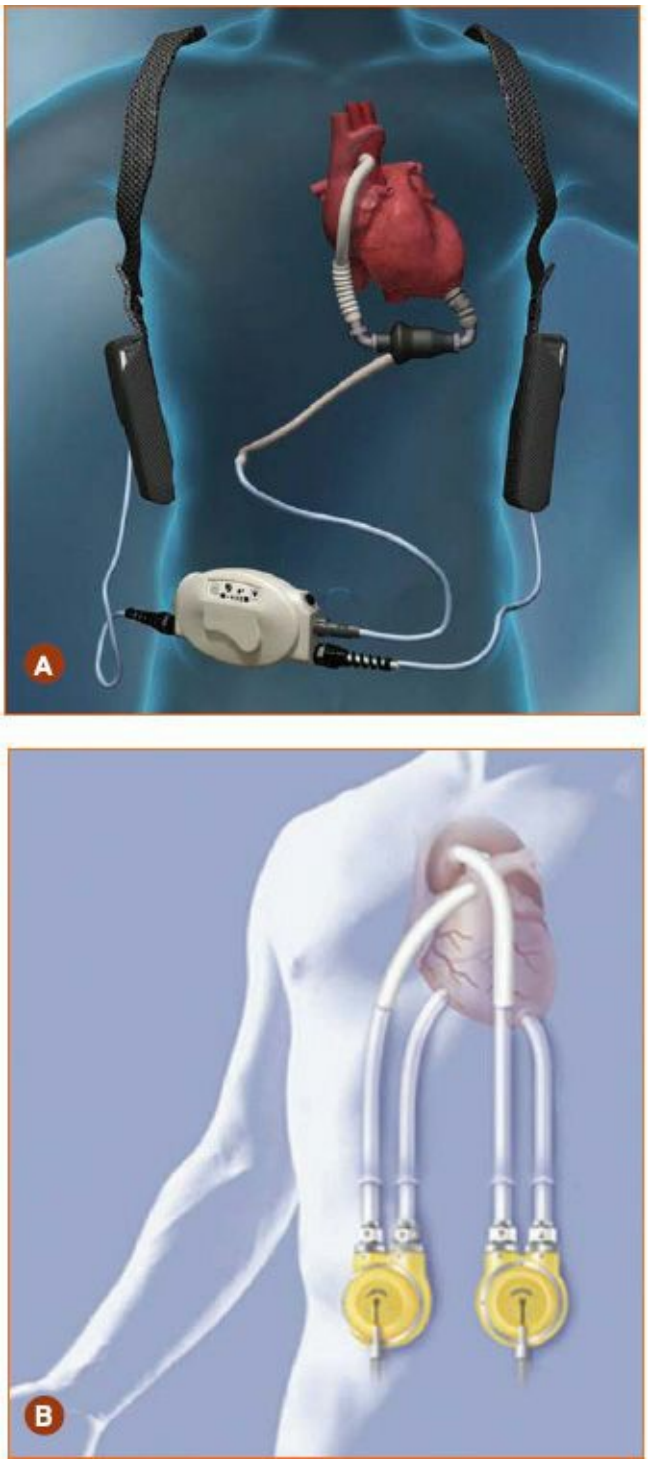


Figure 15-24 **A.** A left ventricular-assist device. **B.** A right ventricular-assist device.

Power requirements for VADs are usually less than those required for ECMO. Some VADs can operate for extended periods on batteries. The CCTP, in addition to ensuring that the transport vehicle has adequate power to supply or charge the VAD, should ensure that all necessary adapters, connectors, and charging units accompany the patient during transport. Almost all VADs have some ability to be manually operated using a hand or foot pumping accessory in case of mechanical or power failure. Be certain that such emergency equipment also accompanies the patient.

Complications of VADs in the early postimplantation period include bleeding, device malfunction, and thromboembolism. When a single-sided RVAD or LVAD is implanted, close observation and interventions to avoid failure of the opposite ventricle are extremely important. Later complications include infection and gastrointestinal problems (often seen when totally implanted VADs compress the gut, altering digestive processes). Anticoagulation requirements for VADs range from a single aspirin

taken daily to full systemic anticoagulation and close observation of clotting times. Point-of-care coagulation monitoring devices may be needed during transport.

VAD cannulas are usually tunneled through the chest into the heart. Invariably, these connections are large and may be affected by both cannula and patient positioning. As in ECMO, filling a VAD depends on gravity as well as patient fluid volume status. In cases of cardiac arrest, it may be inadvisable to perform CPR depending on the type and placement of VAD cannulas. Treatment of arrhythmias either pharmacologically or with defibrillation is typically attempted before considering CPR. Disconnection of VAD driver devices, while typically recommended by manufacturers, is not routinely done during defibrillation.

Finally, while most VADs provide pulsatile flow (meaning that pressure waveforms will be clearly visible on hemodynamic monitoring devices), some provide only centrifugal flow, which produces no pulsatile waveforms. Regardless of whether VAD flow is pulsatile, CCTPs should be aware that hemodynamic waveforms representing VAD flow will not match cardiac electrical activity on transport monitoring equipment. Additionally, pressure waveforms representing the cardiac activity of the patient may be visible interposed on pressure waveforms generated by the VAD. Interpretation of these data requires practice and experience.

A CCTP would not be expected to care for a patient with a VAD independently, nor should a CCTP ever accept that responsibility. A critical care registered nurse with specialized VAD training or a perfusionist should always accompany a patient with a VAD during transport. The CCTP provides an additional pair of skilled hands to assist these specialists.

Summary

Effective IABP therapy rests on an understanding of the mechanical cardiac cycle and the hemodynamics of cardiac blood flow and aortic pressures. The arterial waveform offers a window into this information.

Patients with a number of cardiac-, systemic-, and procedure-related conditions can benefit from IABP treatment. Common factors in many of these conditions include alterations in cardiac workload and its frequent consequence and disruption of the myocardial oxygen supply-demand balance.

Properly timed IAB pulsation produces a number of helpful hemodynamic effects: reduced afterload and HR, improved diastolic pressure, and lowered systolic pressure. These effects, in turn, lower MVO_2 and improve coronary artery and peripheral arterial perfusion.

IABP therapy is highly technical. In addition to the knowledge of physiology required, it requires a high degree of familiarity with the specific equipment used during transport, the ability to troubleshoot the equipment when problems arise, and—when transporting by air—awareness of the effects of atmospheric pressure changes on IAB function.

A CCTP may also need to assist a critical care registered nurse or perfusionist in transporting patients with VADs.

Case Study

YOU AND YOUR CRITICAL CARE TRANSPORT TEAM are dispatched to a suburban hospital for a 52-year-old man in the cardiothoracic intensive care unit (CTICU) with cardiogenic shock. On obtaining a more detailed patient report before leaving your base station, you learn that the patient underwent coronary artery bypass graft surgery and mitral valve replacement less than 24 hours ago. Since arriving in the CTICU after surgery, the patient's condition has been unstable, requiring the placement of an IABP, transfusion of numerous blood products, and administration of multiple inotropic and vasoactive medications. Your team has been requested to transport the patient by helicopter to a university hospital

for further and more advanced cardiac care not available at the referring facility. Your total flight time to the university hospital is 25 minutes.

On your arrival in the CTICU, you and your partner are met by the patient's nurse who says, "This patient is sick! He has required two-on-one nursing care ever since he has gotten to us. His blood pressure has been all over the place, and we have been titrating his 'pressors' continuously." The nurse takes you out to the hallway to give you a more detailed report. She reports to you that the patient had an acute inferior wall MI two days ago. He was brought to the local emergency department by an ALS ambulance, and an MI was diagnosed by the emergency department physician. The patient was immediately transferred to the cardiac catheterization lab, where he was found to have an ejection fraction of 20% accompanied by severe (> 95%) stenosis in five major vessels. The patient underwent stent placement, and an IABP was inserted to help the patient's heart muscle recover from the damage caused by the MI.

In the cardiac care unit 16 hours later, the patient experienced excruciating chest pain and shortness of breath. A 12-lead ECG confirmed that the patient was experiencing another MI caused by the occlusion of the just-placed stent and rupture of a papillary muscle, resulting in mitral valve regurgitation. A cardiothoracic surgeon was consulted, and the patient was taken to the operating room for an emergency coronary artery bypass graft procedure and valve repair. The patient was in surgery for 6 hours and has been in the CTICU for 12 hours.

As you walk in the patient's room to complete your assessment, you notice that the patient is intubated and receiving mechanical ventilation and the following infusions:

- Propofol (used for sedation during ventilator use)
- Milrinone
- Epinephrine
- Fentanyl
- Norepinephrine
- Insulin

The ventilator settings are as follows: tidal volume, 700 mL; rate, 12 breaths/min (assist control); fraction of inspired oxygen, 100%; and positive end-expiratory pressure, 5 cm H_2O. The patient has bilateral pleural chest tubes and one mediastinal drainage tube that are draining into a water-seal container with 900 mL of blood in the collection container. You also notice that he has a pulmonary artery catheter inserted through the right internal jugular vein, a left radial artery line, an indwelling urinary catheter, and a transvenous pacemaker. Despite receiving the aforementioned medications, the patient remains hypotensive with systolic readings as low as 60 mm Hg and no higher than 96 mm Hg. His CO is 3.0 L/min with a pulmonary artery pressure of 20/12 mm Hg and a dampened central venous pressure waveform reading of 2 cm H_2O. The IABP is on an assist ratio of 1:1 and is triggering from the patient's ECG rhythm. Other pertinent vital signs are as follows: noninvasive blood pressure, 76/32 mm Hg; arterial blood pressure, 80/41 mm Hg; pulse rate, 88 beats/min and normal sinus rhythm; Spo_2, 97%; respiratory rate, 12 breaths/min; and average hourly urinary output, 40 mL.

You and your partner prepare the patient for transfer to your helicopter by attaching your equipment to the patient. You maintain the infusions at their current rates because you are satisfied with the patient's current blood pressure and HR. Once in the helicopter, you notice that the patient is beginning to breathe more than the set ventilatory rate, his HR is increasing, and he seems to be becoming agitated. You and your partner discuss your standing protocols for ongoing sedation. The decision is made to titrate the propofol infusion from 10 µg/kg/min to 20 µg/kg/min and initiate a 1,000-mL normal saline fluid bolus to

assist in preventing a drop in blood pressure.

You arrive at the university hospital and prepare to transfer your care to the accepting nurse. You note that the patient is much less agitated and is no longer breathing at more than the set ventilatory rate. His blood pressure has responded appropriately to the normal saline fluid challenge and is significantly improved.

1. For this trip, what additional equipment might you need that is not already located in the helicopter?
2. Do you think a consultation with medical control should be made before departure? If so, what kind of orders are you going to request from the command physician?
3. What was the rationale for the insertion of the IABP in the case?

Analysis

Because most flight programs do not always carry their IABP, the flight crew must remember to reconfigure the aircraft to make room for the IABP. Additional IV pumps and tubing might be needed owing to the complexity of this patient's condition. It is always better to have extra supplies than not enough.

It is imperative that a consult with medical control be made before leaving the referring facility. The patient has multiple signs of dehydration and underresuscitation, which need immediate attention. When you call the medical control physician, make sure you have all pertinent lab results (ie, electrolytes, coagulation studies, and blood gases) so you can relay them to the physician. Remember, you are the medical control physician's eyes; the physician cannot see the patient, so you need to paint the clearest picture possible.

This patient is in desperate need of albumin and/or packed red blood cells for fluid replacement, which the flight crew did not address. You may also want to discuss blood pressure management if needed during transport. It is a good idea to plan ahead and ask the command physician which pressor to titrate if the blood pressure should fall. In this case, the flight crew did not consult medical control but, for obvious reasons, should have made the call.

This patient had a massive MI that affected a large part of his heart muscle. The damage to his heart muscle has left him with a very inefficient "pumping heart." The IAB was inserted to relieve the heart of the stressors and to take over the workload while giving the heart a rest. This patient has gone into cardiogenic shock despite use of the IABP, which should tell you that there is little collateral assistance from within the heart. This patient may even be a candidate for heart transplantation. This patient's CO is extremely poor, and the pulmonary artery catheter readings suggest that the patient is volume depleted, which needs to be addressed.

Prep Kit

Ready for Review

- In IABP therapy, a balloon connected to a pump via a catheter has been inserted into the aorta to provide temporary assistance to a failing heart.
- The IAB catheter is typically threaded into the descending aorta through the femoral artery.
- The balloon is connected to a console to shuttle helium gas, inflating the balloon at the onset of diastole and deflating just before systole (ventricular ejection).
- An ECG machine determines when the balloon should be inflated and deflated.

- Inflation and deflation are timed to the cardiac cycle, resulting in significant augmentation of flow to the coronary and renal arteries during diastole (increased supply) and substantially reduced afterload during systole (decreased demand).
- One of the CCTP's main roles in transporting a patient receiving IABP therapy is to ensure proper timing by reading the patient's ECG and pressure waveforms and continuously monitoring the patient's condition and all devices, modifying the timing if necessary.
- Other CCTP responsibilities include securing the patient to prevent movement of the balloon and ensuring that all equipment has the necessary power supply.
- The AV valves (mitral and tricuspid) lie between the atria and the ventricles, and the semilunar valves (aortic and pulmonic) are the exits from the ventricles. The purpose of the cardiac valves is to prevent the backward flow of blood in the heart.
- The AV valves have chordae tendineae, which attach the edge of the valve to the papillary muscles attached to the endocardium and hold the AV valves in place in their closed position and prevent them from prolapsing into the atria during systole or ventricular contraction. The semilunar valves do not have chordae tendineae; opening and closing are related to the pressure changes in the heart, aorta, and pulmonary artery.
- Systole and diastole include five phases: atrial systole, isovolumetric contraction, ventricular ejection, isovolumetric relaxation, and ventricular filling.
- In atrial systole, the pressure in the ventricles increases. The atria contract, extra blood is ejected from the atria into the ventricles, mitral and tricuspid valves are open, and pulmonary and aortic valves are closed.
- Isovolumetric contraction occurs between the closure of the AV valves and the opening of the semilunar valves (in which there is no change in ventricular blood volume) immediately before the blood is ejected through the semilunar valves. The pressure in the ventricles rises abruptly.
- During ventricular ejection, pressure in the left ventricle exceeds pressure in the aortic root, resulting in the aortic valve opening.
- During isovolumetric relaxation, pressure in the ventricles is below the arterial pressure. Ventricles are no longer contracting, mitral and tricuspid valves are closed, and the pulmonary and aortic valves are closed.
- Ventricular filling occurs once the mitral and tricuspid valves open.
- Pressure waveforms are one of the main variables evaluated to determine the effectiveness of IABP therapy.
- The dicrotic notch, a slight bump in the aortic pressure waveform that signals the onset of diastole, occurs during isovolumetric relaxation as the valves bulge under the pressure of the blood from the aorta and then spring back slightly.
- In heart failure, myocardial oxygen supply and demand are mismatched. IABP therapy offers a mechanical means of rebalancing them by helping to increase the blood flow to the heart muscle, thereby decreasing the workload.
- Each IABP console allows the operator to control the volume of gas shuttled back and forth to the balloon with each counterpulsation cycle. This control is variously referred to as augmentation or balloon volume.
- The arterial pressure waveform that the IABP console monitors may come from the central lumen of the IAB catheter, from the fiberoptic catheter, or from a peripheral arterial catheter in the patient.

- IAB inflation and deflation can be set to trigger from the ECG, pressure changes, a pacemaker, an internally preprogrammed rate, or combinations of these. The most reliable is the ECG. The provider caring for the patient chooses the trigger best suited to the patient.
- The IABP device can pump in several modes, called assist ratios or IABP frequency. IABP waveform evaluation is usually easiest in the 1:2 assist ratio, which allows comparison of pressure waves of the unassisted cycle with the assisted one. In this mode, every other contraction is augmented by the balloon pump.
- When evaluating a waveform in the 1:2 mode, the peaks created by the inflation of the IAB are usually the highest pressure peaks and are referred to as the diastolic augmentation waveforms. The pressure waveform that follows is referred to as the assisted systole waveform because the deflation of the IAB assists the ventricle in ejecting blood. The third pressure waveform is referred to as the unassisted systole because the balloon pump is not moving and the waveform reflects what would normally occur without IABP intervention.
- To evaluate for correct IABP timing, the pressure peaks, slopes, and inflation and deflation points of each of these pressure waveforms must be evaluated in a systematic manner, as follows:
  - Identify systole and diastole of each pressure waveform.
  - Identify diastolic augmentation, assisted systole, and unassisted systole.
  - Identify and evaluate the point of inflation.
  - Identify and evaluate the end-diastolic dip in pressure created by balloon deflation.
  - Evaluate the slope of diastolic augmentation pressure and the slope of assisted systole.
  - Evaluate diastolic augmentation peak pressure.
  - Compare the peak pressure of assisted systole with the peak pressure of unassisted systole.
- Early inflation is reflected on the waveform by a shortened normal pressure decrease that follows diastole or as an opened V and with a lessened slope on the diastolic augmentation waveform. Early inflation can force the premature closure of the aortic valves, decrease the stroke volume, and damage the aortic valve.
- Late inflation causes little harm but does not maximize the benefits of IABP therapy.
- Early deflation also results in the benefits of IABP therapy not being fully realized.
- Late deflation, which can be extremely detrimental, is characterized by a widened appearance of the diastolic augmentation waveform base and a prolonged rate of rise in the assisted systolic waveform. Late deflation *worsens* myocardial ischemia and needs to be avoided.
- IABP therapy reduces cardiac work and myocardial oxygen consumption and improves peripheral perfusion to patients with a variety of conditions and undergoing cardiovascular and surgical procedures.
- Patients receiving IABP therapy are candidates for transport in ground ambulances or in fixed- or rotary-wing aircraft. Some issues to consider when using these vehicles include space and weight constraints, battery life and vehicle power supply, and loading, unloading, and securing the pump in the vehicle.
- Many IABPs are capable of operating on 110- to 120-V AC power or 24-V DC power, although the latter may require an adapter cable. Ensuring a match between IABP power requirements and the available power supply in the transport vehicle is crucial.
- In aircraft, space limitations may require reconfiguration of the pump and monitor module.
- Once the IABP is in the transport vehicle, it is critical to secure the pump so that it remains stable for

safe operation throughout transport.

- Steps directly related to operating an IABP during transport include the following (other steps are needed for quality care):
  - Ascertain current IABP settings and note typical pressures.
  - Determine IAB catheter model, size, and insertion depth.
  - Ascertain that the balloon tip location has been verified by chest radiograph.
  - Attach new ECG leads and secure each lead over the electrode with 2″ cloth tape.
  - Ensure that the IAB catheter is taped securely to the patient's leg.
  - Apply a knee immobilization splint to the leg in which the IAB was inserted to prevent leg flexion during transport.
  - Ensure that the appropriate connectors to attach the IABP to the transport console are available. Determine the console that will be used at the receiving facility, and be certain to take necessary adapters or connectors.
  - Move the patient to the transport stretcher. Connect and secure all pumps, monitors, ventilators, and other equipment.
  - Transfer the IABP to the transport console.
  - Establish power to the transport IABP console.
  - Open the helium tank and verify pressure.
  - Follow the IABP console instructions for start-up.
  - Optimize IABP timing in a 1:2 mode.
  - Assess pressures every 5 minutes or with any changes in patient condition. Check insertion site and pulses every 15 minutes.
- Atmospheric pressure changes can affect IAB performance. With ascent, balloon pressure and volume can rise. With descent, balloon pressure and volume can decrease. Some IABPs compensate for pressure changes automatically.
- The autofill mode should be used during air transport; if the autofill mode cannot be used, a manual fill must be performed at the same intervals that an autofill would occur.
- Patient assessment parameters useful for evaluation of effectiveness of IABP therapy are vital signs, oxygenation, urine output, peripheral perfusion, central nervous system (mentation), and overall general condition of the patient.
- To detect compromised circulation to the left subclavian artery, the CCTP should palpate or use a handheld Doppler ultrasound device to assess the left radial pulse and compare it with the right radial pulse. A pulse oximeter probe on a finger of the left hand also provides early warning of this complication.
- Inspect the insertion site, buttocks, and posterior hip area for evidence of bleeding. Note hematomas, and mark their borders to monitor progression.
- If the femoral artery is used as the insertion site, assess and document the presence of the distal pulses and CRT in the extremity used and compare the pulses and CRT with those in the other leg. Splint the knee to prevent excessive movement of the leg. The sudden loss of pulses or CRT could signal IAB occlusion of the femoral artery, causing ischemia in the limb. Notify medical control immediately.
- Emergency situations to troubleshoot when an IABP is in use include cardiac arrest, balloon rupture or leak, console failure, an empty helium tank, excessive bleeding, and catheter migration or accidental removal.

- If cardiac arrest occurs, the trigger select should be set to "pressure" and CPR started. Defibrillation should be provided as necessary. There is no need to disconnect the IABP or any associated monitoring equipment when shocking the patient.
- Balloon ruptures are rare. Inspect the IAB tubing often for the presence of blood in the air channel of the tubing. The gas lumen and channel of the catheter should never contain blood. If blood is noted in the gas lumen of the catheter, IABP therapy should be discontinued immediately. For signs or symptoms of gas embolus, the patient should be placed in left lateral recumbent position, high-flow oxygen should be administered, and the patient should be transported to the nearest appropriate facility.
- Carefully inspect the patient and tubing to determine the cause of a gas loss alarm. If a source of a leak cannot be determined, assume that an IAB leak is a possibility.
- If the IABP console becomes disabled, perform manual inflation and deflation as soon as possible. The balloon must not remain idle (ie, immobile) for more than 30 minutes, or clots can accumulate in the folds of the balloon.
- An empty helium tank should be indicated by the IABP console screen. First ascertain that the tank valve is opened. Should a tank require replacement, close the valve on the depleted helium tank and replace the tank with a full one.
- If excessive bleeding is noted from the insertion site, apply direct pressure over the site to control the bleeding. Consult with medical control about discontinuing infusions of anticoagulant medications or, if bleeding cannot be controlled, diverting to the closest appropriate facility.
- Accidental catheter migration or removal can occur. Note the location and insertion mark of the IAB catheter before moving the patient.
- ECMO is life support for patients with cardiac and/or respiratory failure and must be managed by a specially trained critical care nurse or perfusionist.
- The leading complication of ECMO is bleeding, but complications can also include pump failure, cannula dislodgement, cardiac arrest, or air embolus. CCTPs need to carefully assess electrical and gas requirements before transport.
- CCTPs should ensure that all emergency equipment accompanies the patient with VAD, including manually operating materials in case of mechanical or power failures. Complications of VADs include bleeding, device malfunction, and thromboembolism in the early postimplantation period. Infection and gastrointestinal problems can also occur.
- Coagulation monitoring devices should be considered for transport.
- CCTPs should treat arrhythmias pharmacologically or with defibrillation before considering CPR for patients with VADs.
- CCTPs should know that the hemodynamic waveforms representing VAD flow will not match cardiac electrical activity, and interpretation of the data requires practice and experience.
- CCTPs should never be expected to care for patients with VADs independently.

Vital Vocabulary

afterload An expression of cardiac work related to the forces that must be overcome to eject blood from the ventricle.

aortic regurgitation Backward flow of blood through the aortic valve from the aorta into the left

ventricle.

assisted systole The pressure waveform that follows the diastolic augmentation peak.

assist ratio A setting on the IABP that allows the operator to determine how often the pump inflates the balloon. A 1:1 setting means the balloon inflates with each heartbeat; and 1:2, with every other heartbeat, etc; also called IABP frequency.

atrioventricular (AV) valves The valves (mitral and tricuspid) that separate the atria from the ventricles.

caudal Pertaining to or in the direction of the feet.

central lumen The lumen or port of the IAB catheter used to guide initial catheter insertion and to monitor arterial pressure during operation.

cephalad Toward the patient's head.

chordae tendineae The thin, fibrous strands stretching out from the apexes of some of the papillary muscles of the ventricles, extending upward and attaching to the edges of the AV valves, which help keep the cusps of the valves from turning inside out when pressure builds up in the ventricles.

diastole The relaxation phase of the heart cycle, in which the ventricles are dilated and filling with blood.

diastolic augmentation The increase in aortic pressure during diastole that IAB inflation produces, improving coronary and peripheral perfusion, and that may be thought of as a "second systole."

diastolic augmentation waveforms The waveforms caused by IAB inflation during diastole.

dicrotic notch The brief increase in aortic pressure reflected in a notching of the wave; caused by the sudden closure and spring back of the aortic valve leaflets; signals the start of diastole.

extracorporeal membrane oxygenation (ECMO) An adjunct to oxygenation and ventilation that consists of pumps, oxygenators, and heat exchangers to ensure adequate patient oxygenation, thereby replacing the function of the lungs in gas exchange.

Frank-Starling curve States that the force of the cardiac muscle contraction is proportional to the amount of stretch placed on the muscle fibers (meaning that the more the heart is stretched by the incoming blood, the more forcefully the ventricles contract and the more blood that is ejected); demonstrates how changes in ventricular preload lead to changes in stroke volume.

gas lumen The lumen or port of the IAB catheter that carries helium between the IAB and the pump console to inflate and deflate the balloon.

intra-aortic balloon pump (IABP) therapy A procedure involving a balloon inserted into the aorta and connected to a pump via a catheter, helping to increase the blood flow to the coronary arteries during diastole (inflation) and decrease afterload of blood from the left ventricle (deflation).

isovolumetric contraction The early stage of ventricular contraction during which ventricular blood volume is unchanging because all valves are closed (the semilunar valves have not yet opened).

isovolumetric relaxation The early stage of ventricular relaxation during which ventricular blood volume is unchanging because all valves are closed (the AV valves have not yet opened).

myocardial oxygen consumption (MVO_2) The volume of oxygen that the heart muscle consumes; an expression of the level of oxygen demand in the heart.

papillary muscles A type of muscle in the ventricle from which the chordae tendineae extend and attach to the cusps of the AV valves.

preload The amount of blood that flows into the ventricle passively from the atria; related to the overall volume status of the patient.

relative contraindication A condition that makes a particular treatment or procedure somewhat inadvisable but does not completely rule it out.

semilunar valves The valves (aortic and pulmonic) that are the exits from the left and right ventricles into the aorta and the pulmonary artery, respectively.

systole The contraction phase of the heart cycle when the ventricles pump blood out of the heart through the aorta and the pulmonary artery into the systemic and pulmonary circulatory systems.

timing In the context of IABP therapy, a method for coordinating the IAB inflation-deflation cycle with the cardiac cycle (inflation during diastole and deflation synchronous with systole).

unassisted systole Pressure waveform reflecting what would normally occur without IABP assistance.

ventricular-assist device (VAD) Sometimes an alternative to heart transplantation, this mechanical pump is surgically implanted and helps maintain a heart that can no longer function properly. It has primarily been used to support patients who are waiting for a heart transplant.

Gastrointestinal and Genitourinary Emergencies

Authors

Sean M. Kivlehan, NREMT-P

Metabolic Regulation of

Acid-Base Status: Andrew Bartkus, RN, MSN, CEN, CCRN, CFRN, NREMT-P, FP-C

Objectives

1. Understand the anatomy and physiology of the gastrointestinal system, including the alimentary canal and accessory organs (p 630–634).
2. Understand the anatomy and physiology of the genitourinary system, including the urinary system and the male and female reproductive systems (p 634–638).
3. Differentiate between upper and lower gastrointestinal bleeding (p 639).
4. Understand the pathologies related to common disorders of the gastrointestinal system, including peptic ulcers, gastritis, esophageal varices, Mallory-Weiss syndrome, diverticulitis, angiodysplasia, inflammatory bowel disease, and ulcerative colitis (p 639–642).
5. Properly assess the signs and symptoms as well as describe the management of the various gastrointestinal conditions (p 643–646).
6. Describe laboratory results as they relate to specific gastrointestinal system disorders (p 645–646).
7. Describe gastrointestinal system imaging, including endoscopy, colonoscopy, angiography, and scintigraphy, as well as other in-hospital assessment and management techniques (p 646).
8. Understand the pathologies related to diseases of the gastrointestinal system, including intestinal obstructions, ileus, liver disease, choledocholithiasis, and pancreatitis (p 648–660).
9. Understand the pathologies related to common disorders of the genitourinary system, including both acute and chronic renal failure, urinary tract infections, testicular torsion, penile fracture, and priapism (p 661–666).
10. Properly assess the signs and symptoms as well as describe the management of the various pathologies discussed (p 646–665).
11. Describe genitourinary system laboratory results as they relate to the specific disorders (p 662–666).
12. Describe various gastrointestinal- and genitourinary-related feeding and drainage tubes, including their assessment, maintenance, and potential complications. Examples include various feeding tubes, different types of urinary catheters, ostomies, Jackson-Pratt drains, and T-tubes (p 667–674).
13. Understand flight considerations for patients with feeding or drainage tubes (p 672).
14. Understand acid-base physiology (p 674).
15. Examine how the body's chemical buffer system mitigates acid-base imbalances (p 674–675).
16. Describe how to interpret blood gas samples (p 675–677).
17. Understand the pathologies related to an imbalance of acid-base, their clinical features, and their treatment. Pathologies include metabolic alkalosis, metabolic acidosis, and renal metabolic acidosis (p 674–679).

18. Understand flight considerations for patients with gastrointestinal and genitourinary tract complications (p 679–680).

Introduction

Homeostasis (stability in the body's internal environment) depends on a number of metabolic processes that involve the gastrointestinal (GI) and genitourinary (GU) systems. Unfortunately, these processes can be the target of a number of pathologies causing a range of complications, such as malnourishment, pain, and shock. These conditions require a thorough assessment and diagnosis followed by appropriate management—a process that is inherently difficult because the signs and symptoms that accompany abdominal conditions may be obscure. A detailed understanding of related anatomy and physiology is therefore required for the CCTP to successfully manage a patient with a GI/GU condition during transport, along with any complications that may arise.

Anatomy and Physiology

Intricately complex yet stunningly efficient, the GI system consists of a specifically arranged network of organs and ducts devoted to the digestion of food and the extraction of its nutritional content. The alimentary canal (also referred to as the GI tract) consists of the mouth, pharynx, esophagus, stomach, small intestine, and large intestine; food travels through these structures and finally exits the body via the rectum. The alimentary canal is lined with continuous specialized tissue that allows for the absorption of digested nutrients from food while maintaining a protective barrier from waste and microorganisms. During mechanical and chemical digestion, food turns into the basic molecular building blocks required by the body's cells. Enzymes that aid in this digestive process are secreted by a variety of accessory organs, including the salivary glands, liver, gallbladder, and pancreas.

Unnecessary side products from the digestion process are either defecated via the anus or excreted by the GU system. Cooperation between the liver and kidneys allows for safe passage of toxic nitrogen-containing compounds during their exit from the body.

GI System

GI Tract Tissue

Although the alimentary canal contains numerous specialized cells and tissues, four layers are seen almost continuously from the esophagus to the rectum **Figure 16-1**: the mucosa, the submucosa, the muscularis externa, and the serosa.

The **mucosa** forms the first and innermost layer that is exposed to the lumen, or cavity, of the canal. This moist mucous membrane consists of three sublayers:

- The surface epithelium consists of a thin layer of simple columnar epithelium interspaced with goblet cells that secrete mucus. This mucus moistens the surface of the GI tract and protects the lining from being digested itself. Specialized absorption cells are found in the epithelium as well.
- The lamina propria, located immediately above the epithelium, consists of loose areolar connective tissue filled with capillaries and lymph nodules. It provides limited access to the circulation for digested molecules.
- A layer of smooth muscle called the muscularis mucosae lies above the lamina propria, creating folds in the tissue to increase the surface area available for nutrient absorption.

The **submucosa** consists of connective tissue just beyond the mucosa. Blood and lymphatic vessels weave through this layer to connect the vessels of the mucosa to systemic circulation. The submucosal

nerve plexus resides here, permitting innervation of smooth muscle and secretory cells. The elastic character of the submucosa allows for restoration of a structure's original shape after it is distended by food.

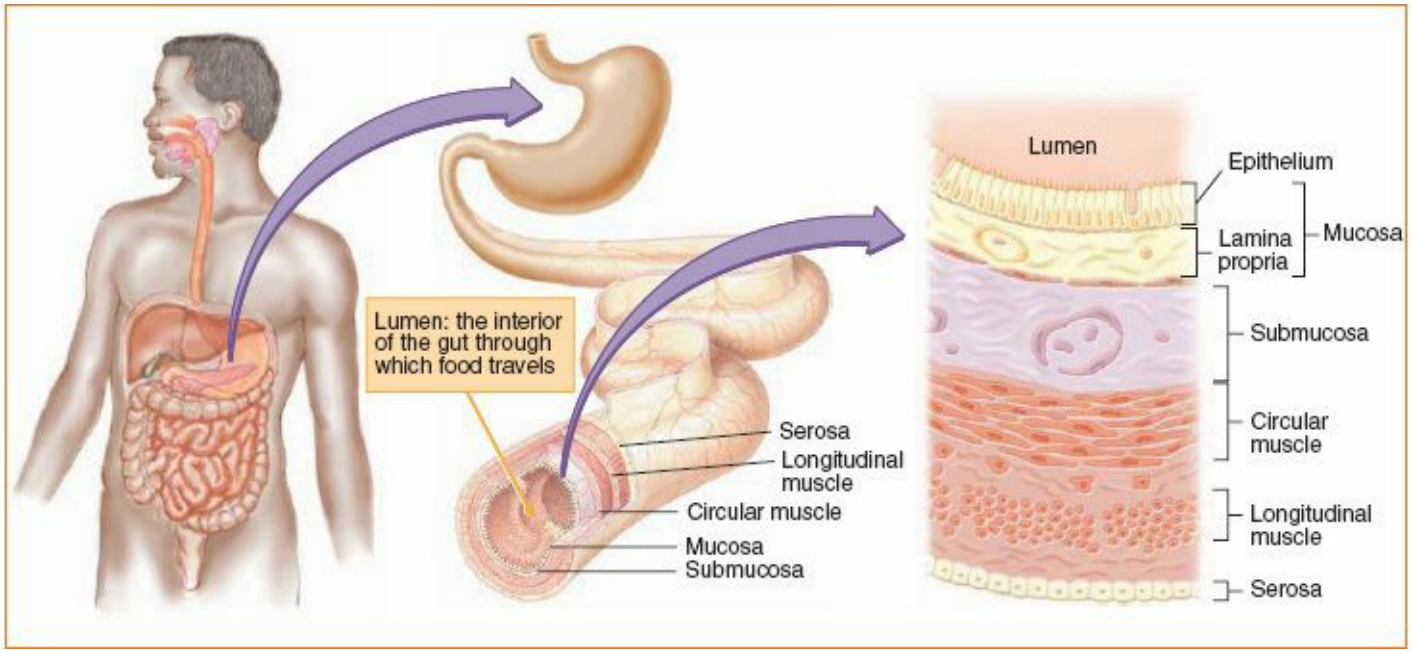

Figure 16-1 Gastrointestinal tract layers.

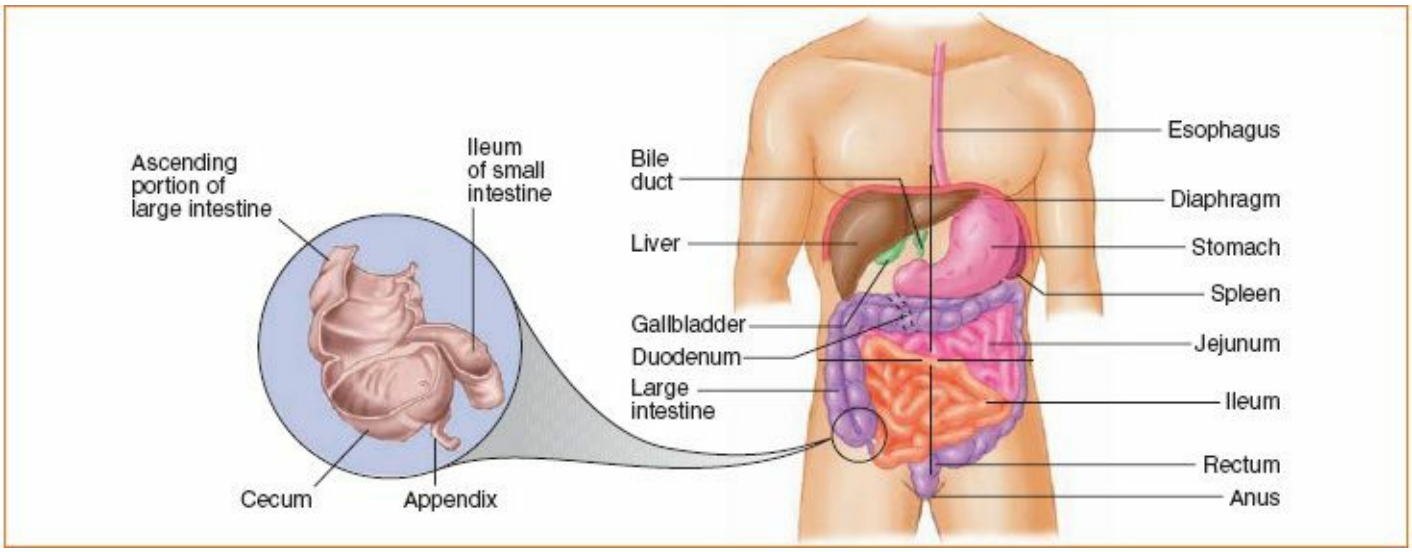

Figure 16-2 Overview of the gastrointestinal system.

The **muscularis externa** forms the muscle bulk of the GI tract. It is divided into two layers of smooth muscle: an inner circular layer and an outer longitudinal layer. The arrangement of these two layers facilitates the mechanical digestion methods of segmentation and peristalsis.

The **serosa** (commonly referred to as the visceral peritoneum) consists of areolar connective tissue lined with simple squamous epithelium, called the mesothelium. The serosa is meant to be a protective layer, covering all peritoneal GI organs.

Alimentary Canal

The alimentary canal **Figure 16-2** maintains a chemical environment that is beneficial for the digestion of food, without altering the environment of the rest of the body.

Mechanical digestion begins the moment food enters the oral cavity. Mastication (chewing) tears and

grinds food into more manageable chunks. The increase in the surface area of the food that results from this process facilitates chemical digestion, which begins when food within the mouth is moistened with saliva. Saliva contains salivary amylase, an enzyme that breaks down starch.

The food bolus, once sufficiently chewed, is pushed into the oropharynx by the tongue in preparation for swallowing. Swallowing becomes a largely involuntary process once initiated, albeit a fairly complicated one. More than 22 muscles are used to block off the nasopharynx with the soft palate and uvula, the larynx with the epiglottis, and the mouth with the tongue, thereby forcing food into the esophagus.

The esophagus is a 25-cm tube of muscle connecting the oropharynx with the stomach. A substantial flow of blood is supplied to the muscles of the esophagus via several arteries and returned through a large network of veins in the submucosa. Peristalsis, a series of wavelike contractions of the esophagus, carries food to the stomach in less than 8 seconds. The bolus of food arrives in the stomach via the gastroesophageal sphincter, which closes following the passage of a bolus, preventing backflow.

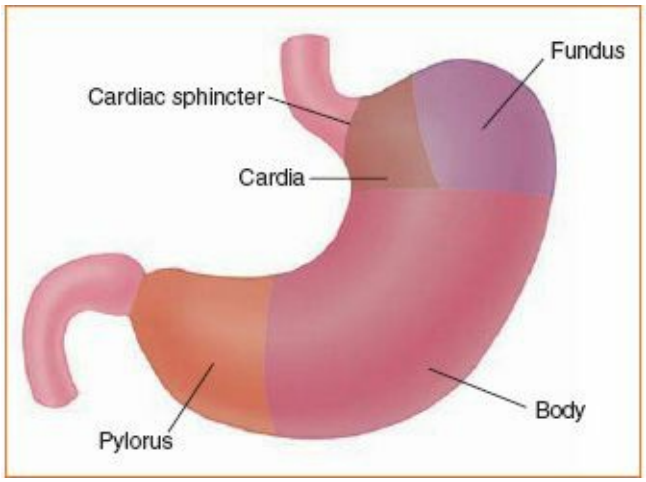

Figure 16-3 Anatomy of the stomach.

The stomach stores food while continuing chemical and mechanical digestion through a variety of enzymes and muscles. The stomach, which is bound superiorly by the esophagus and inferiorly by the small intestine, is a 15- to 25-cm J-shaped widening of the GI tract. When the stomach is full, it can expand up to 4 L. Mechanical digestion is continued and completed by the stomach muscles. A bolus of food enters the stomach at the cardia region via the cardiac sphincter. The stomach terminates at the pyloric sphincter, which regulates the exit of materials from the stomach **Figure 16-3**.

Throughout the stomach, glands consisting of specialized mucous neck cells produce a number of secretions, collectively termed gastric juice. Included in this juice are mucin, hydrochloric acid, intrinsic factor, pepsinogen, and lipases, all of which aid in the digestive process. The end result of the digestive actions that occur in the stomach is chyme, a liquid mixture of partially digested food, gastric juice, and water that is ready for entry into the small intestine.

The small intestine is a long, 2.5-cm-wide canal that twists throughout all four quadrants of the abdomen. Digestion is completed, and the bulk of nutrient absorption takes place here. This organ is divided into three areas: the duodenum, the jejunum, and the ileum. The superior mesenteric artery provides blood supply to all three of these regions via its vast network of vessels in the mesentery.

Chyme begins its journey through the small intestine at the duodenum. The small intestine also receives bile and pancreatic juice at the duodenum, both of which aid in further digestion.

The large intestine facilitates the transformation of chyme into feces and inevitable expulsion from the alimentary canal via the rectum and anus. The large intestine is divided into six regions: cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum **Figure 16-4**. The more

proximal sections (cecum, ascending colon, and transverse colon) provide water and electrolyte absorption, whereas the latter areas (descending colon, sigmoid, and rectum) provide storage for feces and muscles for propulsion to the rectum.

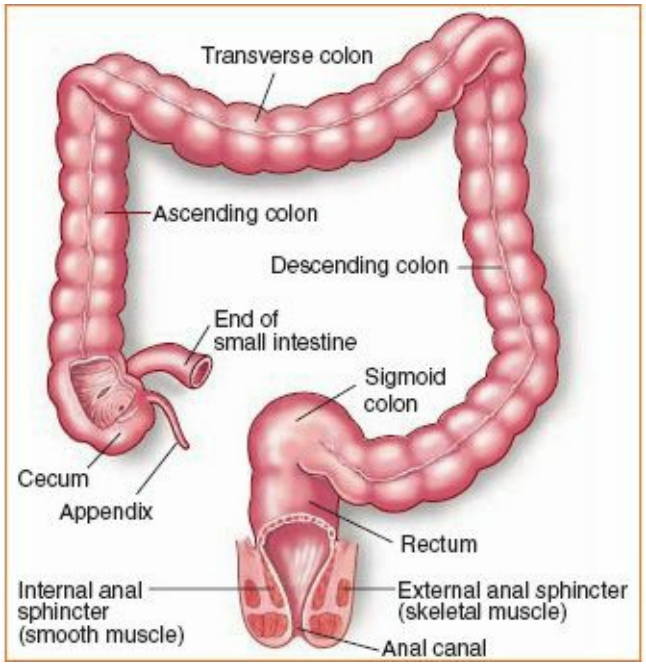

Figure 16-4 Anatomy of the large intestine.

Chyme is deposited into the cecum from the ileum of the small intestine, beginning the final leg of its journey through the body. The appendix attaches posteromedially to the cecum, about 2.5 cm inferior to the ileocecal valve. Chyme is pushed upward into the ascending colon, where water and electrolytes are reclaimed from unusable end products of digestion. Anaerobic bacteria residing here prepare a significant amount of vitamins B and K for absorption as well.

The transverse colon proceeds across the abdomen until it makes an inferior turn, after which it becomes the descending colon. These two sections function mainly to store feces. The muscularis externa begins to thicken gradually along the length of these areas to assist with the movement of increasingly compact feces.

The sigmoid colon starts at the level of the pelvis, taking an S-shaped path into the rectum, a 13-cm muscular tube. A defecation reflex is stimulated by the stretching of the rectal wall by feces buildup, resulting in the opening of the internal anal sphincter. The external anal sphincter is voluntarily controlled. Once it is opened, feces are defecated through the anus.

Accessory Organs

The alimentary canal does not accomplish the feat of digestion on its own. Similar to any other functioning system, it receives outside support from several accessory organs—namely, the salivary glands, liver, gallbladder, and pancreas.

Three pairs of extrinsic salivary glands inhabit the tissues surrounding the oral cavity, secreting saliva to initiate the chemical digestive process **Figure 16-5**. The saliva produced by these extrinsic salivary glands aids in digestion not only by providing enzymes that break down starches in food, but also by moistening food to facilitate bolus formation. In addition, saliva cleanses the mouth. Tiny internal salivary glands are located throughout the oral cavity as well, supplementing the secretion of the extrinsic glands. Secretion of saliva by all of these glands is amplified by stimulation of the salivatory nuclei in the brain stem, whether it is by the sight, smell, or taste of food. Alternatively, sympathetic nervous system stimulation promotes secretion of a thicker saliva with a higher concentration of mucin, resulting in a dry

mouth.

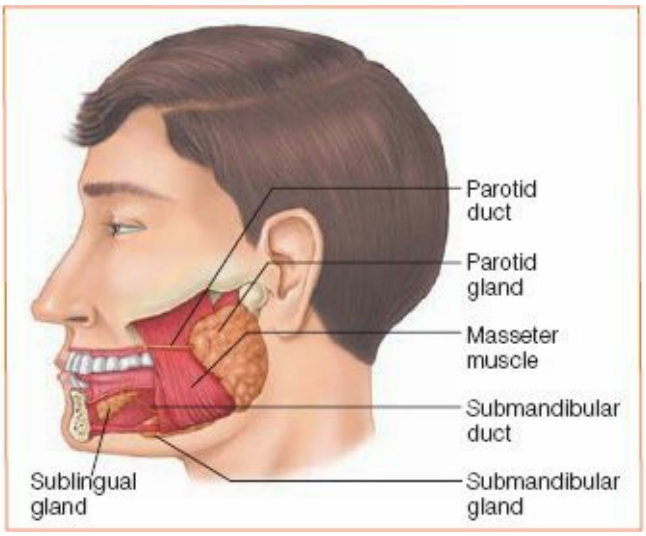

Figure 16-5 The salivary glands.

The liver is the largest solid organ in the body, as well as the most vascular, containing more than one fifth of a person's total blood volume at any given time **Figure 16-6**. It serves as a central terminal through which all blood returning to the central circulation from the alimentary canal must pass. It provides three functions critical to the body's functioning: metabolic regulation, hematologic regulation, and bile production. Although the liver dominates the right upper quadrant of the abdomen, the majority of its bulk actually rests within the right thoracic cage; in this position, the ribs are able to provide some protection from trauma. During forceful exhalation, the liver rises as high as the fourth intercostal space just below the right nipple, and sprawls past the midline approaching the left nipple. Normally the liver can be palpated inferior to the right ribs during inspiration only, remaining within the thoracic cage during expiration.

The porta hepatis provides the gateway into the liver for the hepatic portal vein, hepatic artery, and common hepatic duct, all of which arrive via the lesser omentum. These three vessels bifurcate upon entry, separating the liver into right and left functional lobes that are distinct from the superficial lobes. The hepatic portal vein and hepatic artery continue to branch out until they eventually form the liver's functional unit, a lobule. Inside a lobule, the incoming oxygen- and nutrient-rich blood is drained into liver sinusoids, where it comes into direct contact with hepatocytes and Kupffer cells. Hepatocytes, the most metabolically active cells in the body, account for 80% of the cells in the liver. They produce and secrete bile, process fundamental molecules into macromolecules (such as glucose into glycogen), store fatsoluble vitamins, and turn toxic nitrogen-containing wastes into urea. Kupffer cells are macrophages that reside in the sinusoids and engulf bacteria and old cells. The liver sinusoids drain blood into central veins that will eventually fuse to form the hepatic vein and ultimately the inferior vena cava, returning the blood to the systemic circulation. The secreted bile drains into a bile duct, which passes it into the common hepatic duct. From there the bile is either secreted directly into the duodenum or stored in the gallbladder.

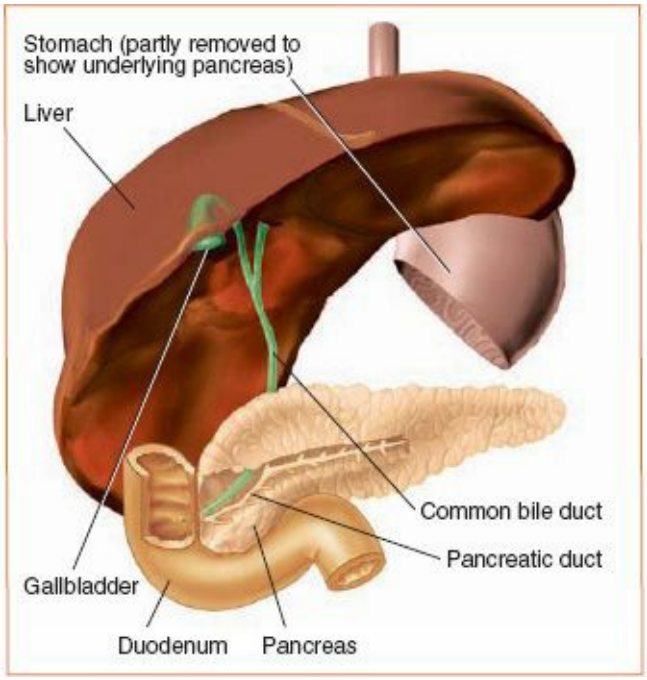

Figure 16-6 The liver, gallbladder, and pancreas.

Bile is a fat emulsifier required for the digestion of fats within the small intestine. As much as 1 L of bile is produced per day, and excess amounts are stored in the gallbladder, a small muscular sac located just inferior to the right lobe of the liver and protruding from under the liver at the level of the ninth rib. The gallbladder is about 10 cm long and can hold up to 50 mL of bile. Water and ions are reabsorbed here, concentrating the bile. Bile enters and exits via the 4-cm-long cystic duct, which connects to the common hepatic duct, or bile duct, allowing transit to the duodenum. The intestinal hormone cholecystokinin (CCK) regulates contraction of the gallbladder. CCK also relaxes the hepatopancreatic sphincter, permitting entry of bile and pancreatic juice into the small intestine via the major duodenal papilla.

Pancreatic juice is a solution of digestive enzymes secreted by the pancreas, a 12.5- to 15-cm-long retroperitoneal organ found in the left upper quadrant. The head of the pancreas is framed by the duodenum, the body runs along the inferior aspect of the stomach, and finally a tail reaches the spleen. The release of pancreatic juice is an exocrine function, but the pancreas also has an equally important endocrine function—the production of insulin and glycogen.

Microscopically, the pancreas contains millions of acini lobules, each consisting of a ring of secretory cells around an intralobular duct through which the secreted pancreatic juice drains into the main pancreatic duct. This duct empties into the common bile duct; thus, it shares a pathway to the duodenum with bile. Zymogen granules within the acinar cells secrete trypsinogen, chymotrypsinogen, procarboxypeptidase, pancreatic amylase, lipases, and nucleases, which mix with water and bicarbonate to make up pancreatic juice. Enzymes such as trypsin within the duodenum convert the various proteins to their active forms, preventing any self-digestion by these powerful enzymes. Collectively, these enzymes account for the majority of digestion that occurs in the small intestine. The bicarbonate balances the acidity of newly arriving chyme from the stomach, and the water serves to further dilute the chyme prior to absorption.

Scattered throughout the acini lobules are islets of Langerhans, cells of the pancreas that secrete a variety of endocrine hormones directly into the bloodstream. Numerous insulin-secreting beta cells work alongside alpha cells, which produce glucagon, and delta cells, which produce somatostatin. Insulin facilitates the absorption of free glucose molecules into cells from the bloodstream. Glucagon stimulates glycogen production in the liver during times of glucose surplus. Somatostatin has numerous regulatory

functions, including the inhibition of overall pancreatic function.

GU System

Urinary System

The many nutrients and ions absorbed into the bloodstream by the tissues of the alimentary canal serve a useful purpose to the body for only a certain period of time. Eventually, as a result of metabolic reactions, the molecules and atoms are either incorporated into useful products or leftover as waste. The renal system provides a path for waste to leave the body **Figure 16-7**. The kidneys continuously filter blood, managing its volume, maintain appropriate balances between acids and bases, and discard toxins and excesses by producing urine. Because the kidneys are extremely vascular, about one fourth of the cardiac output passes through them every minute. The remainder of the urinary system—the ureters, urinary bladder, and urethra—provides for transport and storage of urine during its journey out of the body.

The kidneys are a pair of retroperitoneal organs that stretch from the T12 to the L3 vertebrae. The position of the liver forces the right kidney to be slightly lower. Kidneys weigh an average of 150 g, with a length of 12 cm, a width of 6 cm, and a depth of 3 cm. The adrenal glands, seated on top of the kidneys, are important in endocrine function because they produce catecholamines in response to stress. Although the 12th ribs provide the kidneys some protection, they remain relatively vulnerable to external trauma. Three layers of tissue provide some measure of protection from such trauma:

- The renal fascia, the outermost layer, consists of dense fibrous connective tissue that encloses the kidneys and adrenal glands, securing them to the abdominal walls.
- A layer of adipose tissue directly beneath the renal fascia provides a cushion from sudden movements.
- The renal capsule, which is made up of more fibrous connective tissue, coats the kidney itself.

Internally, the tissues of the kidneys can be divided into three zones: the outermost renal cortex, the medulla, and the innermost pelvis. The functional unit of the kidney, the nephron, lies across the border between the cortex and medulla. The renal pelvis is an open space that allows pooling of urine and drainage into the ureter. **Figure 16-8** and **Figure 16-9** show the nephrons of the kidney and the glomerulus, respectively.

Upon entering the kidney, the renal artery immediately branches off into vessels of decreasing diameter. This culminates in the afferent arteriole that feeds blood into the glomerulus, a meshwork of capillaries contained within the glomerular capsule. The high pressure of the incoming blood forces fluid and solutes through openings in the capillary cell wall, which are then collected by the glomerular capsule and drained into the proximal convoluted tubule. The size of the openings in the capillary walls prevents erythrocyte and large-protein leakage, while podocytes that wrap around the capillaries help filter out macromolecules.

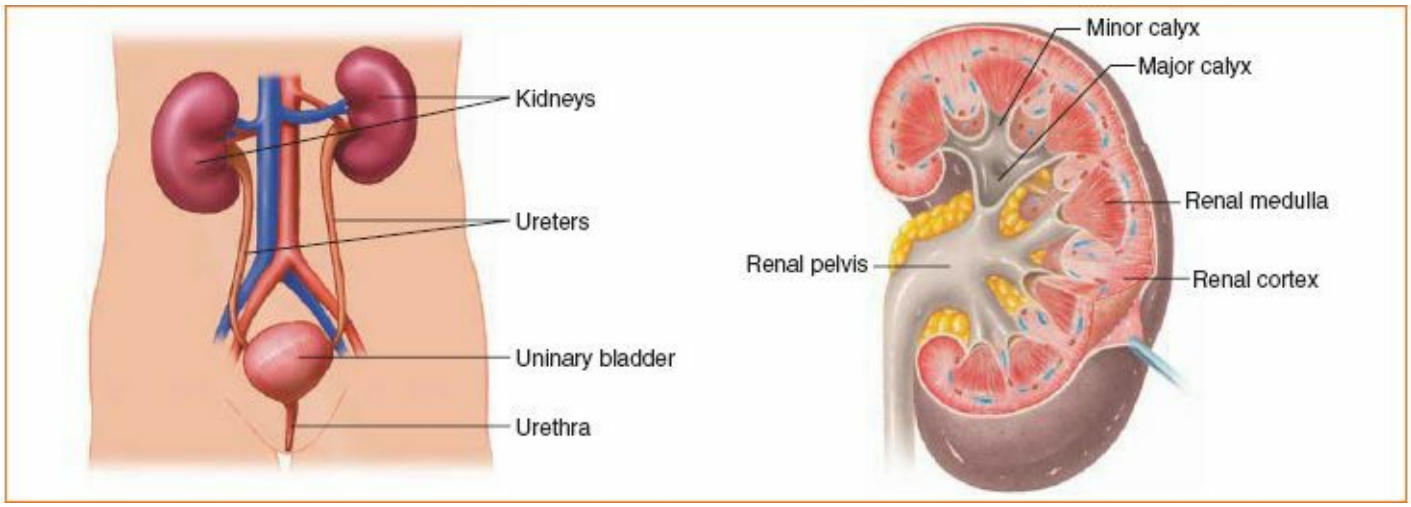

Figure 16-7 Organs of the urinary system.

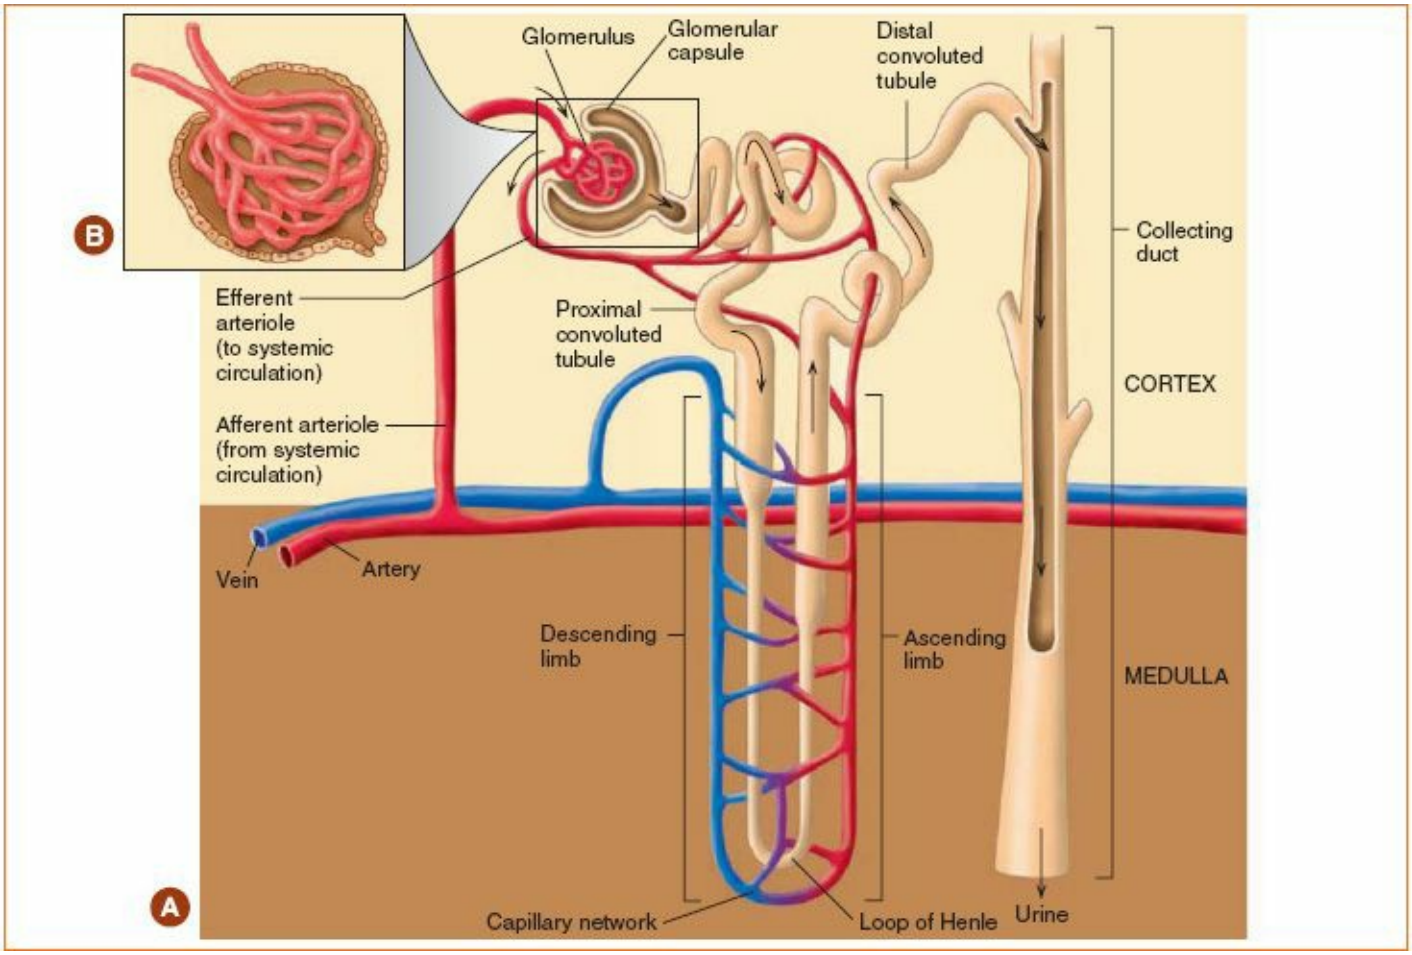

Figure 16-8 **A.** The nephrons of the kidney. Part of the nephron is located in the cortex, and part is located in the medulla. **B.** The glomerulus, close up.

Once filtered, blood exits the glomerulus by way of the efferent arterioles, which then divide into the peritubular capillaries. The proximal convoluted tubule descends into the renal medulla, and subsequently straightens out. After a distance it turns 180° to take a parallel path back to the cortex. This portion, called the loop of Henle, is where the bulk of ion absorption and reabsorption occurs. A series of osmotic gradients between the lumen of the loop of Henle and the medullary tissues result in ion exchange as material moves along this pathway, which plays a significant role in the dilution and concentration of urine.

The loop of Henle becomes the distal convoluted tubule upon its reentry to the cortex, eventually making its way to the collecting duct. The peritubular capillaries are entangled with the proximal and distal convoluted tubules as well as the loop of Henle, reabsorbing water and solutes not meant to be excreted.

The effectiveness of the glomerulus in filtering blood provides a benchmark for the evaluation of overall renal function, termed the **glomerular filtration rate (GFR)**. The normal GFR in an adult is about 125 mL/min. Various pathologies can affect the GFR, and a decrease in the rate will result in a number of metabolic alterations.

A second test frequently employed in assessing glomerular function—and hence renal function—is creatinine clearance. **Creatinine** is the metabolized form of creatine that is eliminated through the urine. The normal elimination rate for men is 95 to 145 mL/min, and the normal rate for women is 75 to 115 mL/min.

Specialized cells known as juxtaglomerular cells are present in the walls of the afferent and efferent arterioles. These cells secrete renin, an enzyme that plays an important role in the activation of the renin–angiotensin–aldosterone system (which helps regulate blood pressure). In between the afferent and efferent arterioles and the distal convoluted tubule is another class of specialized cells, the macula densa. These cells detect chemical changes in the concentration of the filtrate. This region is collectively referred to as the juxtaglomerular apparatus, and is present in every nephron.

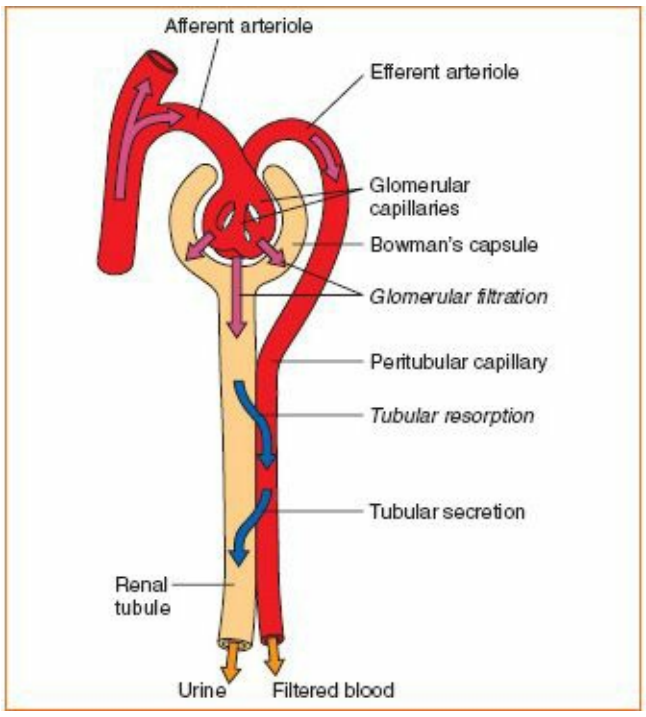

Figure 16-9 The glomerulus of the kidneys. The nephron carries out three blood-filtering processes: glomerular filtration, tubular reabsorption, and tubular secretion.

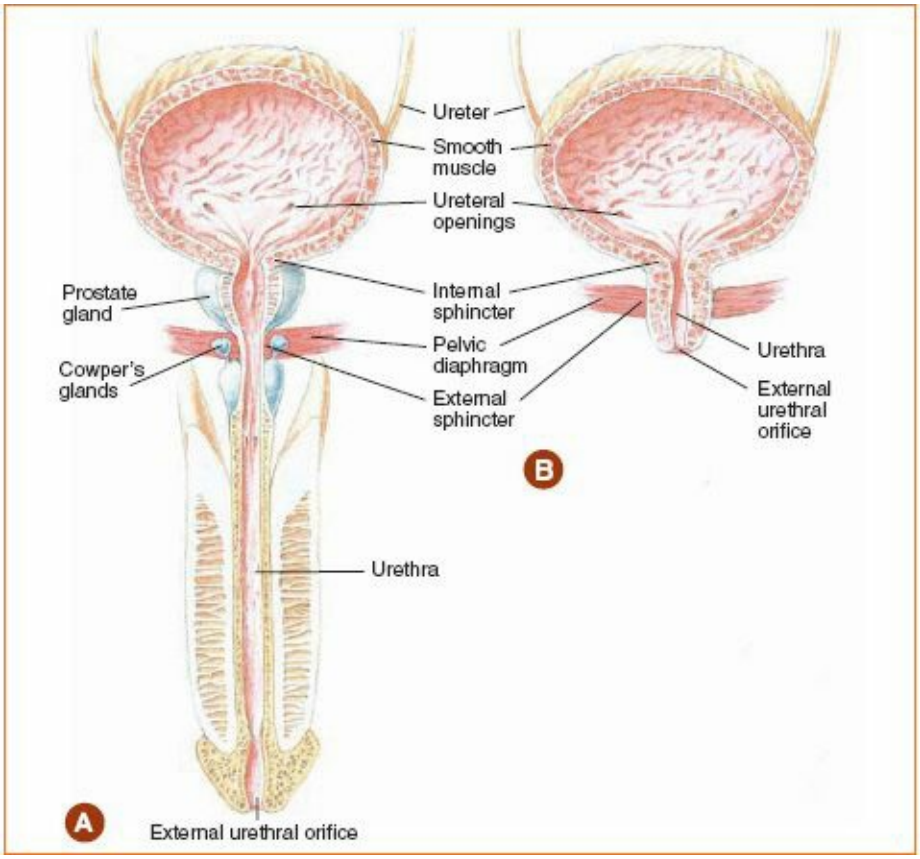

Figure 16-10 Structure of the urinary bladder and urethra. **A.** Male. **B.** Female.

The ureters, a pair of 30-cm long muscular tubes running a course to the urinary bladder, are essentially a continuation of the renal pelvis. Although gravity plays a role in the movement of urine, **peristalsis** is also a significant contributor. The ureters enter the urinary bladder in the trigone region at its base. The urethra also drains the bladder here, so there are actually three connections to the bladder at this point (hence the prefix "tri"). The bladder is a hollow, muscular organ that is located directly posterior to the pubic symphysis. It has a urine storage capacity upwards of 0.5 L and can be palpated in the lower abdomen when distended.

The urethra is another muscular tube, about 20 cm long in men and 3 to 5 cm long in women. It drains the bladder, providing an exit route for urine from the body **Figure 16-10**.

Male Reproductive System

The purpose of the male reproductive system is to generate sperm and provide a means for its delivery to a fertilizable egg in the female partner. The testes are the fundamental male reproductive organ; they consist of a pair of 4- × 2.5-cm oval-shaped spheres, suspended external to the body in a sac of skin called the scrotum. Housing outside the body is required to allow sperm production at 91°F (33°C), about 3° lower than core body temperature. Each testis is covered by two distinct layers of tissue: the outer tunica vaginalis, which folds over itself, and the inner tunica albuginea. The tunica albuginea is a tough fibrous capsule that protects the testis and penetrates it, dividing it into hundreds of lobules. Inside these lobules, sperm are created in the seminiferous tubules. The testes receive their blood supply from the testicular arteries and drain into their complementary veins. These blood vessels branch from the abdominal aorta, and along with auto-nomic nerve fibers travel to and from the testes through the spermatic cord **Figure 16-11**.

Newly made sperm drain into the efferent ductules and then move to the epididymis, where they will mature. When stimulated by smooth-muscle contractions arising from ejaculation, sperm are forced into the ductus deferens (vas deferens), a 45-cm tube that exits the scrotum via the spermatic cord. The ductus

deferens travels anterior to the pubic bone and then posterior to the bladder, finally joining with the seminal vesicle duct to form the ejaculatory duct. The two ejaculatory ducts pass through the prostate gland and terminate in the urethra, which serves as an exit route for both sperm and urine in the male.

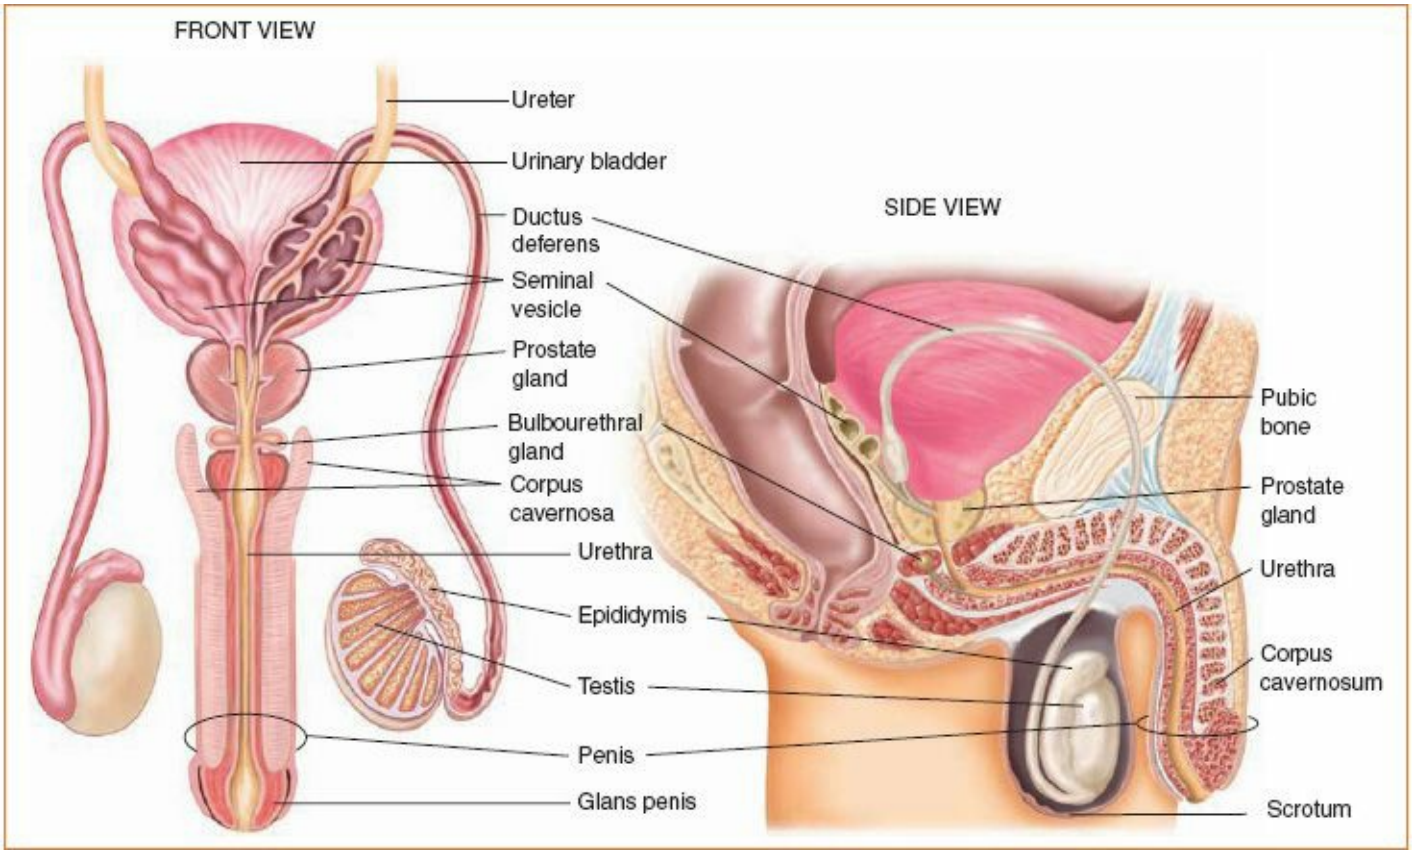

Figure 16-11 The male reproductive system.

The male reproductive system also includes five accessory glands: a pair of seminal vesicles, a pair of bulbourethral glands, and the prostate gland. The seminal vesicles are each about 6 cm long and lie on either side of the posterior bladder. The alkaline secretions of the seminal vesicles both provide the sperm with energy and facilitate their journey by relaxing the cervix and uterus in the female. The bulbourethral glands, which are much smaller than the seminal vesicles, are located just inferior to the prostate gland. The secretions of these glands neutralize any acidic urine encountered in the urethra, thereby protecting the sperm from degradation. The prostate gland surrounds the urethra and ejaculatory ducts and sits immediately inferior to the bladder. Its secretions activate sperm and provide additional nutrients for the sperm's journey.

Taken collectively, the secretions of the seminal vesicles, bulbourethral glands, prostate gland, and sperm are termed semen. Semen is the transport medium by which sperm enters the female's reproductive system, permitting introduction to an egg and potential fertilization. The final leg of the semen's journey in the male sends it through the penis, which the urethra passes through. Three vascular spaces made up of erectile tissue surround the urethra within the penis: the corpus spongiosum and a pair of corpora cavernosa. When the male is sexually stimulated, these three compartments engorge with blood following a parasympathetic release of nitric oxide, a local vasodilator. This process results in penile erection, turning the normally flaccid penis into a rigid structure.

Female Reproductive System

The female reproductive system produces and develops eggs, preparing them for fertilization by a sperm. In addition, the uterus of the female provides a home for a developing embryo during gestation. The main female reproductive organs are the ovaries, which are located on either side of the uterus within the

peritoneum **Figure 16-12**.

Ovarian follicles within the ovary contain oocytes, or immature eggs. During the process of ovulation, an oocyte is dispelled from a vesicular follicle and the ovary each month in a female of childbearing age. The fallopian (uterine) tubes, a pair of 10-cm tubes originating adjacent to the ovaries and terminating in the uterus, take in the expelled oocyte.

Cilia within the fallopian tubes project the oocyte toward the uterus. Situated between the bladder and rectum, the uterus is the cavity in which embryonic development occurs following fertilization. The uterus flexes superiorly around the urinary bladder and is divided into four portions: the superiormost fundus, the central body, the inferior isthmus, and the cervix. The cervix is the narrow point of attachment to the vagina, commonly referred to as the cervical canal. The uterus consists of three thick tissue layers: the outermost perimetrium, the muscular myometrium, and the inner endometrium. A developing embryo will lodge within the endometrium for the duration of gestation. The uterine arteries provide the uterus with its significant blood supply through a network of arcuate arteries. Every month a major portion of the endometrium of the uterus is shed and regenerated through the menstrual (uterine) cycle unless fertilization has occurred.

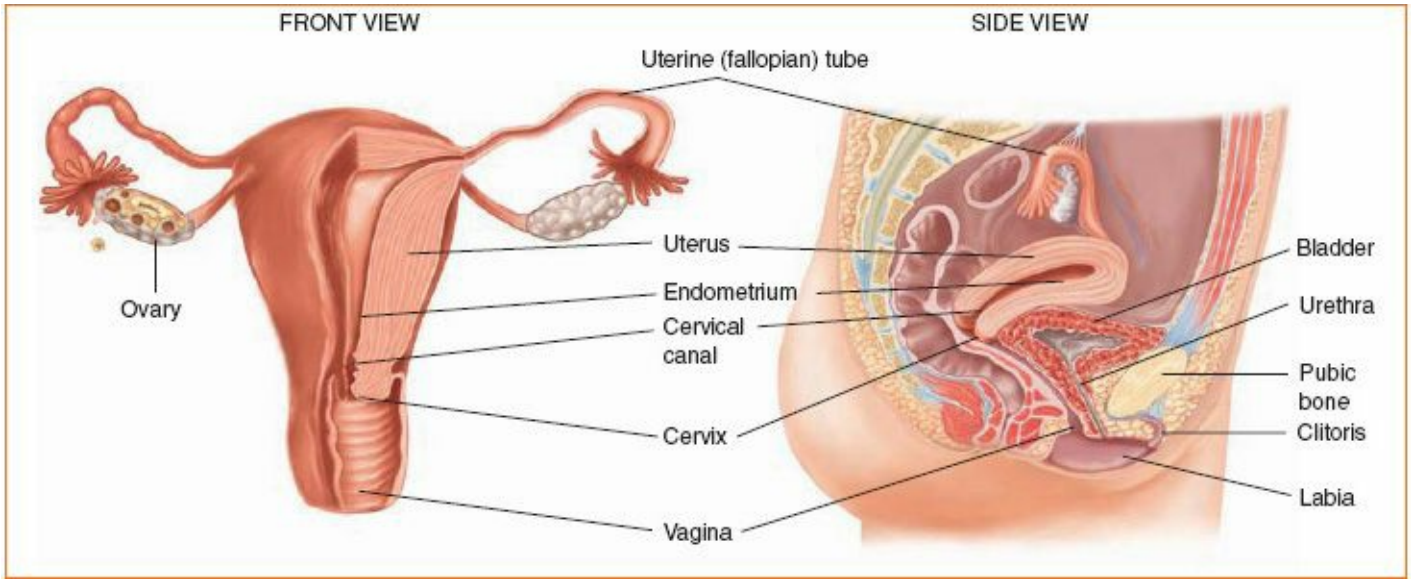

Figure 16-12 The female reproductive system.

The vagina connects the uterus to the external vaginal orifice. During intercourse, the vagina receives semen from the penis, guiding it into the uterus for possible fertilization. The vagina also serves as the birth canal during childbirth. In females, the urethra exits the body just anterior to the vagina, separating the urinary and reproductive tracts.

Special Populations

Injuries and conditions that involve the GI system may be initially missed in pregnant patients. As the gravid uterus grows, the abdominal viscera stretches to accommodate the growing uterus. As this viscera stretches, the pain perceived by the pregnant patient may indeed be referred pain. For example, a large right lower lobe pneumonia may be "felt" by the pregnant woman in the right lower quadrant of the abdomen. Although these patients are typically good historians, where they feel discomfort in the abdominal region may not be the cause or initiation of the pain.

The abdominal/uterine area of a pregnant patient should never be tender or painful. When you are assessing pregnant patients, the uterus and abdominal region should be gently palpated. In addition to

feeling for uterine contractions and fetal movement, the uterus/abdomen should be assessed for tenderness. This tenderness may reflect a uterine/placental or abdominal injury. It may also reflect chorioamniotitis and infection of the amniotic membranes. This infection can lead to profound and overwhelming sepsis in the pregnant patient.

Conditions Affecting the Alimentary Canal

Epidemiology and Pathophysiology

The GI tract contains a multitude of structures operating under harsh conditions. A variety of pathologies are capable of disrupting its normal activities, many of which reach the clinical level only upon breaching the protective layers of intestinal mucosa. Disturbance of the mucosa can expose mesenteric vasculature, nerves, lymph, and inner tissue layers to the extreme changes in pH levels and digestive enzymes of the GI lumen. This exposure accounts for the common symptoms of GI abnormalities: abdominal pain, tenderness, and bleeding. Bleeding is the most common significant finding.

Overall, GI bleeding can be classified into one of two categories based on the location of the bleeding. Upper GI bleeding originates proximal to the **ligament of Treitz**, which supports the junction of the duodenum and the jejunum. Any bleeding distal to this location is referred to as lower GI bleeding.

Upper GI bleeding occurs up to six times more often than lower GI bleeding, but they share a comparable mortality rate of 6% to 10%. Extrinsic factors such as alcohol and tobacco use, diet, and nonsteroidal anti-inflammatory drug (NSAID) use are known to increase the incidence of upper GI bleeding. Recent GI surgery and illness increase the risk as well. In addition, the severity of the bleeding increases steadily with age for those older than 60 years. In patients younger than 60 years without significant comorbidities, the mortality rate is less than 0.1%. The amount of bleeding can vary greatly, from microscopic amounts of blood to massive hemorrhaging.

Although a large percentage of people may develop some degree of lower GI bleeding in their lifetime, it accounts for less than 1% of hospital admissions in the United States. Incidence is closely correlated to age, increasing 200-fold between 30 and 80 years of age. Males are 40% more likely to experience lower GI bleeding than females.

Differentiating between upper and lower GI bleeding can prove difficult, because 80% of GI bleeding presents with rectal bleeding of some kind **Table 16-1**. Endoscopy is the preferred method of locating the bleeding source.

Conditions Affecting the Upper GI Tract

Peptic Ulcers

Peptic ulcers are the leading cause of upper GI bleeding, accounting for more than 50% of acute cases **Figure 16-13**. They are characterized by an erosion of the mucosal lining of the GI tract in either the stomach (gastric ulcer) or the duodenum (duodenal ulcer). Once that defensive lining is disrupted by 1 to 3 mm or more, exposure to the acids and pepsin in the pylorus and duodenum can cause ulceration. An ulceration that is deep enough can penetrate a blood vessel, leading to major or minor bleeding. Continued ulceration can result in a perforation of the gastric or duodenal wall, causing peritonitis. Finally, scar tissue from past ulcers can obstruct the GI tract. Peptic ulcers are common in the United States, with a lifetime prevalence of 10%. Despite this, they only account for about 0.1% of US hospital admissions. Although psychological stress is commonly indicated as a contributing factor to ulcer formation, there is a significant lack of evidence to support this theory.

TABLE 16-1 Causes of Upper and Lower GI Bleeding

Type of Bleeding	Cause
Upper GI bleeding	Peptic ulcers Gastritis Esophageal varices Mallory-Weiss syndrome
Lower GI bleeding	Diverticulitis Angiodysplasia Inflammatory bowel diseases (ulcerative colitis, Crohn's disease, cancer)

Abbreviation: GI, gastrointestinal.

TABLE 16-2 Causes of Peptic Ulcers

Helicobacter pylori infection
Nonsteroidal anti-inflammatory drugs
Alcohol use
Tobacco use
Stress-related erosive syndrome
Curling's syndrome
Cushing's syndrome
Zollinger-Ellison syndrome
Gastritis

The bacterium ***Helicobacter pylori*** is the most frequent cause of peptic ulcers, being involved in 70% to 80% of cases. *H pylori* are highly motile spirilla bacteria that colonize the mucosa of the stomach and duodenum. Once inside the mucous layer, they remain protected from gastric acid and begin to produce toxins that cause local tissue inflammation. The inflammation leads to tissue damage and erosion, which results from the tissue's increased susceptibility to the acids and digestive enzymes in the lumen. NSAIDs such as aspirin inhibit the defenses of the mucosa against irritation by reducing production of prostaglandins, the hormones that mediate the inflammatory response in tissues. When their production diminishes, mucosal damage from acidic gastric juice is not corrected promptly and erosion ensues. Use of alcohol and tobacco increases the acidity of the gastric juice, further irritating the lining.

Other causes of peptic ulcers are listed in Table 16-2. **Stress-related erosive syndrome** is a frequent cause of peptic ulcers in critically ill patients, with an incidence of nearly 100%. Poor mucosal perfusion as a result of multiple comorbidities, trauma, or burns also reduces the efficiency of the mucous barrier. This general decrease in resistance to gastric juice allows the formation of numerous shallow ulcers throughout the esophagus, stomach, and duodenum. Ulcers associated with severe burns are termed Curling's ulcers, and those accompanying episodes of increased intracranial pressure are Cushing's ulcers. It is thought that the increased intracranial pressure causes excess vagal stimulation, which results in a marked increase in acidic gastric secretions. Less common causes of ulcers include hypersecretion of acid into the GI lumen, such as by a tumor, as seen in **Zollinger-Ellison syndrome**.

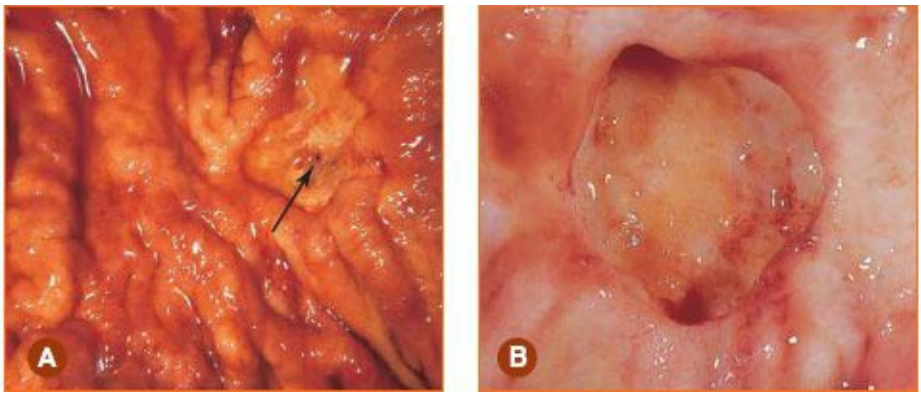

Figure 16-13 Peptic ulcers. **A.** Gastric ulcer, which eroded a blood vessel in the base of the ulcer (arrow) and bled profusely. **B.** Large chronic duodenal ulcer.

Gastritis

Inflammation of the gastric mucosa, termed **gastritis**, is a common precursor to upper GI bleeding. Causes of gastric inflammation vary widely and can be broadly separated into acute or chronic pathologies. Common causes of gastritis are listed in **Table 16-3**.

As previously mentioned, the mucosal lining of the esophagus, stomach, and duodenum forms an important barrier between gastric contents and internal tissues of the body. A dynamic equilibrium is established across this barrier between the aggressive and defensive components. Hydrochloric acid and pepsin in the gastric juice assault the mucosa, whereas bicarbonate, prostaglandins, and rapid cell renewal protect it. When this equilibrium is disturbed, inflammation of the epithelial cells occurs as a result of the ensuing immune system response. An inflamed lining is unable to provide its typical defensive mechanism and becomes susceptible to erosion into the well-perfused submucosal layer. As expected, gastritis is a common cause of peptic ulcers. Once the blood vessels in submucosa are breached, GI bleeding begins.

TABLE 16-3 Causes of Gastritis
Corrosive chemical ingestion
Alcohol abuse
Helicobacter pylori infection
Autoimmune disorders (type A gastritis)
Reactive gastritis
Radiation exposure

Acute gastritis is characterized by a rapid onset of mucosal inflammation frequently accompanied by mild to severe upper GI bleeding **Figure 16-14**. Ingestion of corrosive chemicals, for example, can burn the epithelial lining of the GI tract within a short time period. Depending on the chemical, these burns can cause significant inflammation and subsequent necrosis of tissues with varying degrees of hemorrhage. Chemical burns commonly affect external perioral tissues, the oral cavity, and the tongue as well. Many household cleaners such as bleach are potent enough to trigger this process.

Many cases of acute gastritis are an exacerbation of a chronic GI condition. Alcohol-induced gastritis, commonly referred to as hemorrhagic gastritis, presents as numerous lesions along the gastric

mucosa. Extensive tissue damage is found in up to 20% of chronic alcoholics. Minor bleeding occurs frequently and often goes unnoticed in these patients, but an episode of severe hemorrhage can occur suddenly after even a small intake of alcohol. *H pylori* cause acute gastritis during the primary period of infection. The initial immune system response to the invading bacteria triggers an inflammation of the mucosal tissues, which is self-limiting and resolves within 11 to 14 days. Occasionally, the bacteria are fully eliminated from the body following the immune defense. More typically, however, chronic gastritis develops.

Autoimmune disorders targeting the GI system can cause chronic inflammation of mucosal lining and also inhibit certain metabolic pathways crucial to digestion. In **type A gastritis**, the intrinsic factor secreted by mucosal parietal cells is attacked by autoantibodies. The inhibition of intrinsic factor results in a decreased absorption of vitamin B_{12}, resulting in pernicious anemia. A more common form of chronic gastritis is **type B gastritis**, or antral-predominant. In this case, inflammation of varying severity is caused by *H pylori*, with an incidence approaching 100% in the elderly.

Reactive gastritis is a chronic mucosal edema that results from recurring contact of the mucosa with antagonistic substances such as bile, pancreatic juice, or NSAIDs. Also commonly referred to as reflux or chemical gastritis, reactive gastritis is most commonly seen in patients following gastric surgery. Bile or pancreatic juice refluxed from the duodenum into the stomach will damage the surface of epithelial cells and cause a decreased mucosal blood flow. Diminished blood flow inhibits immune response and, as a result, inflammation in this situation is minor to nonexistent.

Radiation exposure causes varying forms of gastritis depending on the amount of radiation involved. Substantial tissue necrosis occurs in the mucosa during the first few weeks following exposure. An accompanying decrease in blood perfusion to the area will inhibit digestive processes. Scar tissue formation is common following cell replacement. Ulcerations may occur as well, either acutely or chronically.

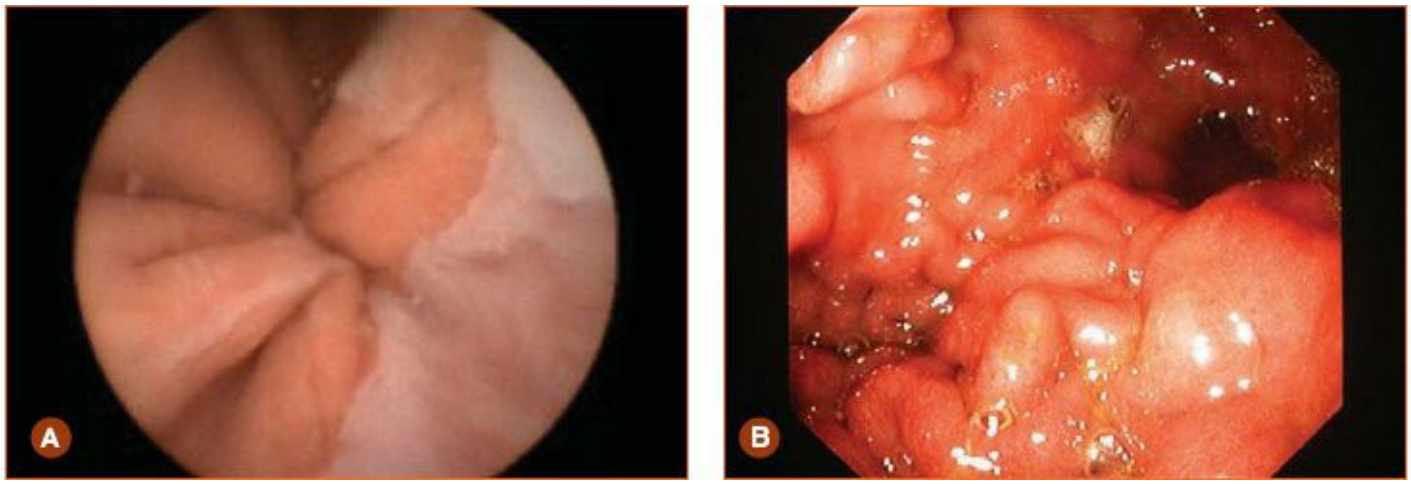

Figure 16-14 **A.** Normal stomach. **B.** Gastritis.

Esophageal Varices

Just as erosion of mucosal lining into a blood vessel will initiate GI bleeding, so will the reverse process —swelling of esophageal veins into the lumen of the esophagus, called an **esophageal varix** **Figure 16-15**. These exposed veins are susceptible to sudden rupture, resulting in severe hemorrhage; this phenomenon accounts for about 14% of upper GI bleeding. Mortality immediately following a variceal rupture ranges from 35% to 40%. Unlike other causes of GI hemorrhage, in which active bleeding typically stops without intervention in 80% to 90% of cases, esophageal varices spontaneously stop bleeding only 50% of the time. If left untreated, mortality rises to 70% after 1 year.

Swelling of the esophageal veins is a result of increased venous pressure in the hepatic portal system. When **portal hypertension** occurs, venous blood will use alternate pathways for its return to the vena cava via the **azygos system**. The azygos system also serves to drain a portion of the esophageal venous blood, and overuse of this system causes pooling in these veins. The lower portion of the esophagus drains blood into the left gastric vein, which is adversely affected by portal hypertension as well. Increases as small as 5 mm Hg in portal venous pressure are capable of producing varices, with the risk of rupture growing exponentially as pressure continues to rise. Although varices can occur anywhere along the esophagus, stomach, and duodenum, ruptures leading to GI hemorrhage most frequently occur at the gastroesophageal junction.

Figure 16-15 Mucosal surface of the esophagus illustrating varices, which appear as tortuous elevations of the mucosa (*arrows*).

Portal hypertension results from liver damage, usually cirrhosis. In **cirrhosis**, buildup of fatty acids, along with chronic destruction of liver tissue and fibrosis, obstructs blood flow. In the United States, liver cirrhosis is primarily caused by chronic alcohol use or hepatitis C, which together account for more than 60% of all diagnoses.

Mallory-Weiss Syndrome

Mallory-Weiss syndrome involves a longitudinal laceration of the esophageal mucosa **Figure 16-16**, typically in the distal esophagus at the gastroesophageal junction. The tear develops as a result of repeated significant changes in local pressure, such as those seen in repeated vomiting. GI bleeding occurs once the tear reaches the vascular submucosa. Mallory-Weiss tears are implicated in about 5% of upper GI bleeds, with a mortality of less than 10%. In as many as 90% of cases, bleeding stops spontaneously. Cofactors increasing the likelihood of a tear include hiatal hernias, chronic alcohol use, and increasing age.

Conditions Affecting the Lower GI Tract

Lower GI bleeding is frequently the result of an exacerbation of a chronic condition. This type of bleeding, which is characterized by bleeding distal to the ligament of Treitz, can occur in the jejunum, ileum, large intestine, rectum, and anus. A number of conditions can cause bleeding. The severity of

bleeding can vary greatly.

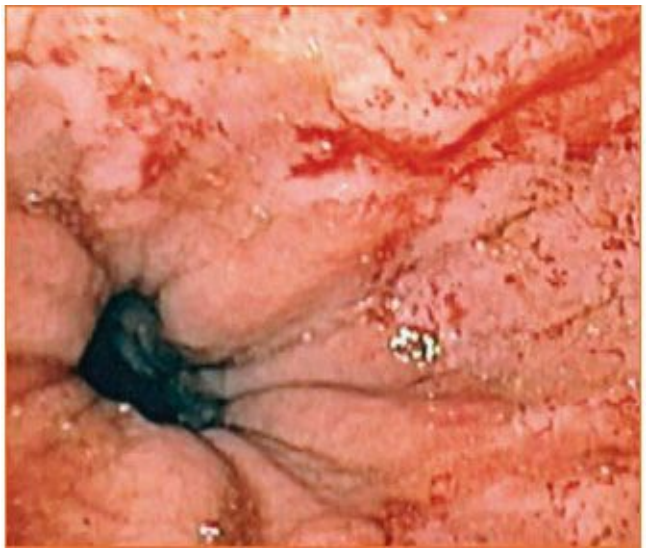

Figure 16-16 Mallory-Weiss syndrome.

Diverticulosis and Diverticulitis

Diverticulosis is a common disease of the lower GI tract in the elderly. Small pouches called **diverticula** outcrop from the mucosal lining of the large intestine, typically in the descending colon and sigmoid colon **Figure 16-17** and **Figure 16-18**. These outcroppings are a consequence of strong Haustral muscle contractions, which push tissue against a mucosa that weakens with age. The diverticula are generally painless and can be found in half of all US men older than 60 years.

Diverticulitis, an inflammation of the diverticula, occurs in as many as 25% of diverticulosis cases. It is frequently a result of infection from invading intestinal bacteria. Inflamed diverticula are painful, and 3% to 5% of them bleed.

Diverticulosis is the most common cause of lower GI bleeding, being responsible for 42% to 55% of cases. Bleeding can be heavy because arterial blood vessels are incorporated into developing diverticula. Certain risk factors are known to increase the incidence of diverticulosis, including a low-fiber diet, chronic constipation, and NSAID use.

Angiodysplasia

Angiodysplasia is a malformation of submucosal blood vessels in the GI tract **Figure 16-19**. Although it can occur anywhere in the alimentary canal, more than three fourths of all cases present in the cecum and ascending colon. These thin-walled, winding vessels are highly susceptible to rupture. Bleeding as a result of angiodysplasia is the second most common cause of lower GI bleeding, accounting for 20% to 30% of cases.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a collective term covering two idiopathic colon pathologies that are together responsible for about 10% of the cases of lower GI bleeding: ulcerative colitis and Crohn's disease **Figure 16-20**. Common causes of inflamed colon or colitis are listed in **Table 16-4**.

Ulcerative colitis is an inflammation of the rectal mucosal and submucosal tissues. In this condition, ulcers that occasionally bleed form throughout the colon. Inflammation spreads into the colon in 75% of cases, a situation termed pancolitis. The incidence of ulcerative colitis is highest in whites aged 20 to 25 years.

Crohn's disease is a less organized inflammation of the GI tract in which all layers of the mucosa

may be affected. This inflammation is not contiguous, as is seen in ulcerative colitis, but rather results in scattered ulcerations and fibroses throughout the large and small intestines. Minor bleeding occasionally occurs from these ulcers as well as from small tears that may develop in the mucosa. Only about 1% of patients diagnosed with Crohn's disease experience significant GI bleeding. The disease is thought to be hereditary and is found most commonly in whites.

TABLE 16-4 Causes of an Inflamed Colon or Colitis
Ulcerative colitis
Crohn's disease
Bacterial infection
Viral infection
Radiation colitis

As ulcerative colitis and Crohn's disease move into chronic states, scar tissue formation over ulcerations can result in a thickening of the mucosa and partial bowel obstructions. Because both diseases share similar symptoms, 20% of cases are diagnosed as indeterminate colitis.

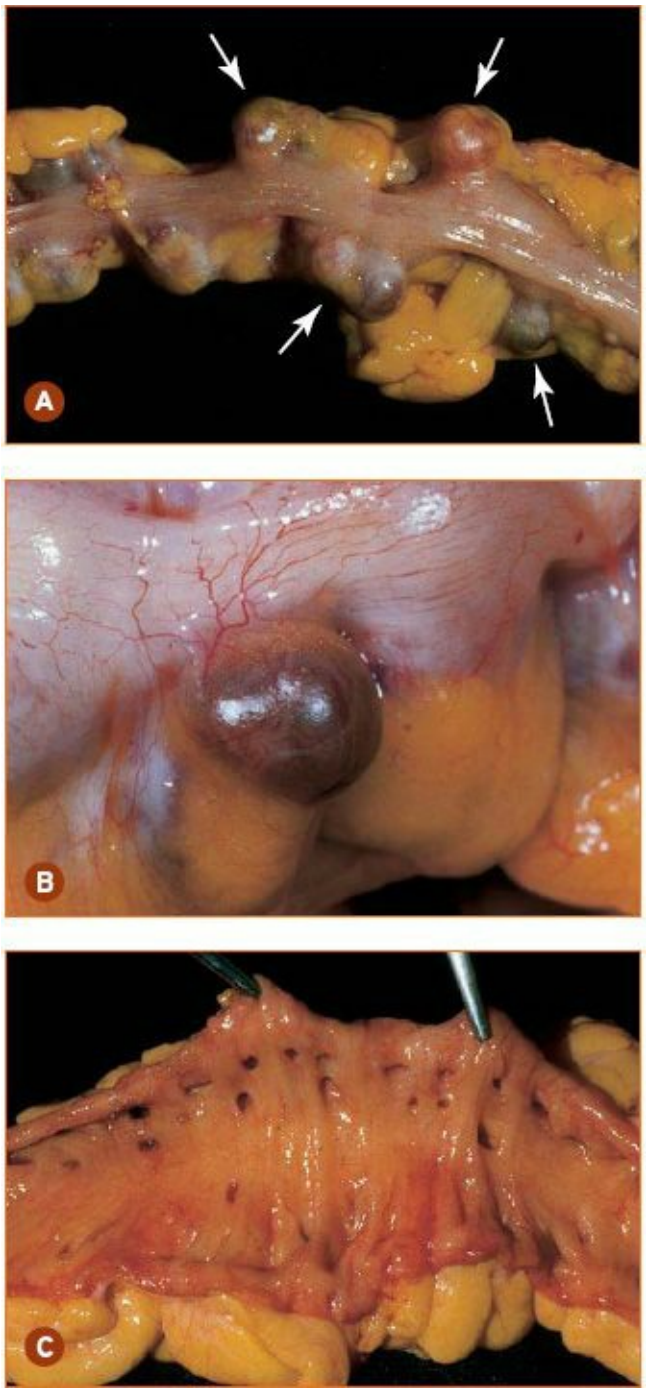

Figure 16-17 Diverticulosis of the colon. **A.** Exterior of the colon illustrating several diverticula projecting through the wall of the colon (arrows). **B.** Closer view of the diverticulum. **C.** Interior of the colon, illustrating openings of multiple diverticula. Several of the openings are well demonstrated in the mucosa just below the clamps.

Figure 16-18 Diverticula of the colon demonstrated by injection of barium contrast material into the colon (barium enema). Diverticula filled with contrast material appear as projections from the mucosa (arrows).

Figure 16-19 Angiodysplasia.

A variety of infectious diseases of the colon are also commonly referred to as IBD. These cases are self-limiting and rarely result in significant bleeding, including bacterial infections by *Shigella, Salmonella*, and *Campylobacter*. Viral causes include the Norwalk-type virus and cytomegalovirus in

immunosuppressed patients. Patients on continued antibiotic therapy may experience growth of *Clostridium difficile*, which can cause permanent mucosal damage.

Radiation colitis occurs in 75% of patients who have received radiation doses of 40 Gy or more to the abdomen or pelvis. Chronic mucosal thickening can result, as well as ulcerations throughout the colon. Although the major complication of this condition is abdominal pain and diarrhea, anemia and lower GI bleeding can occur as well.

Assessment

Signs and Symptoms

The signs and symptoms of patients who experience GI bleeding vary depending on the origin and severity of the bleeding. Slow, chronic bleeding can result in the presence of **melena**, black tarry stool containing partially digested blood. If the bleeding in either the upper or lower GI tract is minimal enough, blood in the stool may be detectable only by laboratory testing. **Table 9-8** describes the various signs and symptoms associated with the stages of blood loss. Diffuse abdominal pain accompanies even minor bleeding, and will be described as a chronic stomachache or nonspecific burning sensation. The presence of even small amounts of blood in the stomach can cause irritation and subsequent vomiting. Emesis containing partially digested blood, known as **hematemesis**, has a coffee-ground appearance. Many patients experience weight loss, anemia, and malnutrition as a result of poor nutrient absorption over damaged mucosa.

Complaints of frequent dizziness and syncope are common in patients with GI bleeding. Fever as a result of infection can occur in patients who experience GI bleeding as well. Therefore, temperature should be assessed in patients with GI dysfunction or bleeding. Often it is necessary to obtain a rectal temperature because of intubation. In such cases, gently insert the thermometer into the rectum without causing further pain to the patient. It is important to be aware that rectal temperatures are normally higher than oral ones, with a normal reading of around 99.5°F

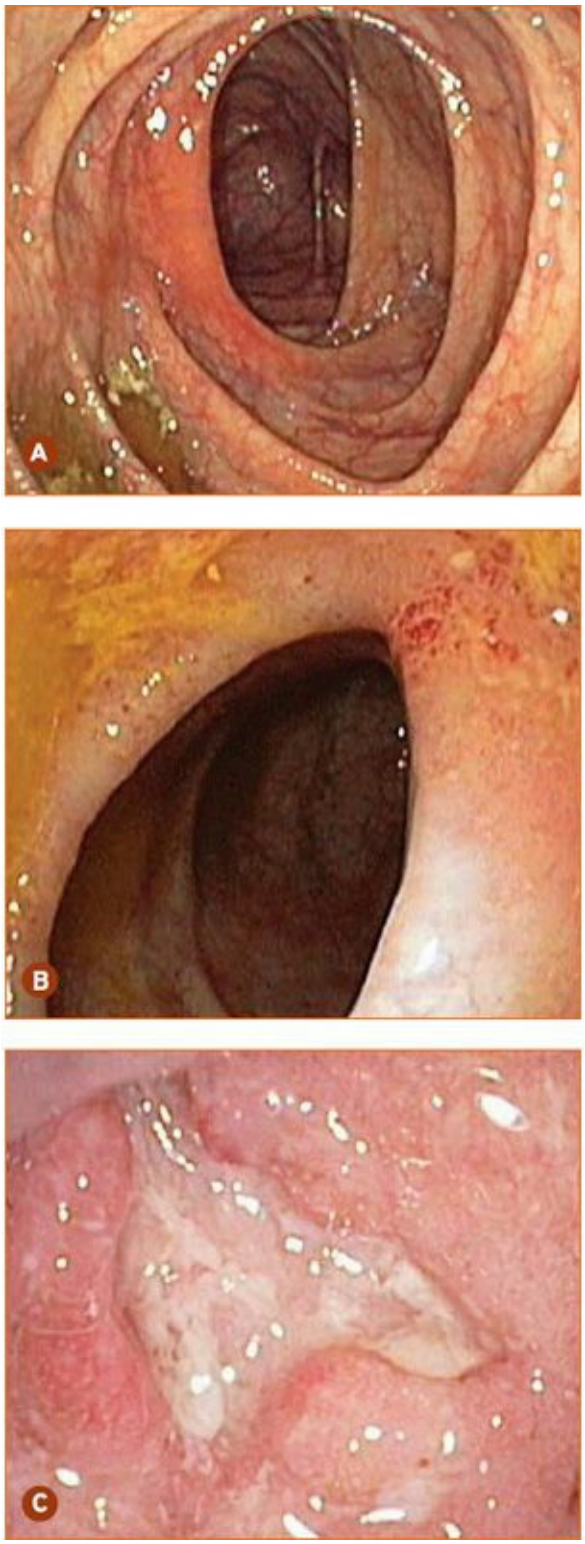

Figure 16-20 **A.** Normal colon. **B.** Ulcerative colitis. **C.** Crohn's disease.

Diarrhea is the most common symptom associated with lower GI disorders, as a result of reduced water absorption efficiency associated with damaged or infected mucosa. Dehydration frequently results from this problem, as do electrolyte imbalances that can trigger cardiac arrhythmias.

Significant GI bleeding is usually acute and can present with hemodynamic instability and shock. Vomiting large amounts of bright red blood can signify acute bleeding in the upper GI tract—for example, from ruptured varices, an ulcerated submucosal blood vessel, or Mallory-Weiss syndrome. **Hematochezia**, the presence of bright red blood in the stool, indicates active lower GI bleeding. When coupled with diarrhea, significant blood and fluid loss can result. Hypotension may or may not be immediately apparent, and testing for orthostatic changes should be performed. Other signs of shock such

as tachycardia, diaphoresis, and altered mental status accompany blood loss. When paired with a decreased level of consciousness, vomiting can result in airway compromise.

When assessing for rectal bleeding, the CCTP should be aware that external sources of bleeding may exist in the area of the anus, such as **pressure ulcers**. Pressure ulcers arise from prolonged pressure on body tissues, and are commonly seen in patients confined to a bed. As many as 25% of nursing home patients are observed to have pressure ulcers, with their treatment incurring considerable costs on the health care system. Pressure ulcers are classified on a scale of stages 1 through 4 **Figure 16-21**. Stage 1 ulcers are reversible, characterized by warmth and some blanching; stage 4 ulcers have full-thickness tissue necrosis, often with muscle and bone involvement. If ulcers are present, the CCTP should take care to avoid further pressure on the area while bandaging any exposed bleeding tissue. It is unlikely that these ulcers would produce life-threatening blood loss, but they do cause severe pain and infection can also become severe.

Some abdominal diseases produce distinctive pain in specific locations, aiding in their diagnosis. For example, peptic ulcers cause a burning epigastric pain that peaks 1 to 3 hours after eating and is usually relieved by antacids. Heartburn pain frequently accompanies peptic ulcers. Gastric ulcer pain is exacerbated with a full stomach, whereas duodenal ulcers are more painful at night, when the stomach is empty. Esophageal varices present initially with painless bleeding that develops into a burning pain. Diverticulitis typically presents with sharp intermittent pain to the lower left abdominal quadrant, commonly referred to as a left-sided appendicitis. Gastritis and inflammatory bowel disease generally cause vague abdominal discomfort, making it difficult to differentiate between them based on signs and symptoms alone. The patient's medical history and presence of risk factors for certain diseases should always be considered during the assessment to aid the prehospital provider in selecting the appropriate treatment.

Signs and Symptoms

GI Bleeding

- Diffuse abdominal pain
- Chronic stomachache
- Nonspecific burning sensation
- Vomiting, often with blood present
- Hematemesis
- Melena
- Hematochezia
- Weight loss
- Anemia
- Malnutrition
- Dizziness
- Syncope
- Fever
- Diarrhea
- Dehydration
- Hypotension

Figure 16-21 A pressure ulcer develops when pressure decreases blood supply and thus oxygenation to an area of tissue. **A.** Stage 1. **B.** Stage 2. **C.** Stage 3. **D.** Stage 4.

Differential Diagnosis

GI Bleeding

- Peptic ulcer disease
- Gastritis
- Esophageal varices

- Zollinger-Ellison syndrome
- Abdominal aortic aneurysm
- Gastric tumor
- Esophageal cancer
- Cholecystitis
- Cirrhosis
- Esophagitis
- Syncope
- Angiodysplasia
- Disseminated intravascular coagulation
- Celiac sprue (syndrome in which intestines lose their ability to absorb)
- Irritable bowel syndrome
- Hemorrhoids
- Antibiotic use
- Infectious diarrheal processes

Transport Management

GI Bleeding

- Provide airway control: suction and intubation.
- Provide ventilatory support with oxygen.
- Designate nothing by mouth.
- Place two large-bore IV tubes.
- Provide fluid resuscitation.
- Draw blood samples, provide blood infusion.
- Continuously monitor blood pressure.
- Continuously monitor pulse oximetry.
- Continuously monitor the electrocardiogram (ECG).
- Obtain lab values.
- Place nasogastric (NG) or orogastric (OG) tube.

Laboratory Data

Laboratory testing and monitoring are essential in the diagnosis and management of chronic GI bleeding **Table 16-5**. Hemoglobin and hematocrit values appear normal during the first 24 to 48 hours of bleeding owing to an equivalent loss of plasma and red blood cells. Eventually the hematocrit value decreases as interstitial fluid shifts to blood vessels in the body's attempt to maintain blood pressure. Hematocrit values also fall as blood is diluted with crystalloid fluids during resuscitation. Fluctuations in the hematocrit value over time indicate active bleeding.

A coagulation profile can determine the existence of clotting deficiencies requiring specific treatment. Prolonged prothrombin time (PT) and activated partial thromboplastin time (PTT) are suggestive of liver disease, and a liver function test should be performed. Thrombocytopenia may be chronic or a result of platelet loss from hemorrhage. Infusion of fresh frozen plasma and platelets may be

required in these patients.

Blood urea nitrogen (BUN) levels increase following upper GI bleeding owing to digestion and absorption of blood proteins in the large intestine. A decreased GFR due to hypoperfusion of the kidneys secondary to hypovolemia will exacerbate this increase. An elevated BUN-to-creatinine ratio rules out kidney failure as the cause of the increased BUN level. A ratio greater than 36 is highly suggestive of upper GI bleeding.

An adrenergic response to GI bleeding results in hyperglycemia, whereas the insult to mucosal tissues stimulates an increase in the white blood cell (WBC) count. Serum electrolyte disturbances can occur as well, including hypernatremia and hyperchloremia from fluid resuscitation and hypokalemia from excessive vomiting. The CCTP needs to review the most recent labs in the chart as part of his or her assessment before transfer.

Imaging

The most effective method of localizing the origin of GI bleeding is to search the mucosa. **Endoscopy**—specifically, esopha-gogastroduodenoscopy—is the method of choice because it is capable of visualizing more than 90% of the upper GI tract with a 90% to 95% diagnosis rate. Endoscopes are equipped with therapeutic tools that allow immediate treatment of an actively bleeding site upon discovery. Hemostatic methods available include the use of heater and bipolar electrocautery probes to cauterize a bleeding vessel and injection sclerotherapy (injection of small doses of either epinephrine or clotting factors). Gastric lavage is required prior to endoscopy to facilitate viewing of the internal structures. Complications from endoscopy are relatively rare, with an incidence of less than 1%.

Visualization of lower GI mucosa is possible via **colonoscopy**, although the procedure is more complicated than endoscopy. To view the mucosa effectively, bowel preparation methods are required to clear the colon. Colonoscopy allows visualization of the entire rectum and large intestine, up to the ileocecal junction.

TABLE 16-5 Normal vs Abnormal Laboratory Values

Test	Normal	Abnormal
Hemoglobin	14-17.5 g/dL	< 14 g/dL
Hematocrit	41%-50%	< 41%
Prothrombin time	10-13 s	Varies
Partial thromboplastin time	< 40 s	Varies
Blood urea nitrogen (BUN)	8-23 mg/dL	> 23 mg/dL
Creatine, serum	0.6-1.2 mg/dL	Varies (unchanged or small rise)
BUN:creatine ratio	10:1	> 10:1
Glomerular filtration rate	125 mL/min	< 125 mL/min
Blood glucose	70–110 mg/dL	> 110 mg/dL (early)
White blood cells (leukocytes)	4,500-11,000/μL	Varies, elevation indicates infection

Angiography is an alternative to endoscopy or colonoscopy when significant active bleeding is present. When this imaging technique is used, dye injected into blood vessels will leak into the lumen of

the GI tract at the site of the bleeding. A bleeding rate of at least 0.5 mL/min is required for effective assessment via this means. Angiography is more frequently used to diagnose lower GI bleeding because of the lower success rate of colonoscopy as opposed to endoscopy in such cases.

Technetium-99m–labeled red blood cell **scintigraphy** can detect GI bleeding rates as low as 0.1 mL/min, although with less specificity than angiography. In this technique, red blood cells attached to radioisotopes are injected into the bloodstream, and subsequent scanning of the abdomen detects their presence in the GI lumen. The tagged cells remain in the circulation for as long as 48 hours, allowing repeat studies to be performed if necessary. Successful detection of GI bleeding occurs as often as 93% of the time, although localization is accomplished with a frequency of only 67% to 97%.

Various noninvasive imaging techniques are available as well and form a cornerstone of acute abdominal assessment. These techniques include abdominal ultrasounds, computed tomography (CT) of the abdomen, and magnetic resonance imaging (MRI). **Figure 16-22** shows a normal abdominal CT scan.

Management

The fundamentals of patient care must be ensured before any specific treatment is attempted. In particular, it is important to control and maintain the patient's airway. During acute GI bleeding, airway compromise occurs primarily by either of two ways: physical obstruction or mechanical obstruction. Physical obstruction of the airway by blood and/or vomit must be cleared with suctioning. Mechanical obstruction of the airway by the tongue or head positioning as a result of a decreased level of consciousness, secondary to hypovolemic shock, must be managed by airway adjuncts and intubations. Rapid intubations are indicated in patients with a high risk for aspiration, such as patients who are lethargic or have an altered mental status.

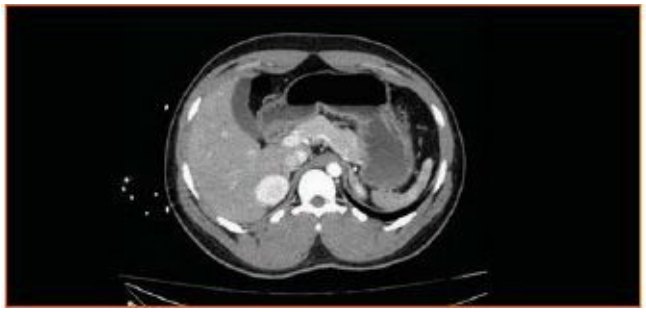

Figure 16-22 A normal abdominal computed tomographic scan.

Supplemental oxygen should be administered via non-rebreathing mask in the alert, conscious patient. Ventilations should be assisted as necessary with a bag-mask device and high-flow oxygen.

Any patient with acute GI bleeding should be designated NPO (nothing by mouth) because of the likelihood of undergoing endoscopy and/or surgery shortly after hospital admission. Two large-bore IV catheters (14 to 16 gauge) should be placed immediately. Fluid resuscitation should begin immediately in any patient who exhibits signs of shock, to consist of an initial bolus of 20 mL/kg of isotonic crystalloid solution.

Blood samples should be drawn concurrently with IV placement to determine a type and crossmatch, complete blood count, electrolyte levels, and PT and PTT values. Blood loss estimated at greater than 1,500 mL requires administration of packed red blood cells along with fluid replacement. Platelet or fresh-frozen plasma infusion may be indicated based on lab findings as well as volume of packed red blood cells given.

Controversies

Several states across the United States have been grappling with the issue of certified individuals and the administration of blood and blood products. Some states may not allow a non-licensed individual to administer blood or blood products during transport. This may force the sending facility to complete or even discontinue the administration before transfer. Facilities should be aware of their individual state regulations and the composition (as in certified vs licensed) of their critical care transport teams when faced with these types of transfers.

Continuous blood pressure and pulse oximetry monitoring is required to evaluate the patient's progress and the effectiveness of fluid resuscitation efforts. Care must be taken to avoid fluid overload secondary to excessive fluid administration in patients with comorbidities, specifically those with cardiac-related conditions. Placement of a pulmonary artery catheter or other hemodynamic monitoring device should occur as soon as possible because it allows for a detailed and current analysis of hemodynamic status. Continuous ECG monitoring is necessary to observe the patient for a variety of arrhythmias that may develop secondary to electrolyte imbalances or hypoxia.

Along with treating the immediate concerns of GI bleeding, other factors such as incontinence, diarrhea, and constipation need to be addressed. Incontinence will most often be controlled with a Foley catheter placed prior to transport. Foley catheter placement and management is discussed in detail later in this chapter. Diarrhea control, particularly during extended transports, is necessary. This can usually be accomplished with loperamide treatment. Oral rehydration therapy is important for patients with chronic diarrhea; IV fluids may be used if the oral route is unavailable. In infectious processes, the patient will commonly be administered an antibiotic to control the cause of the diarrhea. Chronic constipation is typically managed with an osmotic laxative such as milk of magnesia. When managing any of these three conditions, it is important to ensure that any underlying cause of the condition is being addressed.

Upper GI Bleeding

NG or OG tube placement is indicated in any patient with upper GI bleeding to facilitate clearing of gastric contents. Suctioning via these tubes permits an estimation of blood loss and an evaluation of the consistency of the gastric contents as coffee-ground, bright red, or blackened. Gastric lavage should be performed with 250 to 500 mL of water or saline to remove the remaining stomach contents. Gastric lavage is a necessary precursor to endoscopy, allowing the provider to determine the extent and activity of the bleeding. However, gastric lavage is not performed during transport; it is an in-house procedure that must occur before transport.

Endoscopy is performed at the hospital when the patient's condition is stable. It may serve both diagnostic and therapeutic functions. Once the bleeding site is located, injection sclerotherapy—injection of small doses of either epinephrine or clotting factors into the insult site—can be performed via endoscopy. Epinephrine causes a local vasoconstriction that results in decreased blood flow to the area; clotting stimulators such as human thrombin or fibrin glue will slow or stop the bleeding process significantly.

Endoscopic variceal band ligation can be used to control bleeding esophageal varices. This technique involves the placement of rubber bands around the varix, which shuts off its blood supply. Cauterization methods and hemostatic clip placement are alternatives to these treatments.

Figure 16-23 Sengstaken-Blakemore tube. © C. R. Bard, Inc.

Vasopressin administration induces vasoconstriction of the splanchnic arteries, which reduces mesenteric blood flow and thereby reduces portal hypertension. This effect can be beneficial to the patient with esophageal varices, in that it substantially reduces blood flow to the region. Nitroglycerin is commonly administered in conjunction with vasopressin to control subsequent rises in coronary artery blood pressure. An alternative to vasopressin is octreotide, a synthetic version of somatostatin. Many cardiac complications associated with vasopressin-nitroglycerin treatment may be avoided by initiating in the patient the more selective vasoconstriction that octreotide provides.

Treatments for endoscopic and pharmacologic refractory variceal hemorrhage include balloon inflation and shunt placement. Balloon tamponade of variceal bleeding is effective in controlling the hemorrhage in as many as 90% of cases. In this procedure, a **Sengstaken-Blakemore tube** **Figure 16-23** or a **Minnesota esophagogastric tamponade tube** is inserted nasally and introduced to the stomach via the esophagus. A gastric balloon is then inflated to place pressure on the cardia region of the stomach. A second esophageal balloon can be inflated if necessary to further tamponade bleeding. Although balloon placement has a high success rate in initial bleeding control, it is associated with a high rate of bleeding recurrence upon removal. Given this fact, it is rarely used today.

A more frequently employed procedure is the placement of a **transjugular intrahepatic portosystemic shunt** to control variceal bleeding **Figure 16-24**. The introduction of a shunt into the systemic venous circulation results in a significant decrease in hepatic portal pressure and, therefore, a significant decrease in the pressure in the esophageal collateral veins. Shunt placement has a greater than 90% success rate with less than 30% bleeding recurrence.

Proton pump inhibitors should be administered to reduce gastric acidity in any patient suspected of having a peptic ulcer. Antacids can greatly reduce gastric acidity in a short period of time, thereby reducing ulcer irritation. Prophylactic acid inhibition is common in patients admitted to an intensive care unit to prevent the development of stress ulcers. Patients testing positive for *H pylori* should be treated with antibiotics specific to the bacteria, such as omeprazole and clarithromycin.

Figure 16-24 Transjugular intrahepatic portosystemic shunt placement. Reprinted with permission from the *American Journal of Roentgenology*.

Lower GI Bleeding

Management of the patient with lower GI bleeding is similar to that of the patient with upper GI bleeding. Attention must be paid to fluid loss through water shifts in the colon and the associated dehydration and electrolyte abnormalities that can occur. Endoscopic methods of cauterization and coagulation are common first-line treatments. Intra-arterial injection therapy with vasopressin or various hemostatic agents is associated with a 70% success rate. Surgical methods such as colon resection and removal are indicated in bleeding refractory to endoscopic and colonoscopic techniques, but are infrequently required.

Intestinal Obstructions

Blockage of the GI tract can occur in the small or large intestine through a variety of pathologies. The convoluted small intestines are far more susceptible to obstruction than are the large intestines, which are wider in diameter. Obstructions are classified as partial, simple, complete, or strangulated. Although a partial intestinal obstruction can cause some discomfort and malnutrition, a complete blockage stops normal GI function, resulting in death if not treated promptly.

Epidemiology and Pathophysiology

Postoperative adhesions are the major cause of intestinal obstructions, accounting for up to 60% of obstructions. Other common causes include tumors, hernias, and Crohn's disease. Of those patients diagnosed as having an intestinal obstruction, 40% are strangulated obstructions. Overall, intestinal obstructions are fairly common in the United States, accounting for up to 20% of all acute surgical admissions to hospitals.

Mechanical Obstruction

A mechanical obstruction is the result of a physical blockage of the intestinal lumen and can be classified into one of three categories: extrinsic, intrinsic, or intraluminal **Table 16-6**.

Extrinsic causes, which originate external to the intestines, include adhesions, hernias, volvulus, and masses. **Adhesions** are bands of connective tissue that can distort the normal anatomy of the abdomen. They are most often the result of improper healing or scar tissue growth following abdominal surgery. A **hernia** is a protrusion of an organ from its tissue lining. Overall, postsurgical adhesions are the most common cause of mechanical intestinal obstruction, followed by hernias. A **volvulus** is a twisting of the intestine onto itself, usually resulting in strangulation. **Masses** often originate from surrounding abdominal

organs that put pressure on the intestines and may be tumors, aneurysms, or abscesses.

Intrinsic causes arise from the intestinal lining itself, such as diverticula, neoplasms, or intussusception. An **intussusception** is a prolapse of the intestine into an adjacent segment.

An intraluminal obstruction is commonly the result of an ingested foreign body or a fecal impaction. Figure 16-25 through Figure 16-28 show intestinal obstructions caused by hernias, volvulus, a mass, intussusception, and a foreign body, respectively.

Chyme, fluids, and digestive products cannot pass an intestinal obstruction, and immediately begin to accumulate proximal to the blockage. This buildup, along with swallowed air, will distend the lumen proximal to the obstruction. GI tract distention stimulates an increase in digestive juice secretion and peristalsis, worsening the situation. The continually increasing intraluminal pressure also increases the permeability of mucosal capillary beds, allowing vascular fluid to flow into the intestinal lumen. This phenomenon, which is termed **third spacing**, can lead to dehydration, electrolyte imbalances, and hypovolemia.

Over time, the stagnation of intestinal contents facilitates significant bacterial growth. As bacteria enter the mucosal tissues, infections leading to peritonitis or sepsis may occur. If luminal distension proximal to the blockage site continues unchecked, a bowel rupture can occur. Once ruptured, the contents of the GI tract will irritate surrounding tissues and likely cause peritonitis.

TABLE 16-6 Causes of Intestinal Obstruction

Type of Obstruction	Cause
Mechanical	Extrinsic • Adhesions • Hernias • Volvulus • Masses Intrinsic • Diverticula • Neoplasms • Intussusception Intraluminal • Foreign body ingestion • Fecal impaction
Nonmechanical (ileus)	Postoperative Acute colonic pseudo-obstruction Abdominal inflammation Peritonitis Heavy metal poisoning Metabolic abnormalities Spinal cord injury

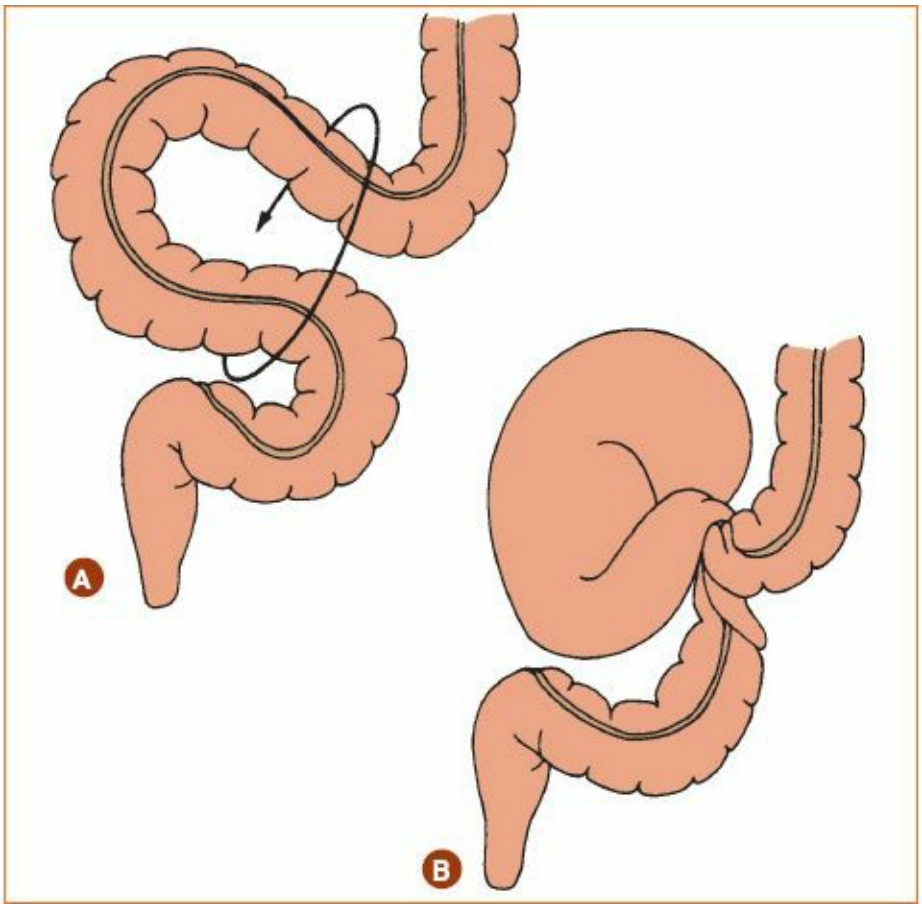

Figure 16-25 The pathogenesis of volvulus. **A.** Rotary twist of the sigmoid colon on its mesentery. **B.** Obstruction of the colon and interruption of its blood supply caused by volvulus.

Figure 16-26 A colon carcinoma demonstrated by barium enema. The tumor narrows the lumen of the colon, which appears as a filling defect in the column of barium (*arrows*).

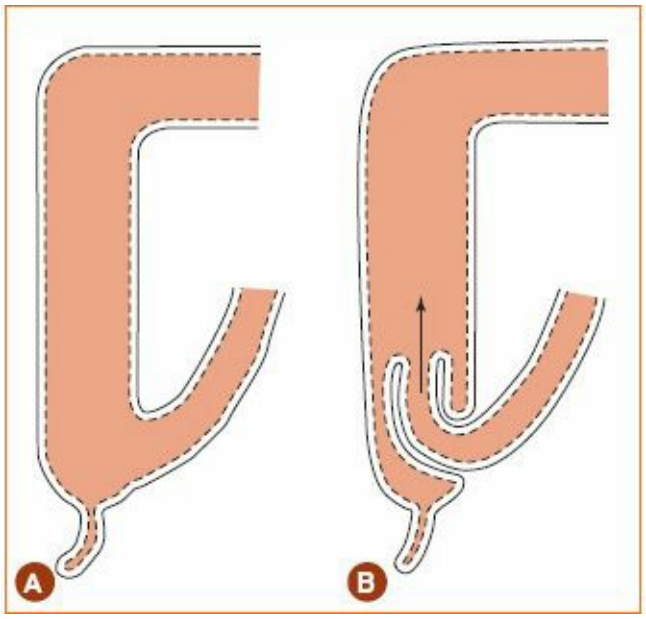

Figure 16-27 The pathogenesis of intussusception. **A.** Normal anatomic relationships. **B.** Vigorous peristalsis carries the distal ileum into the cecum. The *dashed line* indicates mucosa.

Distal to the obstruction site, tissue ischemia occurs secondary to arterial occlusion. This ischemia inhibits any residual GI functioning and eventually results in necrosis.

Ileus

Ileus is the lack of movement of the GI contents through the intestines in the absence of a mechanical obstruction. The most common type occurs postoperatively and is idiopathic, possibly resulting from the use of an anesthetic, which interferes with mesenteric innervation. The use of opiate-based medications inhibits intestinal motility, and the frequent administration of these medications after surgery may be a factor in postoperative ileus as well. Postoperative ileus is transient, usually lasting 48 to 72 hours after surgery. This type of ileus and other types of reversible ileus are also known as acute colonic pseudo-obstruction, or Ogilvie's syndrome. Other causes of ileus include abdominal inflammation, peritonitis, heavy metal poisoning, metabolic abnormalities, and spinal cord injury.

Figure 16-28 A foreign body.

Assessment

Signs and Symptoms

Moderate to severe abdominal pain accompanies distention proximal to the intestinal obstruction, with eventual vomiting. Excess bacterial growth causes bad breath, along with exceptionally foul-smelling vomit. The vomit may contain large amounts of bile and may have an appearance similar to feces depending on the location of the obstruction.

The intestinal mucosa become inflamed secondary to ischemia and necrosis. This inflammation, along with bacterial infiltration into the tissues, can cause a fever as the patient's immune response develops. Shock can develop from third spacing of fluids, vomiting, and diarrhea, manifesting as tachycardia, altered mental status, cool and clammy skin, and hypotension.

In a patient with an intestinal obstruction, the abdomen is tender and distended on palpation, typically with diffuse pain. Palpation of the mass may suggest obstruction. Initially, hyperactive and high-pitched bowel sounds may accompany an obstruction, followed by an eventual cessation of sound as GI function is increasingly inhibited.

Laboratory Data and Imaging

Laboratory testing functions mostly to determine the degree of dehydration and electrolyte imbalance from an intestinal obstruction. Hemoglobin and hematocrit values become elevated as the blood becomes more concentrated following excessive vomiting. Metabolic alkalosis frequently occurs as electrolyte shifts compensate for the loss of hydrogen ions through vomiting. White blood cell counts increase as the extent of tissue ischemia and necrosis expands.

Signs and Symptoms

Intestinal Obstruction

- Moderate to severe abdominal pain
- Tender, distended abdomen
- Foul-smelling vomit that may contain bile or appear similar to feces
- Diarrhea
- Bad breath
- Fever
- Shock
- Tachycardia
- Altered mental status
- Cool, clammy skin
- Hypotension
- Hyperactive, high-pitched bowel sounds initially
- Eventual cessation of bowel sounds

Differential Diagnosis

Intestinal Obstruction

- Diverticulitis
- Cholelithiasis
- Endometriosis

- Foreign body
- Gastroenteritis
- Inflammatory bowel disease
- Pancreatitis
- Appendicitis
- Urinary tract infection
- Pelvic inflammatory disease
- Ovarian torsion
- Cholangitis

Transport Management

Intestinal Obstruction

- Stabilize the ABCs.
- Provide fluid resuscitation.
- Provide supplemental oxygen.
- Continuously monitor the ECG.
- Designate NPO.
- Place an OG or NG tube.
- Administer prophylactic antibiotics.

Plain radiography can diagnose an intestinal obstruction by detecting abnormally high air volumes proximal to the obstruction site. A lack of air distal to the obstruction also can be detected, permitting a fairly accurate localization of the problem. **Enteroclysis** can be used in conjunction with radiography to provide a more accurate diagnosis. In this procedure, a barium contrast dye is infused into the duodenum through an OG or NG catheter. The progression of the catheter through the intestines can be monitored on a fluoroscope screen in real time, allowing for observation of the blockage.

A CT scan can be used to diagnose a bowel obstruction with exceptional specificity, and this technique is often used when prior imaging studies produce indeterminate results. An abdominal CT scan is useful in differentiating the cause of the obstruction and observing tissue alterations and inflammations. Abdominal ultrasonography can also be used to diagnose an intestinal obstruction with great accuracy.

Management

After the stabilization of any life threats to the patient's airway, breathing, or cardiac functioning, initial treatment focuses on fluid resuscitation. Isotonic fluid boluses should be administered as needed to maintain adequate perfusion. Supplemental oxygen should be provided through either a nonrebreathing mask or a nasal cannula. The patient's ECG should be continuously monitored for signs of arrhythmias secondary to electrolyte imbalances.

Patients with a suspected intestinal obstruction should be placed on NPO restrictions, and an OG or NG tube should be placed to relieve distention proximal to the blockage. Prophylactic antibiotics are frequently administered to reduce the likelihood of infection and subsequent sepsis.

Foley catheter placement can assist in monitoring fluid resuscitation progress. The Foley catheter may or may not be placed by the CCTP depending on regional protocols. Patients with chronic intestinal

obstruction may receive total parenteral nutrition (TPN) to help them maintain adequate nutrition. Emergency surgery is required in patients with a strangulated bowel. Techniques are directed toward reducing the obstruction through laparoscopic lysis or circumventing the obstruction by a bowel resection. Specific treatment for ileus is aimed at correcting the underlying cause.

NG Tube Insertion

The following equipment is needed to place an NG tube:

- NG tube
- 50-mL irrigation syringe
- Water-soluble lubricant
- Adhesive tape
- Saline for irrigation
- Emesis basin
- Gloves
- Stethoscope
- Low-powered suction unit

Indications for NG tube placement are as follows:

- Evacuation of stomach contents
- Dilution or lavage of poisons in the stomach
- Removal of blood in patients with GI hemorrhage

Contraindications to NG tube placement include severe facial trauma, croup, and epiglottitis. Potential complications of NG tube placement include improper positioning of the tube: (1) turbinate insertion, causing bleeding and pain; or (2) tracheal insertion, causing the patient to cough and choke. If the tube cannot be advanced to its predetermined length, then it has most likely curled in the mouth, throat, or trachea.

Skill Drill 16-1 shows the steps for NG tube placement as follows:

1. Use BSI precautions.
2. Assemble your equipment.
3. Explain the procedure to the patient, and oxygenate the patient if necessary. Position the patient in the sitting position. Ensure that the patient's head is in a neutral position and suppress the gag reflex with a topical anesthetic spray **Step 1**.
4. Examine the patient's nose for deformity or obstruction; determine the best side for insertion.
5. Constrict the blood vessels in the nares with a topical alpha-agonist **Step 2**.
6. Measure the tube from patient's earlobe to the tip of the nose.
7. Measure from the patient's earlobe to the bottom of the xiphoid process.
8. Total the two measurements and mark the correct length on the tube with adhesive tape **Step 3**.
9. Lubricate 6″ to 8″ of the tube with a water-soluble gel **Step 4**.
10. Insert the tube into one nostril. Gently advance the tube toward the posterior nasopharynx **Step 5**.
11. When you feel the tube at the nasopharyngeal junction, rotate it 180° inward toward the other nostril.

12. Gently advance the tube until it is in the nasopharynx. As the tube enters the oropharynx, instruct the patient to swallow **Step 6**.
13. Pass the tube to the predetermined point **Step 7**. Do not force the tube if resistance is encountered.
14. Check placement of the tube in two ways: auscultate over the epigastrium while injecting about 20 to 30 mL (no more than 50 mL) of air into the tube and/or observe for gastric contents in the tube **Step 8**. There should be no reflux around the tube.
15. Apply suction (at a low setting) to the tube to aspirate the gastric contents, and secure the tube in place **Step 9**.

OG Tube Insertion

The following equipment is needed to place an OG tube:

- OG tube
- 50-mL irrigation syringe
- Water-soluble lubricant
- Adhesive tape
- Saline for irrigation
- Emesis basin
- Gloves
- Stethoscope
- Low-powered suction unit

Indications for OG tube placement are as follows:

- Threat of aspiration
- Pressure of the stomach on the diaphragm
- Patient is unconscious

Contraindications to OG tube placement include:

- Esophageal disease or esophageal trauma (use extreme caution)
- Esophageal obstruction

Complications include:

- Patient biting tube

Skill Drill 16-2 shows the steps for OG tube placement:

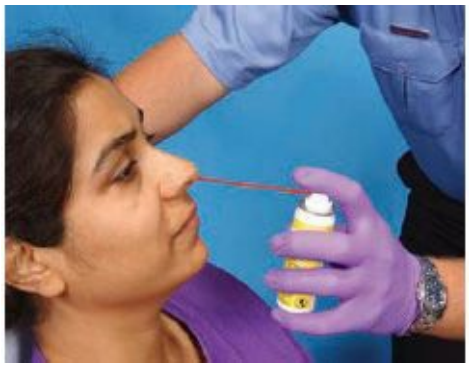
1. Position the patient's head in a neutral or flexed position **Step 1**.
2. Measure the tube for the correct depth of insertion (mouth to ear to xiphoid process) **Step 2**.
3. Lubricate the tube with a water-soluble gel **Step 3**.
4. Introduce the tube at the midline, and advance it gently into the oropharynx **Step 4**.
5. Advance the tube into the stomach **Step 5**.
6. Confirm proper placement: auscultate over the epigastrium while injecting 30 to 50 mL of air and/or observe for gastric contents in the tube. There should be no reflux around the tube **Step 6**.
7. Apply suction to the tube to aspirate the stomach contents, and secure the tube in place **Step 7**.

An NG or OG tube may already be in place upon the CCTP's first encounter with the patient, particularly during interfacility transports. In such cases it is important to ensure continuous proper placement of the tube and to be alert for any potential complications that may arise. Correct placement may also be ensured through pH testing. To accomplish this, use a pH indicator test strip and place a small amount of aspirated stomach contents on it. Proper placement will test acidity, with a pH of less than 6. Aspiration is always a concern for patients with an NG or OG tube inserted, whether for suction or feeding. If a patient appears to be in distress with a tube in place, first attempt to ensure proper placement by injecting a small air bolus into the tube while auscultating the epigastrium. If the patient continues to gag or is vomiting, suctioning and removal of the tube may be necessary. Following such action, reinsertion may be performed if permitted by regional protocols and if the patient's condition allows.

Skill Drill 16-1

Inserting a Nasogastric Tube in a Conscious Patient

1 Explain the procedure to the patient. Ensure that the patient's head is in a neutral position and suppress the gag reflex with a topical anesthetic spray.



2 Constrict the blood vessels in the nares with a topical alpha-agonist.

3 Measure the tube for the correct depth of insertion (nose to ear to xiphoid process). Mark the correct length on the tube with adhesive tape.

4 Lubricate the tube with a water-soluble gel.

5 Advance the tube gently along the nasal floor.

6 Encourage the patient to swallow or drink to facilitate passage of the tube.

7 Advance the tube into the stomach (to the predetermined point).

8 Confirm proper placement: auscultate over the epigastrium while injecting 30 to 50 mL of air into the tube, and/or observe for gastric contents in the tube. There should be no reflux around the tube.

9 Apply suction (at a low setting) to the tube to aspirate the gastric contents, and secure the tube in place.

Skill Drill 16-2

Orogastric Tube Insertion

1 Position the patient's head in a neutral or flexed position.

2 Measure the tube for the correct depth of insertion (mouth to ear to xiphoid process).

3 Lubricate the tube with a water-soluble gel.

4 Introduce the tube at the midline, and advance it gently into the oropharynx.

5 Advance the tube into the stomach.

6 Confirm proper placement: auscultate over the epigastrium while injecting 30 to 50 mL of air and/or observe for gastric contents in the tube. There should be no reflux around the tube.

7 Apply suction to the tube to aspirate the stomach contents, and secure the tube in place.

Liver Disease

Considering the amount of vasculature that passes through the liver, it is easy to imagine the far-reaching implications that any insult to this organ could cause. In general, an insult to the liver is either infectious or noninfectious. If the insult resolves within 6 months without any permanent function deficit, it is termed acute. When symptoms persist longer, chronic liver disease has developed. Regardless of the cause, most cases of chronic liver disease find a common ending—cirrhosis.

Epidemiology and Pathophysiology

Types of Liver Disease

Hepatitis, an inflammation of the liver, is the physiological result of any liver disease. Viral infection by hepatitis types A, B, C, D, and E accounts for 90% of acute hepatitis cases. The remaining 10% of cases result from excessive alcohol consumption, autoimmune disorders, toxins, and drugs. Infection by **hepatitis C virus (HCV)** is especially prominent when the disease becomes a chronic condition, with this infection evolving into chronic hepatitis with a frequency of 80%.

Fulminant hepatic failure is the result of a sudden significant insult to the liver. It occurs less commonly than the hepatitis process, but is associated with mortality rates ranging from 50% to 90%. The leading causes of fulminant hepatic failure are acetaminophen toxicity (39%), idiosyncratic drug reactions (13%), and viral hepatitis (12%). This condition is characterized by the development of encephalopathy within 2 weeks of jaundice onset.

The leading cause of cirrhosis is infection with HCV, with alcoholic liver disease closely following. (It is interesting that the lowest rates of cirrhosis in the United States occurred during Prohibition, when

alcohol was made illegal.) The remaining cases are largely a result of cryptogenic causes, such as nonalcoholic fatty liver disease and hepatitis B virus (HBV) infection; other causes are responsible for only 5% of cases **Table 16-7**. Cirrhosis is characterized by irreversible structural changes to the liver that impair its functioning. Once the disease is advanced, the only cure is liver transplantation.

Course of Liver Disease

Inflammation of liver tissue results in damage to a variety of functional cells, including hepatocytes and Kupffer cells. As cells are destroyed, the basic acinar framework involved in blood detoxification and bile production is disrupted. Liver sinusoids and bile drainage canals are inflamed, creating an increased resistance to portal blood flow and bile passage. The increased portal resistance to blood flow can develop into portal hypertension, which has significant effects on the body **Table 16-8**. Splenomegaly can result from the initial blood backup, decreasing the effectiveness of the spleen's metabolic processes. Collateral circulation in the mesentery increases as blood attempts to find a low-resistance route to the vena cava, resulting in an increased risk for esophageal or gastric varices.

TABLE 16-7 Causes of Hepatitis and Cirrhosis

Condition	Cause
Hepatitis	Viral Alcohol abuse Autoimmune disorders Toxins Drugs
Cirrhosis	Hepatitis C Alcoholic liver disease Nonalcoholic fatty liver disease Hepatitis B Miscellaneous

Bilirubin that is normally conjugated by hepatocytes and excreted via bile begins to build up in the blood, resulting in jaundice. Gray feces develop as bilirubin levels decrease in the GI tract. Urine darkens as bilirubin is excreted through the renal system.

The lack of proper nitrogen fixation by damaged hepatocytes can lead to increased concentrations of blood ammonia. The increased circulating ammonia is thought to be the major neurotoxin responsible for **hepatic encephalopathy**, although the overall mechanism is poorly understood. Cognitive changes are seen from the disruption of cerebral function, followed by cerebral edema and coma in 75% to 80% of cases.

In alcoholic liver disease, the liver cells are distended from fat accumulation, disrupting normal function. Daily ingestion of more than 40 to 80 g of ethanol results in excessively reduced nicotinamide adenine dinucleotide (NADH) production from ethanol oxidation in the liver. Elevated hepatocyte NADH concentrations stimulate triglyceride synthesis; these triglycerides are stored within the cell once produced. The continued fat accumulation over the course of 10 to 12 years will result in an enlarged and jaundiced liver.

Cirrhosis develops once hepatocyte damage and destruction become widespread enough to cause local areas of necrotic tissue, such that liver cells attempt to regenerate themselves. During this process, fibroblasts deposit collagen in a disproportionately high rate throughout the extracellular matrix. The

increase in fibrotic tissue distorts the anatomy of the liver, further impairing its function. This permanent disruption of the liver's structure only insinuates further inflammation and portal hypertension.

TABLE 16-8 Effects of Portal Hypertension
Splenomegaly (enlarged spleen)
Esophageal varices
Gastric varices
Increased serum bilirubin • Jaundice • Gray feces • Dark urine
Azygos system overusage
Ascites
Muscle wasting
Hormonal alterations

Signs and Symptoms

Liver Disease

- Jaundice
- Dark urine
- Gray feces
- General malaise
- Fever and chills
- Ascites
- Weight gain
- Frequent bleeding
- Melena, hematochezia
- Chronic shortness of breath
- Hypotension
- Tachycardia
- Hair loss
- Cognitive disorders
- Spider skin
- Hypoglycemia

Differential Diagnosis

Liver Disease

- Acute hepatitis
- Cholestasis
- Acute hepatic failure
- Chronic hepatitis
- Cirrhosis
- Hepatomegaly
- Liver mass
- Jaundice (icterus)
- Increased **aspartate aminotransferase/alanine aminotransferase (AST/ALT) ratio**
- Increased alkaline phosphatase level

Transport Management

Liver Disease

- Manage the airway.
- Provide fluid resuscitation.
- Monitor the ECG.
- Monitor for GI bleeding, renal failure, and encephalopathy.
- Do not administer medications that are metabolized by the liver.
- Administer antiviral and interferon drugs.
- Administer corticosteroids.

Assessment

Signs and Symptoms

General malaise is the most prominent symptom in early acute hepatitis. Improper nutrient metabolism by the inflamed liver causes generalized fatigue. Fever and chills present as a result of the systemic immune response.

As mentioned previously, portal hypertension results in a series of problems, including ascites and weight gain from abdominal fluid retention, as well as frequent bleeding from platelet retention in the spleen. Melena and hematochezia can occur also as a result of induced GI bleeding from portal hypertension. Chronic shortness of breath can develop from impaired diaphragmatic expansion secondary to hepatomegaly, splenomegaly, and ascites. Vasodilation of the splanchnic artery decreases cardiac afterload with the loss of peripheral vascular resistance, causing hypotension and tachycardia. Hair loss is commonly observed as a result of improper metabolism of hormones.

Figure 16-29 Marked ascites in a patient with advanced cirrhosis.

Laboratory Data and Imaging

Liver function is assessed by evaluating the presence of its synthesized products as well as the absence of its cellular enzymes in the blood. It is important to recognize the distinction between tests for liver function and markers of injury. By the time most lab values become abnormal and symptoms have emerged, 60% to 80% hepatocyte destruction has already occurred.

Albumin is a protein synthesized by the liver that assists in maintenance of osmotic balance in the body tissues. A decrease in its production results in the peripheral edema, **ascites** **Figure 16-29**, and pulmonary edema observed in patients with liver failure. Elevated serum levels of bilirubin indicate hepatocyte insufficiency and are a reliable indicator of the severity of liver damage. A prolonged PT time is the result of decreased clotting factor synthesis by the liver, which is also frequently a result of hepatocyte insufficiency secondary to injury.

Release of enzymes specific to hepatocytes into the bloodstream can be detected through laboratory testing and is useful as a marker of the existence of liver disease and its progression. These enzymes include AST, ALT, and gamma-glutamyltransferase (GGTP or GGT). Elevated serum levels of any of the three can suggest hepatic insult, with increases in ALT being the most specific to the liver. GGT is very sensitive to hepatocyte damage, with its level becoming elevated after even one episode of binge drinking. Elevated GGT levels also suggest cholestasis secondary to a biliary obstruction, particularly in conjunction with elevated alkaline phosphatase (AP) levels.

In patients presenting with an altered mental status, a blood glucose test can reveal hypoglycemia from decreased glucose metabolism and glycogen storage secondary to hepatocyte injury. Elevated serum ammonia concentrations from decreased nitrogen fixation in the damaged liver can result in hepatic encephalopathy. Increased levels of BUN and serum creatinine indicate impaired renal function and can suggest fulminant hepatic failure with hepatorenal syndrome **Table 16-9**.

Although no imaging studies are necessary in the diagnosis of hepatitis, they can prove valuable in differentiating hepatitis from similarly presenting diseases. An abdominal CT scan and ultrasound can support a diagnosis of hepatitis through visualization of an enlarged liver. Severity and progress of the disease can be measured through imaging to some extent as well **Figure 16-30**.

TABLE 16-9 Normal vs Abnormal Laboratory Values in Liver Disease

Test	Normal	Abnormal
Albumin	3.8–5.0 g/dL	< 3.8 g/dL
Bilirubin, serum (direct, conjugated)	0.1–0.3 mg/dL	> 0.3 mg/dL

Bilirubin, total	0.3–1.2 mg/dL	> 1.2 mg/dL
Prothrombin time	10-13 s	> 13 s
Alkaline phosphatase	30–120 U/L	> 120 U/L
Serum ammonia	10–80 μg/dL	> 80 μg/dL
Blood glucose	70–110 mg/dL	< 70 mg/dL
Blood urea nitrogen	8–23 mg/dL	> 23 mg/dL
Creatinine, serum	0.6–1.2 mg/dL	> 1.2 mg/dL
Liver Enzymes		
Aspartate aminotransferase	10–30 U/L	Elevated (usually 42 U/L)
Alanine aminotransferase	10–40 U/L	Elevated (usually 48 U/L)
Gamma-glutamyltransferase	2-30 U/L	Elevated (usually 55 U/L)

Figure 16-30 Advanced hepatic cirrhosis illustrating elevated nodules of liver tissue surrounded by depressed areas of scar tissue.

Management

Treatment of hepatitis focuses on prevention of further injury with a goal of preventing progression to cirrhosis. Antiviral and interferon drugs are administered in cases of infectious hepatitis to suppress the viral load. Many of these drugs are used in the treatment of human immunodeficiency virus (HIV) infection as well. Corticosteroids are frequently administered to reduce inflammation, and are most effective in the early stages of the disease. Pharmacologic treatment of hepatitis is an active topic of research, and usage of specific medications will vary between institutions.

The bulk of treatment is supportive, mainly concentrating on prevention and correction of any complications. In more severe cases of liver disease, neurologic function can be diminished, requiring airway management. Third spacing secondary to hypoalbuminemia can cause hypotension and is treated with fluid resuscitation. ECG monitoring should be done to observe for arrhythmias from electrolyte imbalances, especially hypokalemia. Patients should be monitored for evidence of GI bleeding, renal failure, and encephalopathy. Avoidance of alcohol and medications metabolized by the liver is mandatory. In many cases, dosages of common medications must be reduced in anticipation of the liver's decreased function.

Prevention of ascites through a low-sodium diet, fluid restriction, and diuretics is often necessary in patients with cirrhosis, keeping an eye toward maintaining blood pressure. **Paracentesis**—"tapping" of the abdomen with a needle—can be used to physically remove ascetic fluid from the abdomen, because its accumulation can sometimes amount to as much as 4 to 6 L/d.

There is no cure for hepatitis or the resultant cirrhosis other than liver transplantation. Liver transplantations have a fairly high success rate, with 1-year survival rates ranging from 85% to 90% and 5-year survival rates exceeding 70%. Unfortunately, there are more cases of cirrhosis than there are available livers, and 12% to 15% of patients die awaiting a donor organ.

Biliary Tract Obstructions

Blockage of the biliary tracts at any point will result in a backup of bile and possibly, depending on the location of the obstruction, pancreatic enzymes. These digestive juices accumulate first in the tracts, and then in the organs from which they originated. The damage caused by this type of obstruction is twofold. Distal to the obstruction, normal digestive processes of the GI system are disrupted, while proximal accessory organs and ducts become distended and inflamed.

Epidemiology and Pathophysiology

Most often, the biliary tract system is obstructed by a migrating gallstone. Gallstones in the gallbladder, **cholelithiasis**, are fairly common, affecting around 20 million Americans each year **Figure 16-31**. They can form one of two ways: through accumulation of excess cholesterol in the bile (cholesterol stones) or through accumulation of excess bilirubin and calcium salts in the bile (pigment stones). Both causes result in the crystallization of bile into stones, which may range in size from small grains to the size of a golf ball. Cholesterol stones account for 75% to 80% of gallstone cases in the United States, with the remainder accounted for by pigment and mixed stones. It is also notable that patients with cirrhosis are at higher risk for pigment stones.

Inside the gallbladder, stones may cause inflammation of the gallbladder itself, known as **cholecystitis**. When the stone is inside the biliary ducts, the condition is termed **choledocholithiasis**. The stone may begin to travel into the cystic duct at any time, lacerating the inner walls as it moves. Frequently, it will lodge in either the cystic duct or the distal common bile duct. If the stone lodges in the common bile duct and fully obstructs the lumen, both bile and pancreatic juice will be unable to pass into the duodenum. As pancreatic enzymes accumulate proximal to the obstruction, they begin to digest the tissues of both the ducts and the pancreas, a condition responsible for almost half of all cases of pancreatitis. As enzymes and bile leak through the compromised duct lining, peritonitis can occur and eventually lead to sepsis and shock.

Figure 16-31 Open gallbladder filled with gallstones composed of cholesterol.

Assessment

Signs and Symptoms

Cholecystitis causes colicky pain in the right upper quadrant of the abdomen. This pain tends to emerge following ingestion of high-fat foods, because fatty chyme stimulates gallbladder contraction.

Patients with choledocholithiasis typically present with fever, jaundice, and right upper quadrant pain, which are collectively referred to as **Charcot's triad**. Nausea and vomiting frequently accompany Charcot's triad, along with clay-colored feces. A patient with this condition will also exhibit a positive **Murphy's sign** (pain in the right upper abdomen on deep inspiration during palpation) when the fingers are pressed under the rib cage.

Laboratory Data and Imaging

The effects of biliary tract obstruction can be observed through elevations of the serum values of blocked secretions from the gallbladder and pancreas. Serum bilirubin levels increase, along with serum amylase and lipase. AP and GGT levels will also be elevated. The PT will increase as vitamin K absorption levels decrease owing to a lack of bile in the GI tract. In infective cases, known as **cholangitis**, white blood cell levels also rise.

Transabdominal ultrasonography can detect stones both in the gallbladder and in the biliary duct system. Although this imaging technique's accuracy is decreased in the common bile duct, distention proximal to the obstruction can usually be detected via this technology.

Signs and Symptoms

Biliary Tract Obstruction

- Charcot's triad
  - Fever
  - Jaundice
  - Right upper quadrant pain
- Nausea and vomiting
- Clay-colored feces
- Murphy's sign: tender right upper quadrant

Differential Diagnosis

Biliary Tract Obstruction

- Appendicitis
- Cholecystitis
- Cholangitis
- Diverticulitis
- Gastritis
- Peptic ulcer disease
- Hepatitis
- Inflammatory bowel disease
- Pancreatitis

- Biliary stricture
- Choledocholithiasis
- Pancreatic tumor
- Choledochal cyst

Transport Management

Biliary Tract Obstruction

- Maintain the ABCs.
- Provide oxygen as required.
- Place an IV.
- Monitor the ECG.
- Avoid administering opiates for pain management.

Endoscopic ultrasonography is an alternative technique that is used when transabdominal ultrasonography yields indeterminate results. This imaging technique uses a probe to detect the presence of stones in the common bile duct from the duodenum. This technique has great accuracy, but is also associated with complications secondary to its invasiveness.

If endoscopy is unsuccessful, a **hepatoiminodiacetic acid (HIDA) scan** can be performed. This test is similar to the technetium-99m–labeled red blood cell scintigraphy used to assess GI bleeding. A radiologically labeled chemical specific for bile incorporation is introduced into the patient. This marker's journey is then observed through radiography. Any obstruction to its expected path can be clearly noted, permitting a confident diagnosis of the obstruction. Also, a CT scan and MRI are useful techniques in the diagnosis of both cholelithiasis and choledocholithiasis.

Endoscopic retrograde cholangiopancreatography and percutaneous transhepatic cholangiography are two methods of cholangiography that have excellent accuracy in detecting choledocholithiasis. Both techniques involve injection of contrast dye into the biliary duct system to observe the obstruction. Unfortunately, both methods are also fairly invasive and carry a high risk of complications. For this reason, they are used only when less invasive techniques are unsuccessful.

Management

Immediate treatment of choledocholithiasis involves pain management once general treatment has been performed. Morphine has traditionally been avoided because it can theoretically cause spasm of the biliary ducts at the ampulla of Vater. Despite this, adequate pain management should not be withheld in the case where this is the only agent available.

Definitive treatment occurs at the hospital and focuses on removal of the stone to relieve the obstruction. Endoscopic retrograde cholangiopancreatography is frequently used to remove the stone after fulfilling its diagnostic role. **Lithotripsy** can break apart larger stones through external vibrations, facilitating removal by endoscopic retrograde cholangiopancreatography or percutaneous transhepatic cholangiography. A sphincterotomy is often performed to allow the stones to pass into the duodenum, where they can be caught with a basket or catheter.

Pancreatic Disease

Epidemiology and Pathophysiology

Inflammation of the pancreas, known as **pancreatitis**, can lead to significant impairment of gastrointestinal physiology depending on its level of severity and etiology. The most common causes are gallstones (45%) and alcohol abuse (35%), with the remainder of cases resulting from idiosyncratic drug reactions, tumors, hypertriglyceridemia, hypercalcemia, and congenital defects **Table 16-10**. The majority of cases are mild, self-resolving in 3 to 4 days with a very low mortality. **Systemic inflammatory response syndrome** develops in 10% to 15% of patients, marking a shift to severe acute pancreatitis with a 15% to 40% mortality rate.

Chronic pancreatitis is characterized by the presence of irreversible anatomic changes to the pancreas, along with some degree of function loss. Long-term alcohol use is the major cause of this condition, although the exact pathological mechanisms are unknown. Chronic pancreatitis has an incidence of about a third of that for acute pancreatitis per year in the United States. Pancreatitis is more likely to develop in men than in women, and African-Americans have an incidence three times that of the national average.

The inflammatory process in pancreatitis comes in response to self-digestion of the pancreatic tissue. Pancreatic enzymes are normally produced as inactive precursors that are activated in the GI lumen. When these enzymes become prematurely activated inside either the pancreas or the ducts that drain the secretions, they immediately begin digesting surrounding tissue. Thanks to the retroperitoneal location of the pancreas, the activated enzymes can easily spread throughout the peritoneum as well as to other retroperitoneal organs. Once digestion reaches pancreatic blood vessels, hemorrhaging occurs. As the disease progresses, tissue necrosis begins to occur. The resulting necrotic tissue is susceptible to bacterial infection owing to its lack of integration into the immune system, such that spontaneous infections of the pancreas or peritoneum frequently occur.

TABLE 16-10 Causes of Pancreatitis

Gallstones
Alcohol abuse
Idiosyncratic drug reactions
Tumors
Hypertriglyceridemia
Hypercalcemia
Congenital defects
Systemic inflammatory response syndrome

Pancreatic pseudocysts are aggregates of cellular debris and extracellular pancreatic enzymes that are freed by the process of tissue necrosis. They occur in about 20% of cases of acute pancreatitis and often rupture, furthering the scope of pathogenesis. Increased or unexpected presence of pancreatic enzymes throughout the body is believed to be the cause of the various multisystem complications observed in pancreatitis, although the exact etiology is unknown. Pulmonary complications may include arterial hypox-emia, atelectasis, pleural effusions, pneumonia, and acute respiratory distress syndrome (ARDS). Fluid shifts and enzyme-induced vasodilation can cause hemodynamic instability and shock. The resultant decrease in organ perfusion can lead to acute renal failure. Clotting can become inhibited as a

result of increased blood concentrations of proteolytic enzymes such as trypsin.

Signs and Symptoms

Pancreatitis

- Upper abdominal pain
- Tenderness and guarding of the abdomen
- Tachycardia
- Nausea, vomiting
- Fever
- Turner's sign (discoloration of the lower back and flank)
- Cullen's sign (periumbilical discoloration)
- Jaundice
- Hemodynamic instability
- Shock

Differential Diagnosis

Pancreatitis

- Cholecystitis
- Cholangitis
- Gastritis
- Hepatitis
- Bowel obstruction
- Pancreatic cancer

Transport Management

Pancreatitis

- Administer supplemental oxygen.
- Place an IV.
- Monitor the ECG.
- Replace fluids in patients with hypovolemia.
- Administer packed red blood cells in the hemorrhaging patient.
- Monitor fluid output.
- Place an NG tube.
- Provide pain management (IV or patient-controlled analgesia devices; avoid opiates).

Assessment

Signs and Symptoms

Upper abdominal pain is the primary symptom of pancreatitis. This pain may radiate throughout the abdomen and to the back depending on the level of pancreatic involvement and can be severe at times. Tenderness and guarding of the abdomen often result as part of the pain response, as does tachycardia. Nausea and vomiting are common owing to the presence of gastric irritation. A fever will be present secondary to the body's immune response against the infectious complications of pancreatitis. Discoloration of the lower back and flank, known as Turner's sign, and periumbilical discoloration, known as Cullen's sign, are both rare and nonspecific findings of the retroperitoneal hemorrhage that may occur in severe pancreatitis. If biliary tract obstruction is the cause of the pancreatitis, jaundice may be observed. In severe hemorrhagic cases, hemodynamic instability and shock may occur.

Laboratory Data and Imaging

As the pancreatic cells are destroyed or the walls of ducts are digested, pancreatic-specific enzymes are released into the bloodstream. Serum amylase levels are the most sensitive indicators and frequently are elevated to more than three times their normal levels in case of pancreatitis. The downside to amylase-level measurement is its short half-life, as levels return to normal within 3 to 4 days. Serum lipase levels will rise and remain high later and longer than amylase levels, for 8 to 12 days after the insults. Although elevated levels of these two enzymes support a diagnosis of pancreatitis **Table 16-11**, they can result from a number of other conditions as well.

Liver function testing for elevated AP, AST, GGT, and serum bilirubin can be indicative of a biliary tract origin of disease. An ALT level greater than 150 U/L is highly suggestive of gallstone disease, a leading cause of pancreatitis. A leukocyte count greater than 16,000/μL indicates the presence of an infection, inflammation, or both. Arterial blood gas levels should be monitored for evidence of hypoxemia so that providers can attempt to preempt the development of severe respiratory complications such as ARDS.

A CT scan with contrast can provide a direct visual observation of pancreatic necrosis, peripancreatic abnormalities, abscesses, and overall size of the pancreas. It has 90% specificity and is invaluable in the determination of disease severity. For the detection of gallstones in the bile duct, magnetic resonance cholangiopancreatography (MRCP) has a 90% accuracy rate. Endoscopic retrograde cholangiopancreatography is a favorable alternative to MRCP in patients with pancreatitis with a suspected biliary origin. Along with supporting a diagnosis, it is amenable to performing simultaneous treatment via sphincterotomy and gallstone removal. MRCP is favored in situations in which the administration of iodinated contrast dye is not desired.

TABLE 16-11 Normal vs Abnormal Laboratory Values for Pancreatitis

Test	Normal	Abnormal
Amylase, serum	27–131 U/L	Elevated (usually > 100 U/L)
Lipase, serum	31–186 U/L	Elevated (usually > 60 U/L)
Aspartate aminotransferase	10–30 U/L	Elevated (usually > 42 U/L)
Alanine aminotransferase	10–40 U/L	Elevated (usually > 48 U/L)
Gamma-glutamyltransferase	2–30 U/L	Elevated (usually > 65 U/L)
Leukocytes (white blood cells)	4,500/μL–11,000/μL	Varies, elevation indicates infection

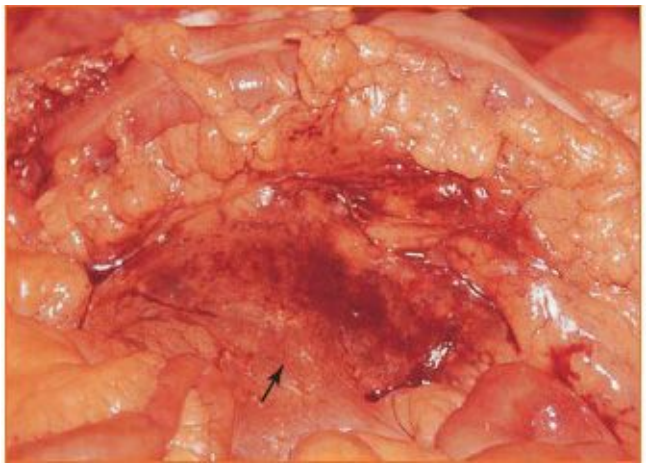


Figure 16-32 Acute pancreatitis. The transverse colon (*upper part* of the photograph) has been elevated to reveal the pancreas (*arrow*) which is inflamed and contains large areas of hemorrhage.

Visualization of the pancreas by abdominal ultrasound is often obstructed by intestinal gas and adipose tissue, such that this imaging modality has a poor success rate in identifying pancreatitis. When combined with endoscopy, it becomes a useful bedside procedure that can assist in the diagnosis of both pancreatitis **Figure 16-32** and gallstones.

Management

General treatment of pancreatitis includes palliative care such as supplemental oxygen administration, IV placement, and ECG monitoring. Fluid replacement is a priority in patients exhibiting signs and symptoms of hypovolemia to prevent decreased renal perfusion. Isotonic crystalloid boluses of 20 mL/kg are recommended, and the administration of packed red blood cells may be required in the hemorrhaging patient. Fluid output should be monitored during hydration therapy and can be facilitated by Foley catheter placement.

NG tube placement can relieve gastric distention. This measure decreases production of secretin, which in turn stimulates pancreatic enzyme secretion. All patients should receive NPO restrictions as well to prevent increased stimulation of pancreatic enzyme synthesis and secretion. In severe cases, TPN may be required.

Pain management is necessary and may take the form of IV narcotics or patient-controlled analgesia devices. Meperidine (Demerol) has traditionally been the preferred analgesic over other opiates because it avoids opiate-induced spasms of the sphincter of Oddi.

Once the patient has entered the hospital, specific treatment of acute pancreatitis focuses on prevention of complications and decreasing pancreatic workload. Prophylactic antibiotic administration to prevent bacterial peritonitis is a controversial but widely used treatment. Peritoneal lavage is used on occasion as well to remove offending substances from the peritoneal space.

Urinary System Conditions

Conditions affecting the urinary system include both acute and chronic renal failure, urinary tract infections, testicular torsion, ovarian torsion, penile fracture, ruptured ovarian cysts, and priapism. This section discusses all of these, except ovarian torsion and ovarian cysts, which are discussed in Chapter 21.

Acute Renal Failure

Epidemiology and Pathophysiology

A reliable flow of blood to the renal vasculature at a consistent rate is required for proper functioning of the nephrons. Significant decreases in renal perfusion pressure disrupt the elimination of waste from the bloodstream by lowering the GFR. When this situation develops in the absence of preexisting renal dysfunction, it is termed **acute renal failure (ARF)**. ARF is a frequently encountered complication in the hospitalized patient, particularly in the intensive care unit, where it is seen in as many as 25% of patients. Disproportionately high mortality rates (70% to 80%) are observed in patients with ARF in the intensive care unit compared with the general patient population (50%). ARF is likely a cause of the multiple comorbidities typically present in the critical care patient.

ARF is classified in terms of its etiology as prerenal, intrarenal, or postrenal. **Table 16-12** summarizes the causes and types of ARF.

Prerenal ARF is the most common cause, implicated in as many as two thirds of cases. This type of ARF is associated with many reversible causes and, if treated promptly and appropriately, can be corrected in up to 90% of cases. Hypovolemia secondary to dehydration or blood loss is often a cause of prerenal ARF, as are congestive heart failure and hepatorenal failure from cirrhosis. A variety of medications, including angiotensin-converting enzyme inhibitors and diuretics, can decrease renal perfusion through systemic vasodilation. Third spacing of fluids from sepsis is another precipitating factor.

TABLE 16-12 Summary of Causes and Types of ARF

Type	Cause
Prerenal	Hypovolemia Dehydration Congestive heart failure Hepatorenal failure Third spacing Sepsis Medications: • ACE inhibitors • Diuretics
Intrarenal	Acute tubular necrosis Contrast dye Interstitial nephritis Glomerulonephritis
	Renal calculi

Postrenal	Blood clots Tumors

Intrarenal ARF is classified as a structural injury to the kidney itself. **Acute tubular necrosis**—the most common cause of intrarenal ARF—is usually a result of renal ischemia or the presence of a toxin. Use of radiologic contrast dye has also emerged as a significant instigator of early ARF. Interstitial nephritis results from adverse reactions to antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), and diuretics.

Glomerulonephritis is another cause of intrarenal ARF, in which glomerular tissue becomes inflamed secondary to an immune response. Glomerulonephritis is a collective term covering about 20 glomerular conditions, with rapidly progressive glomerulonephritis being a severe form that impairs renal function. Glomerulonephritis is characterized by hematuria, initially on a microscopic level but progressing to visible quantities of blood in the urine and accompanied by proteinuria and hypertension. Peripheral edema from fluid buildup secondary to salt retention in afflicted nephrons can lead to congestive heart failure and encephalopathy. Postinfectious causes are frequently implicated in glomerulonephritis development. The most common cause is group A beta-hemolytic *Streptococcus* following pharyngitis infections. Other precipitators of glomerulonephritis include immunoglobulin A nephropathy and lupus.

Postrenal ARF occurs when urine flow distal to the nephrons becomes obstructed. The least frequently observed of the three types of ARF, this condition is associated with bilateral ureter or urethral blockage by renal calculi, blood clots, or lumen-penetrating tumors. Renal calculi, commonly referred to as kidney stones, are a result of salt buildup in the renal pelvis **Figure 16-33**. Most often the calculi consist of calcium-based compounds, although occasionally they are made up of struvite or uric acid. The majority of renal calculi pass through the urinary tract and are excreted without significant complications, although they certainly produce excruciating pain during their travels. A small percentage of calculi become lodged in the lumen of either the ureter or the urethra; these stones can cause life-threatening ARF and infections secondary to the buildup of urine in the kidneys. The urethra and bladder neck are typical sites of obstruction in such cases, as both ureters would require simultaneous blockage to cease all urine flow. Lodged stones can usually be removed through urinary catheterization. (Urinary catheter placement is discussed later in this chapter.)

Figure 16-33 A kidney stone.

One of the earliest external signs of ARF is oliguria, a reduction in urine volume to less than 400 mL/d. A decreased GFR results in a decrease in fluid volume entering the reabsorption tubules. This reduced volume travels slowly through the tubules as a result of a lack of pressure, allowing for elevated reabsorption of fluid and electrolytes—specifically, sodium—to occur. In many cases, the body's compensatory mechanisms for maintaining blood pressure worsen this situation. Any vasoconstrictive effort will further decrease renal perfusion, thereby reducing the GFR. This is especially important to take into account when considering administration of any vasocon-strictive medication to a hypotensive patient with suspected ARF. Eventually, decreased renal perfusion will result in tissue ischemia, injury, and necrosis. When the tubules become necrotic, they lose their ion-exchanging properties, preventing proper

urine formation. Inflammation and extensive shedding of dead tissue will further decrease the flow rate, possibly causing an obstruction.

Assessment

The patient's medical history and family history are important components of the assessment. A family history of renal disease indicates a predisposition to ARF when a precursory disease of ARF is present. The incidence of ARF is increased in patients with diabetes, hypertension, or lupus. The frequency of ARF increases greatly with age as well.

Signs and Symptoms

Signs of ARF include abnormalities in urine production. Oliguria is the most common abnormality, although an increase in urine output can occur if the nephron urine concentration mechanisms become ineffective. Lack of urine production is highly suggestive of an obstruction.

Given that dehydration is often a precipitating factor for ARF, patients commonly present with dizziness, poor skin turgor, thirst, flat neck veins, dry mucous membranes, weight loss, and orthostatic blood pressure changes. If third spacing and fluid retention are the cause of the ARF, the patient may exhibit fever, edema, and ascites. Lower back pain may be present in patients with ARF caused by infection or obstruction.

Laboratory Data and Imaging

The retention of wastes in the bloodstream that results from a decreased GFR provides an easy way to monitor for the existence and severity of ARF. Serum creatine levels will be elevated proportionally to the decrease in GFR. The level of BUN is a less reliable indicator of GFR, however, because it may be altered by numerous other metabolic functions unrelated to renal physiology, although it will also be elevated in ARF. The combined elevation in levels of BUN and serum creatine is known as **azotemia**.

Signs and Symptoms

Acute Renal Failure

- Dizziness
- Poor skin turgor
- Thirst
- Flat neck veins
- Dry mucous membranes
- Weight loss
- Orthostatic blood pressure changes
- Fever
- Edema
- Ascites
- Lower back pain

Differential Diagnosis

Acute Renal Failure

- Azotemia (increased BUN and serum creatine levels)
- Increased or decreased osmolality
- Increased specific gravity
- Increased or decreased fractional excretion of sodium and urine sodium concentration
- Acute tubular necrosis
- Chronic renal failure

Transport Management

Acute Renal Failure

- Ensure and maintain ABCs.
- Place an IV tube.
- Monitor the ECG.
- Maintain perfusing blood pressure through IV fluids.
- Increase the GFR (medication administration and fluid resuscitation).
- Closely monitor serum electrolyte levels.
- If in place, monitor dialysis machinery for potential complications.

TABLE 16-13 Normal vs Abnormal Laboratory Values in Patients with ARF

Test	Normal	Abnormal
BUN	8–23 µg/dL	> 23 µg/dL
Creatine, serum	0.6–1.2 mg/dL	> 1.2 mg/dL
Urinalysis		
• Osmolality	275–295 mOsm/kg	Varies
• Specific gravity	1.003–1.030	Varies
• BUN:creatine	10:1	> 20:1
• Fractional excretion of sodium	1%	Varies
• Urine sodium excretion (over 24 h)	43–217 mEq/24 h	Varies

Abbreviations: ARF, acute renal failure; BUN, blood urea nitrogen.

Urinalysis is critical for differentiating between the various types of ARF. Patients with prerenal ARF exhibit increased osmolality, specific gravity, and BUN:creatine levels, along with a decreased fractional excretion of sodium and urine sodium concentration. Acute tubular necrosis is framed with a nearly opposite set of findings: Urine osmolality is decreased, with an increased urine sodium concentration and fraction excretion of sodium.

Table 16-13 summarizes renal laboratory values for patients with ARF.

Renal ultrasonography is the gold standard in assessing suspected postrenal ARF. It allows for visualization of both renal calculi and the overall renal anatomy. Contrast dye is not used so as to avoid

potential complications from the dye (ie, intrarenal ARF). For this reason, ultrasonography has a distinct advantage over alternative imaging methods in a renal context. A CT scan and MRI are useful for detecting less frequent structural disorders once renal calculi have been ruled out.

Management

Initial treatment of the patient with ARF involves maintaining the ABCs and a perfusing blood pressure. Once these basics are ensured, management focuses on increasing the GFR. This management goal must be factored into the choice of all treatment modalities, but particularly medication administration and fluid resuscitation. Administration of 0.9% normal saline is indicated in dehydrated patients in an effort to treat oliguria. Diuretic administration can increase urine output, potentially increasing the GFR. Serum electrolyte levels must be monitored closely, especially potassium, in an effort to avoid complications from hyperkalemia.

Renal replacement therapy (RRT) is a frequently used treatment for ARF that has not responded to prior less invasive methods of treatment. The modality of choice remains controversial, and options include intermittent hemodialysis (IHD), continuous venovenous hemofiltration, and peritoneal dialysis (PD). IHD is the most commonly used method for both inpatient and outpatient settings. It involves the use of a dialysis machine, filter, extensive water supply, and tubing. The patient's blood is filtered by diffusion through an external semipermeable membrane and then returned to the body. Access to the patient's circulation can be obtained in different ways depending on the duration for which dialysis is required. A non-tunnelled central venous catheter is placed into either the internal jugular or the femoral vein for short-term access, but it carries with it complications such as infection and stenosis. For long-term IHD, an arteriovenous (AV) fistula is the preferred method as a result of increased blood flow, superior long-term patency, and decreased likelihood of thrombosis or infection. To form an AV fistula, a vascular surgeon anastomoses an artery and vein, most commonly in the non-dominant forearm. The typical patient receiving IHD is treated two to three times per week in 4-hour sessions. During continuous venovenous hemofiltration, a crystalloid replacement solution is added to dialysate as a plasma ultrafiltrate is removed. This method is often used when IHD is impossible as a result of severe hemodynamic instability. A convective clearance is used instead of the diffusion used in IHD, and treatment is slow and continuous, being performed over the course of 6 to 12 hours.

PD is infrequently used in the hospital setting although it can be a convenient option for chronic renal failure sufferers in the outpatient setting. This technique involves the insertion of a rubber catheter into the abdomen and the use of the peritoneum as a semipermeable membrane. A dextrose solution is injected into the peritoneal space, where it exchanges across the membrane while removing waste. The most common complication of PD is the increased risk of peritonitis following a site infection.

Chronic Renal Failure

Epidemiology and Pathophysiology

A gradual decrease in renal function over a long time interval is known as **chronic renal failure (CRF)**. The hallmark of CRF is an irreversible destruction of nephrons brought about by the continuous effects of a number of diseases, including diabetes mellitus, hypertension, and chronic infections (such as glomerulonephritis or pyelonephritis). The incidence of CRF in the United States has been steadily increasing over the past 30 years. This disease is diagnosed in more than three times as many blacks as whites. It is 40% more likely to develop in men than in women, and its incidence increases directly with age. Over time, CRF progresses to **end-stage renal disease (ESRD)**, after which dialysis is needed to maintain adequate renal function. The causes of CRF are widespread, although up to 75% of cases can be traced to long-term hypertension, glomerulonephritis, and diabetic neuropathy. A summary of causes is listed in **Table 16-14**.

The degree of severity of renal failure progresses as increasing numbers of nephrons are affected by the disease. When a nephron is compromised, surrounding nephrons are capable of working at overcapacity by increasing their GFRs. This compensatory mechanism permits the kidneys to maintain adequate function up to nephron losses of 70%. CRF is not technically present until the GFR falls below 30 mL/min. A less severe decrease in GFR (30 to 70 mL/min) is more accurately termed chronic renal insufficiency. Significant symptoms of renal failure typically do not emerge until the GFR has decreased to less than 30 mL/min. Symptoms become the most pronounced once the GRF falls below 10 mL/min, at which point the disease is classified as ESRD.

TABLE 16-14 Causes of Chronic Renal Failure
Long-term hypertension
Glomerulonephritis
Diabetic neuropathy
Chronic glomerular disease Chronic infections
Congenital abnormalities
Vascular diseases
Obstructive processes
Collagen diseases
Nephrotoxic agents
Endocrine diseases

Assessment

Signs and Symptoms

The presentation of a patient with CRF varies based on the progression of the disease and the existence of comorbidities. As the GFR decreases, waste retention begins. Many of the symptoms encountered in ARF are then seen, such as azotemia and electrolyte imbalances. Hyperkalemia can result from inadequate potassium excretion and can precipitate cardiac arrhythmias. Elevated BUN and serum creatine levels will be observed, as in ARF. Sodium and water retention may lead to congestive heart failure and edema. As renal erythropoietin synthesis decreases, anemia may develop, resulting in chronic fatigue. Hyperparathyroidism can develop from decreased renal vitamin D metabolism, causing skeletal abnormalities. Patients may exhibit polyuria as a result of the inability of the diseased nephrons to concentrate urine efficiently, a phenomenon known as isosthenuria. Metabolic acidosis frequently occurs in patients with CRF from a combination of acid retention and bicarbonate wasting and can contribute to the symptoms expressed during uremia.

The overall retention of urea and other metabolic waste in the blood leads to uremia, a condition characterized by nausea, vomiting, fatigue, anorexia, weight loss, pruritus, and altered mental status. Patients may present with jaundice if bilirubin retention occurs. Elimination of uric acid through the skin in sweat causes the uremic frost phenomenon, which is characterized by white dust on the skin. In patients with CRF, uremia usually sets in with ESRD and often coincides with the time that dialysis treatment is initiated.

Laboratory Data and Imaging

The results of lab studies in CRF and ESRD are generally parallel to the results seen in ARF. Variations may assist in distinguishing between the various causes of CRF. The most important factor in determining whether the renal failure is acute or chronic is disease duration. Comparing current elevated serum creatinine levels with a patient's readings over the previous months or years is helpful; prolonged elevation is strongly suggestive of chronic disease. If that is not available, signs of metabolic bone disease can also suggest chronic disease. Findings suggestive of this include hyperphosphatemia, hypocalcemia, elevated parathyroid hormone levels, and elevated bone alkaline phosphatase levels. Imaging studies commonly reveal decreased kidney size (< 8.5 cm) as a result of tissue atrophy.

Signs and Symptoms

Chronic Renal Failure

- Azotemia
- Electrolyte imbalances
- Hyperkalemia
- Cardiac arrhythmias
- Congestive heart failure
- Edema
- Anemia
- Chronic fatigue
- Hyperparathyroidism
- Skeletal abnormalities
- Polyuria or anuria
- Metabolic acidosis
- Uremia
- Jaundice
- Uremic frost phenomenon

Differential Diagnosis

Chronic Renal Failure

- Azotemia (increased BUN and serum creatine levels)
- Increased or decreased osmolality
- Increased specific gravity
- Increased or decreased fractional excretion of sodium and urine sodium concentration
- Acute renal failure
- Glomerulonephritis

Transport Management

Chronic Renal Failure

- Identify underlying condition.
- Treat hypertension or diabetes.
- Treat specific conditions (hyperphosphatemia, hypocalcemia, anemia).
- Be alert for and treat any electrolyte abnormalities.
- Monitor the ECG.
- Administer loop diuretics.
- Transport for dialysis.

Management

The best treatment for chronic renal failure is prevention, as there is no definitive cure once it has progressed to clinically detectable signs. Once CRF is recognized, treatment focuses on slowing the progression. Underlying conditions such as hypertension or diabetes must be controlled and managed appropriately. Specific conditions can be treated as needed: erythropoietin for anemia, phosphate binding for hyperphosphatemia, calcium supplements for hypocalcemia, and volume overload with diuretics or dialysis. Electrolyte imbalances can lead to cardiac arrhythmias, and therefore all patients with CRF should have continuous ECG monitoring. In the field, patients with CRF should also receive supplemental oxygen as required.

Peritoneal dialysis and **hemodialysis (HD)** are two options for long-term maintenance of renal function. PD introduces the dialysate solution into the abdominal cavity with a catheter, and the patient's peritoneal membrane acts as the semipermeable membrane for solute separation. HD involves vascular access through either a fistula or an arteriovenous shunt. A fistula, shunt, or arteriovenous graft is a surgically created arterial to venous vessel anastomosis tunneled through the subcutaneous tissue. Solute separation occurs across an artificial semipermeable membrane within a machine. The decision of whether or not to begin renal replacement therapy such as dialysis occurs on a case-by-case basis and does not depend on any specific urea nitrogen or creatinine level. It is typically instated once other treatments have been unsuccessful in alleviating symptoms, such as protein restriction and antihypertensive medications. If symptoms such as anorexia, nausea, encephalitis, pericarditis, or uremia continue even with treatment, the patient should be prepared for dialysis.

For critically ill patients who are unable to tolerate HD or PD but require RRT, a variety of slower, gentler RRTs are available. These include continuous renal replacement therapy, slow continuous ultrafiltration, and a variety of other therapies all provided by dialysis-like machines connected to large-bore venous access cannulas designed to tolerate therapeutic flow rates. These access cannulas can also be used for HD and can be either temporary or tunneled (implanted) dual-lumen catheters. Patients receiving RRT need to be disconnected from their machine and have their catheters flushed to maintain patency during transport. Portable RRT machines able to continue therapy during patient transport are currently not available.

At times the CCTP may encounter dialysis patients who require IV access or even discontinuation of ongoing dialysis as a result of complications during transport. Patients with CRF who are on dialysis typically have poor peripheral vasculature, and obtaining access may be extremely difficult. It is important to ensure that patent venous access is available prior to initiating transport. A fistula, shunt, or arteriovenous graft should never be routinely used for vascular access. An extremity with a fistula should not be used to obtain a blood pressure reading, draw blood, obtain peripheral IV access, or obtain fingerstick blood glucose specimens. If other forms of venous access are lost during transport and a patient's condition deteriorates into extremis (a grave condition) or the patient experiences

cardiopulmonary arrest, the CCTP should consider using a fistula only as a last resort. The likelihood of infection or damage to the fistula is so significant that intraosseous or central venous access (such as external jugular access) should always be attempted before resorting to the use of a fistula.

Complications often arise during dialysis as well; some complications can be treated during dialysis, whereas others may become so severe that dialysis must be discontinued. The most common complication is hypotension, which can usually be treated with small (100- to 250-mL) isotonic saline boluses. Muscle cramping is another frequent complication and is likely associated with rapid volume removal from the patient. Cramps too can be treated with small saline boluses. Anaphylactic reactions to the dialysis machinery are uncommon now, but if a reaction does occur, the dialysis machinery should be immediately removed and the patient treated for anaphylaxis. Severe episodes of hypotension may also necessitate that dialysis be stopped during treatment. If an emergency requires that the dialysis machinery be removed, it should be performed by a provider trained and experienced in operating the equipment in use. If a provider familiar with the equipment is not available, disconnection should be done following the manufacturer's instructions. All medical device manufacturers maintain clinicians on call 24 hours a day to assist in troubleshooting problems. The telephone contact numbers are often prominently displayed on the critical care machinery.

Maintenance doses of many drugs for patients on dialysis may need to be reduced, although the loading doses of drugs that would be given prehospitally do not need to be changed. Certain medications, such as meperidine, and NSAIDs should be avoided though, as should oral antidiabetic agents. The list of medications that need to be reduced in dosage for patients on dialysis is extensive (refer to a publication on the specific topic for a complete list).

Kidney transplantation is the only definitive cure for CRF and has demonstrated increasing success during the past 50 years since its initiation. The 1-year survival rate has been reported to be as high as 95%. Kidney transplantation is the most common transplantation surgery in the United States, accounting for more than 50% of all organ transplantations performed in this country. Unfortunately, the supply of kidneys is lower than the demand for these organs, and many patients remain restricted to dialysis-related therapeutic options.

Urinary Tract Infections

Bacterial flora that live symbiotically in the GI system can cause considerable damage when they are introduced into the urinary system. A **urinary tract infection (UTI)** typically begins in the urethra, because this location is the most proximal to the external environment. The incidence of UTIs in females is higher than in males owing to anatomic differences between the two sexes, such as the shorter urethra in females. More than 20% of females will experience a UTI at some point in their lives. Patients with impaired urination from an obstruction or nervous system disruption are predisposed to UTIs, because urine flow normally cleanses the tracts of pathogens. Patients with bladder catheters are also at a high risk for infection.

Lower UTIs include infections of the prostate, urethra, and bladder, with the latter two infections known as urethritis and cystitis, respectively. Lower UTIs, such as **pyelonephritis**, are more common and less severe than upper UTIs in the kidney. As many as 90% of infections are caused by *Escherichia coli* bacteria, which are normal inhabitants of the GI tract.

Inflammation secondary to the infection causes a burning pain exacerbated by urination, at times accompanied by foul-smelling urine. Pyelonephritis symptoms are more significant and include fever, chills, lower back pain, and nausea with vomiting. Chronic pyelonephritis can develop in patients with underlying renal abnormalities.

The majority of both lower and upper UTIs are treated successfully with antibiotics. On occasion,

surgery may be required to remove an intrarenal or perinephric abscess that forms during the course of pyelonephritis. In more severe cases of pyelonephritis, IV antibiotics may be required, and the CCTP may have to manage the administration during interfacility transports.

Testicular Torsion

Normally, the tunica vaginalis secures the testes inside the scrotum, preventing any excessive movement or rotation. In about 12% of the male population, this attachment is misaligned, allowing some degree of free testicular movement, known as the "bell clapper" deformity. These patients are susceptible to **testicular torsion**, a condition in which one or both of the testes rotate to the point of occluding their blood supply **Figure 16-34**. A rotation of 720°, or two full rotations of the testicle around the axis of the testicular artery and vein, is required to fully tamponade the vessel and cause a resultant buildup of waste products within the testes and scrotal swelling. This condition is extremely painful, and immediate surgical intervention is required to salvage the testis, as necrosis will set in within 12 to 24 hours. The CCTP must be able to recognize the symptoms and initiate rapid transport to an appropriate facility or notify the receiving facility of suspicions upon arrival. Most clinicians prefer that analgesics are not administered prior to diagnosis, although afterwards pain relief should be administered.

Patients will occasionally present with nausea, vomiting, and abdominal pain along with testicular pain. Testicular torsion is most often seen in adolescent males, with the over-whelming majority of cases occurring in males younger than 30 years. Along with developmental abnormality, trauma and exercise are known precursors to testicular torsion.

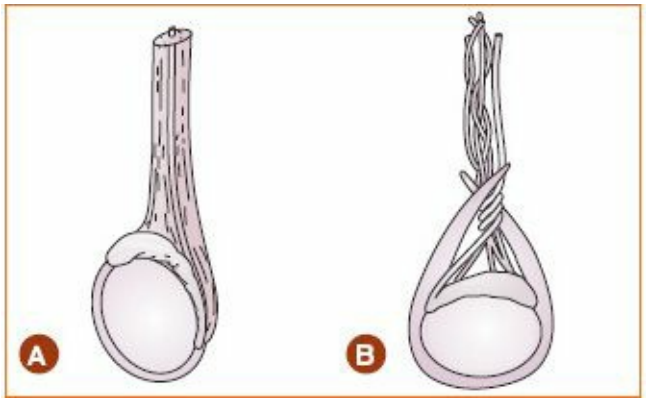

Figure 16-34 **A.** The normal testicle. **B.** Testicular torsion.

The testes are also susceptible to torsion prior to development of the tunica vaginalis. This condition, known as extravaginal torsion, is seen in prenatal males as a result of improper spermatic cord attachment. Typically the testis is unviable if the condition developed in utero, and surgical intervention is not an emergency.

Penile Fracture

During penile erection, the corpora cavernosa and corpus spongiosum are engorged with blood, distending the erectile tissue to the point of elasticity loss. Direct blunt trauma to the penis in this state can result in **penile fracture**. The fracture here is actually a rupture of one or more of the vascular spaces within the penis, mimicking the appearance of a long bone fracture. This event most commonly occurs during sexual intercourse, with a cracking or popping noise being heard at the time of injury, along with the development of moderate to severe pain. The penis will appear swollen and deformed by hematoma formation. Urethral involvement is observed in some cases and should be considered if hematuria exists.

No lab or imaging studies are required for the diagnosis of a penile fracture. Initially, cold

compresses should be placed on the area of injury. Definitive treatment involves reconstructive surgery on the penis. The main treatment goals include restoration of urinary and reproductive functioning. Foley catheter placement is required in cases of urethral injury to allow for proper healing, along with prophylactic antibiotics. In general, penile fracture is a rare condition, but it has a good prognosis following prompt recognition and surgical treatment.

Priapism

Priapism is a prolonged erection of the penis that can be painful and damaging to tissues in the immediate area. Spinal cord transection is commonly cited as the frequent precursor to priapism, but nontraumatic causes exist as well.

The two major classifications of priapism are arterial high-flow and veno-occlusive priapism. Arterial high-flow priapism typically occurs secondary to penile injury, with vessel spasms or clot formation inhibiting blood return. Veno-occlusive priapism, the more painful of the two conditions, is most often seen in patients with sickle cell anemia and certain medication use. Drugs that place men at risk include a number of prescription pharmaceuticals, including psychotropic medications, calcium-channel blockers, and anticoagulants. Intracavernous erectile dysfunction drugs such as papaverine, phentolamine, and prostaglandin E1 are among the most common causes of priapism. There are very few reported cases of priapism from the more popular selective cyclic guanosine ß, 5′-monophosphate inhibitors such as sildenafil citrate (Viagra).

Initial treatment is application of a cold pack followed by administration of either a smooth-muscle relaxant or vasoconstrictive medication. Priapism is infrequently encountered and usually correctible, with the major complication being impotence.

Maintenance Tubes

A variety of tubes may be encountered or placed by the CCPT while caring for a patient with a gastrointestinal or genitourinary condition. The following sections focus on two major types: feeding tubes and drainage tubes **Table 16-15**.

Feeding Tubes

Proper nutrition is necessary for life and must be provided parentally to patients who are extensively incapacitated by either disability or sedation. Enteral nutrition, commonly called tube feeding, can be administered in steps, depending on its expected duration.

Enteral Nutrition

Perhaps the largest obstacle to food intake in the incapacitated patient is the inability to safely and effectively swallow. This can be circumvented by placement of a simple NG tube, which can be used to administer food into the stomach or to remove food. These minimally invasive tubes are often inserted through the nasal orifice with the assistance of the patient in preparation for a short-term event during which temporary enteral feeding is required.

For longer-term situations, a gastrostomy tube (G tube) can be inserted. These tubes are also referred to as **percutaneous endoscopic gastrostomy (PEG) tubes** because of their insertion technique. PEG tubes are placed through a small surgically created opening from the stomach, through the peritoneum, to the abdominal wall **Figure 16-35A**.

Alternatively, a **jejunostomy tube (J tube)** can be introduced directly into the jejunum through a comparable technique, known as a percutaneous endoscopic jejunostomy **Figure 16-35B**. J tubes possess

an advantage over their PEG counterparts in that aspiration risk is largely decreased because food intake occurs distal to the pyloric sphincter. Unfortunately, J tubes are also associated with a higher insertion complication rate owing to the less stable small intestinal wall compared to the thicker stomach lining, which serves to anchor a PEG tube more securely.

TABLE 16-15 GI/GU Maintenance Tubes

Type of Tube	Examples
Feeding tube	NG tube Percutaneous endoscopic gastrostomy tube J tube Percutaneous endoscopic gastrostomy-J tube Total parenteral nutrition
Drainage tube	Straight catheter Foley catheter Suprapubic tube External condom catheter Colostomy Ileostomy Ileoanal anastomosis Kock pouch Ileal conduit urostomy Colon conduit urostomy Jackson-Pratt drain Hemovac drain Davol drain T tube

Abbreviations: GI, gastrointestinal; GU, genitourinary; NG, nasogastric.

A newer procedure known as a PEG-J tube lessens this risk while providing the benefit of decreased aspiration. During this procedure, a PEG tube is placed through the abdominal wall but is then threaded through the duodenum and into the jejunum.

Liquid nutritional products can be administered to the patient through any of these tubes by either a rate-controlled pump or syringe boluses. Proper functioning is confirmed by a lack of pain or resistance while pushing the syringe upon food administration.

Aspiration is the most common complication from a feeding tube that could develop into a life-threatening situation; this problem is easily averted by sitting the patient upright during feeding or vomiting. Bleeding may occur at the insertion site if the tube is pulled on or traumatically removed. Significant hemorrhage from this situation is unlikely, and bleeding is typically self-limited. A third complication involves infection around the insertion site, which may be observed as a reddening or swelling in the immediate vicinity.

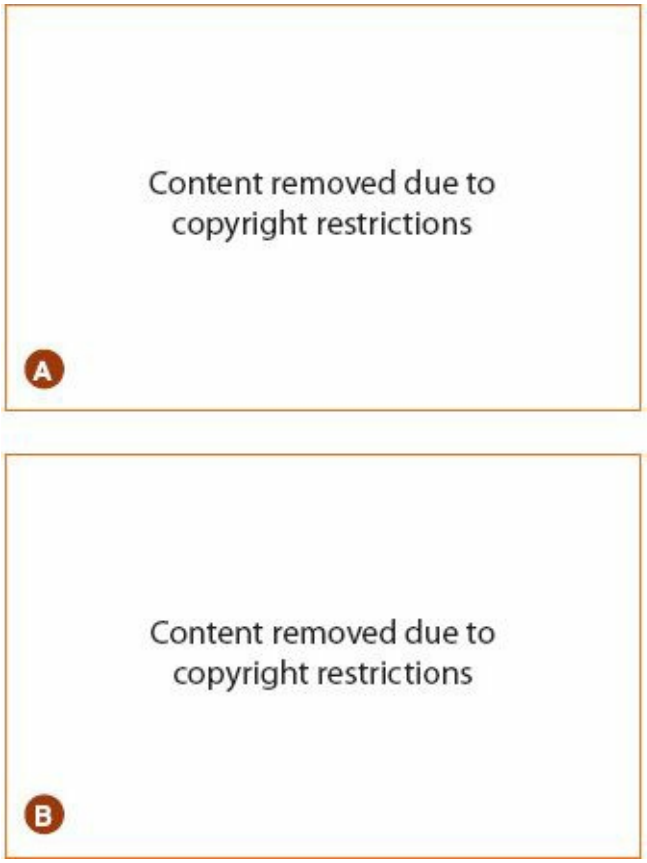

Figure 16-35 **A.** Bard® percutaneous endoscopic gastronomy (PEG) tube. **B.** Bard® jejunostomy (J) tube. © C. R. Bard, Inc.

If the feeding tube becomes clogged, a 30- to 50-mL sterile warm water bolus can be used to clear the blockage. If the tube is removed unexpectedly, the site should be covered with an occlusive dressing until it can be properly replaced. Unmanageable blockage or a removal of the PEG or J tube is not of major concern in the short-term care of the patient, as a brief lapse in feeding can be accounted for later.

Total Parenteral Nutrition

Total parenteral nutrition is an alternative feeding method used when the GI tract is not functioning adequately. During TPN, all required nutrients are administered intravenously to the patient. Typically a central vein is used for administration to prevent osmotic fluid shifts, although some preparations permit peripheral vein usage. Medications are often added to the TPN solution during its creation, but they should not be introduced once that process is complete owing to the potential for contamination. TPN should be used in moderation only when enteral feeding is not an option as a result of the significant GI atrophy that occurs during dormancy.

Patients receiving TPN are at high risk for an air embolus and thrombosis. An air embolus is most likely to occur during line changing or an unexpected disruption. This situation has a high mortality and must be aggressively treated with high-flow oxygen, occlusive dressing placement, and movement of the patient into a left-sided Trendelenburg position. Thrombosis is treated by removing the catheter, followed by anticoagulation and thrombolytic therapy. Continuous monitoring for metabolic abnormalities must be done on the patient receiving TPN, as well as monitoring for electrolyte imbalances that can easily arise.

Management

When transporting a patient with a feeding tube, contact medical direction if the patient has vomited or has diarrhea or a distended abdomen.

Transport Management

Patients With Feeding Tubes

- Examine insertion site for signs of infection, such as redness or swelling.
- Assess for pain at insertion site.
- Assess for any leakage or blockage of tube.
- Keep the patient in a position of comfort.
- Provide supportive care as required.

Drainage Tubes

The digestive system has equally important input and output functions, and the tubes placed in the critically ill patient must achieve both of these purposes. Just as various feeding tubes exist to introduce food to the body that cannot independently consume it, drainage tubes exist to remove waste when it is being retained. Waste products of human metabolism are manifested in urine and feces, which are parenterally removed through Foley catheters and ostomies, respectively.

Urinary Catheters

Types of Urinary Catheters

Different methods of urine collection exist, each with its own advantages and disadvantages.

Straight catheters, often called intermittent catheters, are designed for temporary use and are frequently self-inserted by the patient. They allow for the patient to drain residual bladder contents that could lead to infection. These catheters are associated with less inflammation than catheters intended for longer-term use, but the drainage process must be repeated three or more times per day.

Indwelling catheters, also known as Foley catheters, are used as a more permanent solution to urine retention or incontinence. These pliable rubber catheters are introduced into the bladder via the urethra. A balloon is inflated with 5 mL of saline inside the bladder to prevent inadvertent removal of the catheter. Foley catheters provide complete management of urine for bedridden or incapacitated patients, with minimal upkeep.

When surgery or trauma makes urethral catheter introduction unfavorable, a suprapubic tube may be inserted. This urine collection tube is placed directly into the bladder through the abdominal wall by way of a surgically created stoma.

Male patients have the option of using external condom catheters as well. These catheters are less prone to complications and are a good alternative to diapers.

Each of the four types of urine-collection catheters functions in a similar way; that is, each drains into a bag that allows for clean collection, observation, and measurement of urine output. Two types of collection bags are frequently used—a leg bag that straps to the leg underneath clothes, allowing for greater mobility with a discrete presence, and a down drain bag that hangs on the side of the patient's bed. Larger down drain bags are more commonly used in hospitals and nursing homes. The drains function by gravity, so it is important to ensure they are hung below the patient.

Complications of Urinary Catheters

Common complications of urine collection catheters include clogging, infection, pain, leakage, and dislodgement. Clogging can typically be cleared with a small fluid bolus, although it may indicate dislodgement. Dislodgement is the largest concern during transport. Dislodgement and leakage are corrected by replacing the catheter into the bladder; they are often a result of selecting the improper size

of catheter. Signs of infection—such as pain, irritation, and reddening around the urethral orifice of the insertion site—should be treated promptly with antibiotics.

Transport Management

Patients With Urinary Catheters

- If clogging occurs, clear the catheter with a small fluid bolus.
- If dislodgement or leakage occurs, replace the catheter. A different size may be needed.
- Treat signs of infection with antibiotics.

Management

It would be unlikely for urinary catheter placement to occur during transport, but the procedure is covered here in the event that the CCTP performs it prior to transport. When preparing to place a urinary catheter, gather the following equipment:

- Disposable sterile bladder catheter kit
- Water-soluble lubricant
- Drapes
- Cleansing solution
- Sterile gloves
- Prefilled syringe containing sterile water
- Correct size urinary catheter
- Clamp
- Connecting tubing
- Collecting bag

Indications for urinary catheter placement include drainage of the urinary bladder to precisely measure urine output, incontinence, and acting as an adjunct to diuretic therapy. Contraindications include blood at the meatus (opening) of a trauma patient and a history of urethral stricture (narrowing). When transporting a patient with a urinary catheter by air, air medical considerations include filling the balloon with water. The amount should be equivalent to 10 mL of air.

The steps to place a female urinary catheter are shown in **Skill Drill 16-3** as follows:

1. Prepare equipment.
2. Use BSI precautions.
3. Place the patient in the supine position, with hips flexed and abducted.
4. Using a sterile technique, open the kit and prepare the equipment.
5. Test the balloon on the indwelling catheter by injecting it with sterile water or saline.
6. Position the drapes.
7. Lubricate the catheter.
8. Cleanse the sides of the labia and meatus with a chlorhexidine 2% solution.

9. Insert the catheter into the meatus gently until urine flow begins **Step 1**.
10. Fill the fluid retention balloon until secure **Step 2**.
11. Connect the open end of the catheter to the drainage tube and collection bag **Step 3**.
12. Secure the catheter to the patient's leg with tape.

The steps to place a male urinary catheter are shown in **Skill Drill 16-4** as follows:

1. Prepare the equipment.
2. Use BSI precautions.
3. Place the patient in the supine position.
4. Using a sterile technique, open the kit and prepare the equipment.
5. Position the drapes.
6. Lubricate the catheter.
7. Cleanse the penis from head to base.
8. Insert the catheter gently until urine flow begins. Once urine is observed, gently advance the catheter an additional 2″ to 3″ **Step 1**.
9. Fill the fluid retention balloon until secure **Step 2**.
10. Connect the open end of the catheter to the drainage tube and collection bag **Step 3**.
11. Secure the catheter to the patient's leg with tape.

Skill Drill 16-3

Placing a Female Urinary Catheter

1 Insert the catheter into the meatus gently until urine flow begins.

2 Fill the fluid retention balloon until secure.

3 Connect the open end of the catheter to the drainage tube and collection bag.

Skill Drill 16-4

Placing a Male Urinary Catheter

1 Insert the catheter gently until urine flow begins. Once urine is observed, gently advance the catheter an additional 2″ to 3″.

2 Fill the fluid retention balloon until secure.

3 Connect the open end of the catheter to the drainage tube and collection bag.

Ostomies

Types of Ostomies

An **ostomy** is a surgically created opening of the GI tract through the abdomen that allows for waste removal. The ostomy may originate in the ileum of the small intestine (ileostomy) or anywhere in the large intestine (colostomy), depending on which segments of the GI tract must be bypassed. Urostomies may be created as well to drain urine directly from the urinary tract when a distal portion must be avoided as a result of disease or trauma. Indications for an ostomy include bowel injury or disease, bladder injury or disease, and congenital anomalies, including cancer.

Colostomies **Figure 16-36** and ileostomies drain intestinal contents out of the GI tract and into a collection bag. The drainage from a colonoscopy is more solid than that from an ileostomy because the material has progressed farther through the digestive process. The drainage is collected in a bag attached to the opening and strapped to the patient's body. Sometimes a section of small intestine is surgically modified to create an internal collection site called a Kock pouch. In an ileoanal anastomosis, also known as a J pouch, the anus is preserved, allowing it to function in fecal collection. These methods are beneficial to the patient because they allow less visible collection methods and offer more convenient waste disposal management.

Urostomies divert urine away from the bladder by creating a passageway from the ureter to an abdominal stoma through a piece of ileum or large intestine that is surgically separated from the GI tract. When the ileum is used, it is called an ileal conduit; when the large intestine is used, it is called a colon conduit. An external collection pouch is attached to the stoma and secured to the patient's body.

Figure 16-36 A colostomy.

Management

Complications of ostomies include the following possibilities:

- Obstruction
- Constipation (with colostomies)
- Diarrhea
- Dehydration
- Flatulence
- Leakage
- Tissue necrosis
- Detachment
- Prolapse
- Infection

The patient with an ostomy should be monitored for signs of tissue necrosis and infection, which, if detected, may warrant treatments ranging from antibiotic therapy to surgical intervention. Normal assessment findings for a patient with an ostomy include a pain-free insertion site free of redness or swelling. Detachment or prolapse of intestinal tissue from the stoma may require bleeding control and occlusive dressings as well as surgical reconstruction. When assessing the patient with an ostomy, expose the insertion site to examine for redness, swelling, or leakage. If any of these are found, notify the receiving facility upon arrival. Always ask the patient if the ostomy is functioning normally, without either leakage or obstruction.

The next paragraphs discuss two skills: emptying and replacing an ostomy pouch. An ileostomy pouch needs to be emptied 4 to 6 times a day. A colostomy pouch needs to be emptied 1 or more times per day. Laxatives should not be used by patients with ileostomies, and adequate daily fluid replacement (such as 6 to 8 glasses of water) is a necessity. In addition, the patient should not use soaps that contain baby oil, cold cream, or perfumes.

When preparing to empty or replace an ostomy, gather the following equipment:

- Stoma measuring guide or pattern
- Scissors
- New pouch
- Soft wash cloth
- Soap and water
- Razor for shaving hair on abdomen
- Biohazard bag for soiled pouch

Skill Drill 16-5 shows the steps for emptying an ostomy pouch. The pouch should be emptied when it is one third to half full.

1. Remove the clamp that keeps the pouch closed **Step 1**.
2. If the patient is supine, lift the pouch and position the opening over a waste collection container **Step 2**. If possible, have the patient lie on his or her side with the pouch opening positioned over a waste collection container.

3. Slide your fingers down the outside of the pouch to squeeze the contents out of the pouch.
4. Clean the inside of the pouch opening with a piece of toilet paper.
5. Then rinse out the pouch with room-temperature water using a rubber ear (bulb) syringe.
6. Put the clamp back onto the pouch to close it **Step 3**.

Although ostomy pouches typically only need to be changed every few days, the CCTP may be required to change one under certain circumstances. If there is a leak or rupture of the bag during transport, the pouch must be removed and replaced if the equipment is available. Less emergent reasons to change a pouch include inflammation, pain, or irritation around the insertion site. In such instances, changing the pouch can typically be delayed until arrival at the receiving facility.

Skill Drill 16-5

Emptying an Ostomy Pouch

1 Remove the clamp that keeps the pouch closed.

2 If patient is supine, lift the pouch and position the opening over a waste collection container.

3 Slide your fingers down the outside of the pouch to squeeze the contents out of the pouch. Clean the inside of the pouch opening with a piece of toilet paper. Then rinse out the pouch with room-temperature water using a rubber ear (bulb) syringe. Put the clamp back onto the pouch to close it.

Skill Drill 16-6 shows the steps for replacing an ostomy pouch.

1. Use BSI precautions.
2. Using the measuring guide or pattern, trace the correct opening onto the skin barrier of the new pouch, then cut out the opening you traced **Step 1**.
3. Take off the paper backing that covers the adhesive on the skin barrier of the new pouch **Step 2**.
4. Lay the pouch near you with the adhesive side up.
5. Empty the pouch the patient is wearing **Step 3** (see Skill Drill 16-5 for step-by-step instructions).
6. Remove the pouch by pushing down on the abdomen with the fingers of one hand and peel off the pouch with the other hand **Step 4**.
7. Remove the clamp from the old pouch.
8. Dispose of the old pouch by placing it into a biohazard bag **Step 5**.
9. Wash thoroughly around the stoma with mild soap and warm water **Step 6**.
10. Rinse and dry with a soft cloth. A small amount of bleeding may be normal.
11. Center the new pouch opening over the stoma **Step 7**.
12. Press the skin barrier wafer onto the abdomen, removing all wrinkles or creases in the wafer **Step 8**.
13. Put the clamp from the old pouch onto the opening of the new pouch **Step 9**.

Specific Drainage Tubes

After major abdominal surgery, a number of drainage tubes are placed to both assist in and evaluate the recovery process. **Jackson-Pratt drains** **Figure 16-37** are inserted to remove postoperative buildups of fluid and blood in the abdominal cavity. Prevention of fluid accumulation greatly decreases the risk of infection. The drain is controlled by the patient, who squeezes a bulb to induce suction. A flexible tube connected to the bulb travels through the surgical incision and into the wound site.

Similar surgical drainage tubes include the Hemovac and Davol drains. Both of these draining devices operate similarly to the Jackson-Pratt tube, with the only difference being bulb design.

During liver transplant surgery, a **T tube** is placed to monitor bile drainage from the gallbladder. After the drainage bag has been removed, the tube may remain in place to facilitate examination of the biliary tract through a T-tube cholangiogram test.

Figure 16-37 A Jackson-Pratt drain (in background) and a Hemovac drain (with blue connectors).

These drainage tubes can frequently be obstructed by blood clots, which can be usually cleared by digitally manipulating the tube. Dislodgement can slow the healing process and greatly increase the likelihood of infection, and the drain may need to be replaced through surgical means. Bleeding may occur from the wound site after dislodgement and should be controlled. The wound site and sutures should be monitored for any signs of infection or improper healing.

In-flight Considerations for Maintenance Tubes

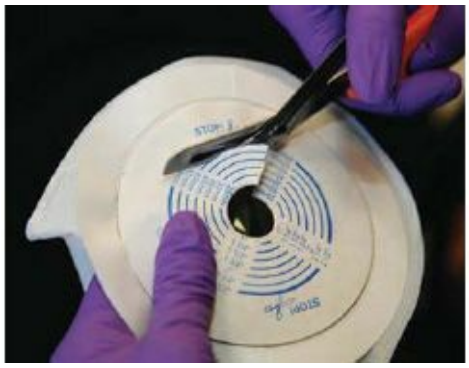
In-flight complications need to be considered for the numerous drainage systems that include closed bags containing air. A decrease in air pressure accompanies increases in altitude. Gas volume increases proportionally to the decrease in pressure, which could lead to distention of drainage devices. Although fixed-wing aircraft typically incorporate pressure-controlling mechanisms, preparations should always be made in the event of equipment failure. Controlling air pressure on rotor-wing aircraft may be more difficult because altitudes may change rapidly and often.

Excess air should be vented from any drainage bag such as a colostomy or urostomy prior to flight in anticipation of changes in air pressure. Further venting may be required during transport, and the CCTP should be sure that the specific device in use can accommodate this manipulation. Similar preparations must be made for Jackson-Pratt and other surgical drainage devices. Be sure to unclamp any feeding or drainage catheters prior to departure, and ensure that they remain unclamped for the duration of travel.

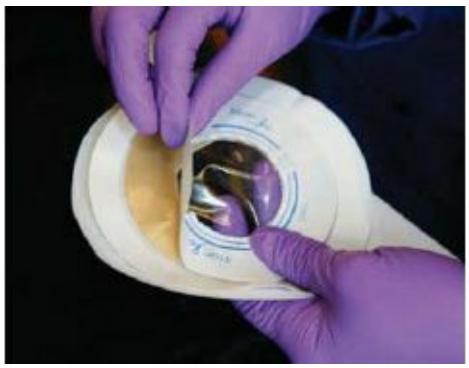
Air transport should be postponed or avoided for any patient with a bowel obstruction if at all possible. The changes in gas pressure will distend the obstructed bowel, leading to significant pain and possible perforation. If transport is unavoidable, measures should be taken to provide for air escape proximal to the obstruction.

Skill Drill 16-6

Replacing an Ostomy Pouch



1 Use BSI precautions. Using the measuring guide or pattern, trace the correct opening onto the skin barrier of the new pouch, then cut out the opening you traced.



2 Take off the paper backing that covers the adhesive on the skin barrier of the new pouch.

3 Empty the pouch the patient is wearing.

4 Remove the pouch by pushing down on the abdomen with the fingers of one hand and peel off the pouch with the other hand.

5 Remove the clamp from the old pouch. Dispose of the old pouch by placing it into a biohazard bag.

6 Wash thoroughly around the stoma with mild soap and warm water. Rinse and dry with a soft cloth.

7 Center the new pouch opening over the stoma.

8 Press the skin barrier wafer onto the abdomen, removing all wrinkles or creases in the wafer.

9 Put the clamp from the old pouch onto the opening of the new pouch.

Metabolic Regulation of Acid-Base Status

Human bodies demonstrate the amazing ability to adapt and function in extreme environmental conditions. From the peaks of mountains, to great depths in the oceans, in hot, arid deserts, remote arctic locations, and the weightless expanse of space, human activities continue. Despite this incredible ability to adapt to outside environmental changes, human bodies require a carefully controlled internal environment for cells to function, organs to perform, and life to continue.

Significant alterations of oxygen and carbon dioxide levels, electrolyte concentration, temperature, glucose levels, and acid-base status will impair cell, tissue, and organ function, eventually leading to death. CCTPs must manage any of these alterations resulting from illness, injury, or extrinsic factors to save lives and improve chances for patient recovery.

Acid-base status is tightly controlled by numerous organs, receptors, and **buffer** systems. Dysfunction of any of this vast array of cells, tissues, organs, and body systems will disrupt this carefully maintained balance and further compromise cell, tissue, and organ function throughout the body. Although the human body can tolerate large quantities of exogenous acids and bases, widespread damage occurs when the body's capacity to sequester, neutralize, and excrete these substances is exceeded. Metabolic alterations of acid-base status are common among a variety of patient conditions discussed elsewhere in this text, such as trauma, toxicology, respiratory, cardiac, endocrine, neurologic, and environmental emergencies, to name a few. Detailed discussion of respiratory acidosis/respiratory alkalosis can be found in Chapter 6.

Acid-Base Physiology

Hydrogen ions (H^+) are single protons released from a hydrogen atom that become an acid when placed in solution. A base (also basic or alkaline) substance has the ability to accept a free H^+. The relationship of acids to bases within the body is the pH value that represents the concentration of free H^+ present. Because additional basic substances are present, they become bound with free H^+, decreasing the amount of free H^+. The normal extracellular fluid pH ranges from 7.36 to 7.44 or 7.3 to 7.5, depending on the reference source. The pH value is inversely related to the amount of free H^+ present. As the free H^+ concentration increases, the pH value decreases (acidosis). As the free H^+ concentration decreases, the pH value increases (alkalosis). Cell protein activity becomes impaired when the pH falls out of the normal range. Cell death begins to occur when the pH falls below 6.8 or increases above 7.8.

Acids and bases are both absorbed into the body from dietary sources. Additionally, H^+ are produced during various metabolic processes, normally creating 50 to 100 mEq each day. Altered

cellular metabolism, changes in excretion patterns, or exposure to various exogenous substances can prompt wide variations of extracellular fluid pH. Intracellular function is altered when excess H^+ from extracellular fluid enter the cells through a **concentration gradient**. This concentration gradient is the dominant mode of cellular exchange with extracellular fluids.

Intrinsic Regulation of Acid/Base

Three principle mechanisms are used to maintain a physiologic acid-base status within the body. Chemical buffers sequester excess H^+ to maintain a normal pH until they are released to offset an increasing pH when excessive bases are present. The respiratory system controls extracellular PCO_2 concentration, which affects carbonic acid (H_2CO_3) and ultimately H^+ concentration. Finally, the kidneys can either excrete acidic or alkalinic (basic) urine to balance whole-body H^+ concentrations.

Chemical Buffer Systems

The human body uses several buffer systems to mitigate the effects of vast fluctuations or loads with acids and bases. Any substance that can alternately bind or release H^+ depending on outside conditions is a buffer. Buffer systems begin activity immediately.

The **bicarbonate–carbonic acid buffer system** is the principle extracellular buffer system. This system operates primarily in the lungs and kidneys, where carbonic anhydrase is present to stimulate the chemical reaction. Carbon dioxide and water (H_2O) are reversibly converted into H_2CO_3 (carbonic acid), which in turn is reversibly converted into H^+ and HCO_3^- (bicarbonate). The reaction reverses itself when large quantities of H^+ are present, ultimately turning excess H^+ into H_2O and carbon dioxide (CO_2), which can be easily excreted.

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O$$

The bicarbonate–carbonic acid buffer system is linked to the lungs and kidneys because these two organs can alter the concentrations of CO_2 and HCO_3^-, respectively, thus affecting the concentration of the remaining components and the direction of these reactions **Figure 16-38**. This system allows the body to mitigate the effects of sudden acid or alkali loads without drastic alterations in extracellular (and ultimately intracellular) pH.

The **phosphate buffer system** operates similar to the bicarbonate–carbonic acid buffer system in that it allows only small pH changes following large variations in the presence of free H^+. This system functions primarily in the renal tubules and intracellular fluids to convert strong acids or bases into weak acids or weak bases, allowing only a minimal effect on overall pH. Phosphate buffers work best in areas of the body with a normally lower pH, such as the renal tubules.

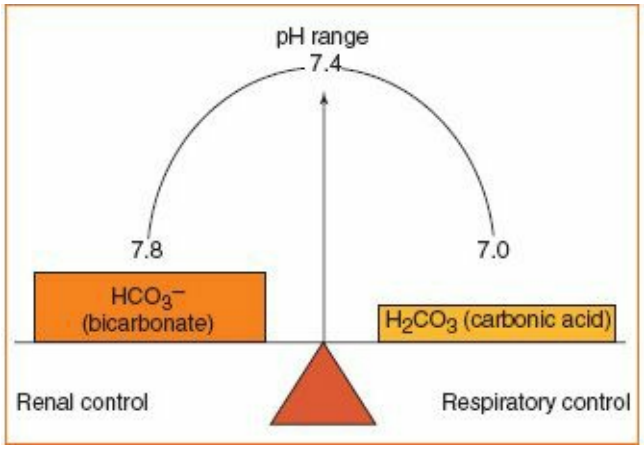


Figure 16-38 The balance of bicarbonate and carbonic acid shifts if either the renal or respiratory system fails, leading to an imbalance.

Hemoglobin, certain bone tissues, and other proteins also act as chemical buffers. Hemoglobin molecules, especially deoxygenated, can absorb a hydrogen ion, and ultimately buffer six times more than other plasma proteins. Venous blood exhibits a slightly lower pH than arterial blood. Other protein buffers take several hours, but provide the majority of total-body buffering capability. Bone buffers also contribute by absorbing and releasing excess H^+ when needed.

Respiratory Influence on pH

Carbon dioxide is a major determinant of acid-base status. Carbon dioxide is produced during normal metabolism and must be continuously excreted. The concentration of CO_2 is directly related to H^+ concentration and inversely related to extracellular fluid pH. In acidic states, alveolar ventilation is automatically increased, resulting in decreased H^+ concentrations (and increased pH) in approximately 3 to 12 minutes. Respiratory adjustment will not completely resolve a primarily metabolic alteration in pH. Respiratory compensation will bridge the delay until renal compensatory mechanisms have a chance to commence, within several hours or up to 7 to 10 days. Any increase in alveolar ventilation above baseline will conversely raise the pH and decrease the available concentration of free H^+. Impaired respiration/ventilation adversely affects acid-base status. A disruption of ventilation for even several minutes has the potential to cause catastrophic acidosis, directly from the retention of CO_2. As mentioned previously, respiratory acidosis and respiratory alkalosis are discussed in depth in Chapter 6.

Renal Influence on pH

The kidneys provide the body's last major line of defense against the catastrophic effects of large quantities of acids or bases. Kidneys excrete either acidic or basic urine depending on the pH of the body. In severe states, kidneys can excrete 500 mEq of H^+ per day, taking 7 to 10 days to reach this capability.

To compensate for a metabolic or respiratory alkalosis, the kidneys allow HCO_3^- to be excreted into the urine. This action decreases the available extracellular fluid HCO_3^-, increases the available free H^+ concentration, and lowers the pH.

In acidic states, the kidneys have three primary mechanisms. Kidneys directly excrete H^+ into the urine when excess H^+ ions are present. Kidneys can reabsorb previously filtered HCO_3^- and return it into circulation, which binds with excess H^+ and corrects all or part of the acidosis. Additionally, kidneys produce additional HCO_3^- to offset excess H^+.

TABLE 16-16 Normal Arterial Blood Gas and Venous Blood Gas Values

Value	Arterial Blood Gas	Venous Blood Gas
pH	7.35–7.45	7.32–7.43
P_{CO_2}	35–45 mm Hg	38–50 mm Hg
P_{O_2}	80–100 mm Hg (adults) 60-70 mm Hg (newborns)	40 mm Hg
HCO_3 (bicarbonate)	21–28 mmol/L (or mEq/L)	23–30 mmol/L

Comp; 2001.

Laboratory Analysis

Blood Gas Analysis

The concentration of free H^+ in extracellular fluid (pH) as well as other key variables can be obtained from an arterial blood gas (ABG) or venous blood gas (VBG) sample. Results also include P_{CO_2}, P_{O_2}, and HCO_3^- measurements. Additional values such as base excess, oxygen saturation, carboxyhemoglobin, lactate, and various electrolytes or blood count values are often included in these panel results. These tests are available immediately on many transport vehicles and can be obtained in most, if not all, hospitals. Many outlying clinics, treatment centers, and offices have advanced **point-of-care (POC) testing** capabilities. Normal values are listed in **Table 16-16**.

Interpretation of Blood Gas Sample Results

Arterial blood gas sample results provide the CCTP with valuable information regarding the existence or type of acidosis or alkalosis. First consider the overall pH. A pH below 7.35 is considered an acidosis, regardless of any compensation (discussed later). A pH above 7.45 is considered an alkalosis, again regardless of any compensation.

Next consider the primary source. An acidosis or alkalosis is primary metabolic, primary respiratory, or mixed (combined). Once the primary source of acidosis or alkalosis is determined, the presence of any compensation should also be evaluated. Overcompensation of a primary condition will not occur. Any evidence of overcompensation indicates another separate primary pathology.

Metabolic acidosis occurs when a patient has a decreased pH (< 7.35) and a decreased HCO_3^- level (< 23 mmol/L). An individual may attempt to compensate by increasing respiratory rate and/or depth, thus lowering the level of P_{CO_2}. These efforts may normalize the pH, but will never overcompensate **Figure 16-39**.

Respiratory acidosis occurs when a patient has a decreased pH (< 7.35) and an increased P_{CO_2} level (> 45 mm Hg). In this instance, the respiratory effort/exchange is inadequate to remove enough CO_2 to maintain a normal pH. If this condition persists over time, renal compensation will begin to occur, demonstrating an elevated HCO_3^- level (> 29 mmol/L) **Figure 16-40**.

Metabolic alkalosis occurs when a patient has an elevated pH (> 7.45) and an elevated HCO_3^- level (> 29 mmol/L.). The patient's P_{CO_2} level may increase in compensation because the alkalosis inhibits respiratory drive **Figure 16-41**.

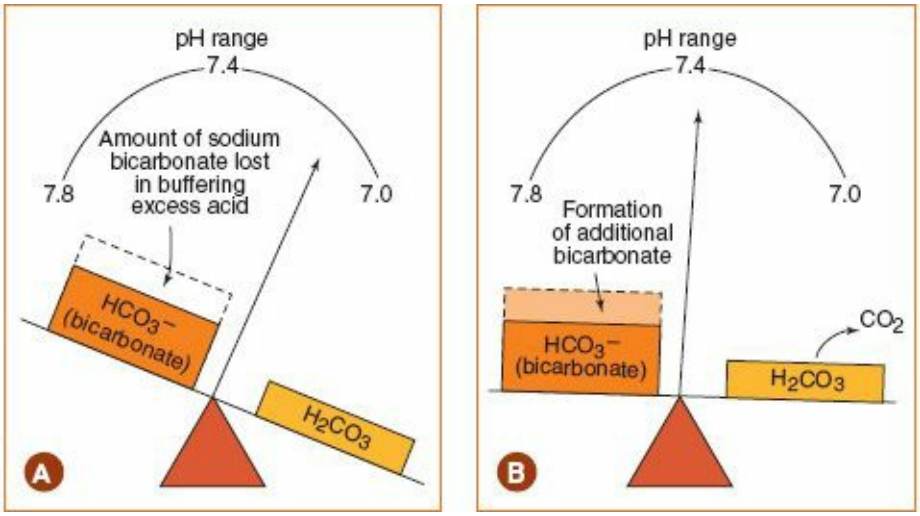

Figure 16-39 **A.** Derangement of acid-base balance in metabolic acidosis. **B.** Compensation by reduction of carbonic acid and formation of additional bicarbonate.

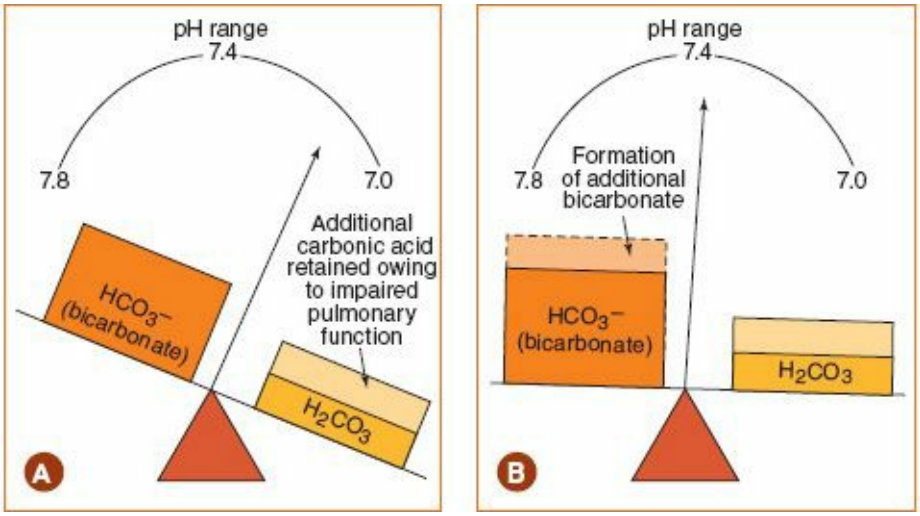

Figure 16-40 **A.** Derangement of acid-base balance in respiratory acidosis. **B.** Compensation by formation of additional bicarbonate.

Respiratory alkalosis occurs when a patient has an increased pH (> 7.45) and a decreased P_{CO_2} level (< 35 mm Hg). This is usually the result of some type of alveolar hyperventilation. Over time, renal compensation mechanisms promote the retention of H^+ and the excretion of HCO_3^- **Figure 16-42**. HCO_3^- values will be lower if this problem persists for several hours to several days or longer.

Mixed acidosis involves a low pH (< 7.35) as well as an elevated P_{CO_2} level (> 45 mm Hg) and low HCO_3^- level (< 23 mmol/L). This occurs when both respiratory and metabolic acidosis are present at the same time in the same patient. Severe trauma, cardiogenic shock, or a drug overdose are common situations in which this may occur.

Mixed alkalosis involves an elevated pH (> 7.45), a low P_{CO_2} level (< 35 mm Hg), and an elevated HCO_3^- level (> 29 mmol/L). This may occur when two seemingly unrelated medical issues manifest at the same time in the same patient. For example, a patient with chronic respiratory alkalosis who experiences a gastrointestinal emergency may have respiratory alkalosis combined with metabolic alkalosis and therefore demonstrate mixed alkalosis.

A patient with one of the primary conditions previously described may present to the CCTP as uncompensated, partially compensated, or well compensated, but not overcompensated unless two pathologic conditions are simultaneously present. Practice is essential for developing comfort in the identification of complex acid-base disorders.

VBG analysis has limitations compared to an ABG determination in certain situations. Both pH and HCO_3^- levels correlate well between venous and arterial blood gas measurements. The Pa_{O_2} level does not correlate well and should not be inferred from the result of a VBG analysis. A VBG analysis can be used as a screening tool for an elevated P_{CO_2} level. The P_{CO_2} values generally correlate well between ABG and VBG analyses, although the relationship becomes less accurate as the patient's perfusion or hemodynamic status deteriorates.

Indirect Measurement of Acid-Base Status

Total blood carbon dioxide, which can be written as either T_{CO_2} or HCO_3^- in clinical practice, provides

an indication of an acid-base abnormality on routine blood work. This test is often included on the basic chemistry panel (Chem-7, SMA-7) and may provide the necessary information to determine a patient's acid-base abnormality. The normal plasma value is 23 to 29 mmol/L.

An elevated TCO_2 value may indicate either a chronic respiratory acidosis with CO_2 retention or a metabolic alkalosis. Low TCO_2 values may indicate either a metabolic acidosis or respiratory alkalosis. In either instance, further evaluation is warranted to determine the cause. This particular test should only be used for screening purposes for the presence of a metabolic acid-base alteration, which can be present as the primary problem or be evidence of compensation for a respiratory alteration. The TCO_2 value provides limited information by itself, but may prompt an attentive clinician to the presence of a significant acid-base disorder. A blood gas with pH measurement remains the definitive test.

Evaluation of Anion Gap

When an acidosis is suspected, its origin can be examined using the anion gap (AG). Acidosis may be present with or without an AG, but this will help exclude or identify possible specific causes of the acidosis. The AG is a calculated value using the sodium (Na), chloride (Cl), and HCO_3^- results. Many laboratory instruments automatically perform this calculation when communicating electrolyte panel results. The formula is:

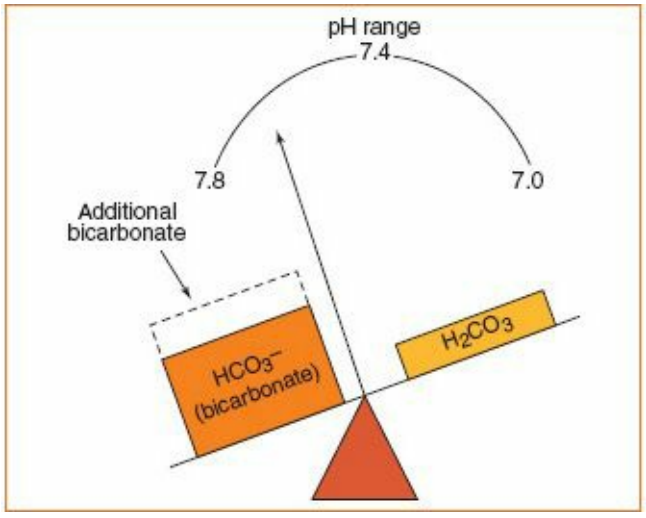

Figure 16-41 Derangement of acid-base balance in metabolic alkalosis. The body's compensatory mechanisms are ineffective.

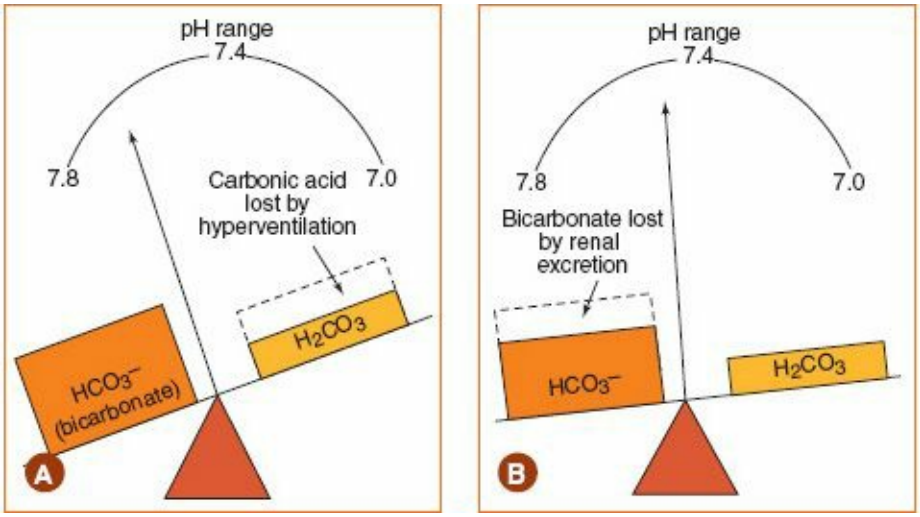

Figure 16-42 **A.** Derangement of acid-base balance in respiratory alkalosis. **B.** Compensation by

excretion of bicarbonate.

$$AG = Na - (Cl + Hco_3^-)$$

The normal AG is 8 to 12 mEq/L. An elevated AG usually represents the presence of lactic acid that is elevated as a result of trauma, shock, seizures, hypoxia, or numerous toxic substances. Toxic substances, including methanol, ethylene glycol, salicylates, and valproic acid, cause an elevated AG without lactic acid. **Alcoholic ketoacidosis** and **diabetic ketoacidosis** also cause an elevated AG acidosis as a result of ketones, without increased lactic acid. Serum lactate levels greater than 5.0 mmol/L indicate **lactic acidosis**.

An acidosis with a normal AG is a **hyperchloremic acidosis**. Relative losses in HCO_3^- are corrected mathematically with an increase in chloride concentrations. Hyperchloremic acidosis occurs from excessive chloride loading, pathologic retention of H^+, or unusual HCO_3^- losses.

Metabolic Alkalosis

When metabolic conditions create an excess of HCO_3^- accompanied by a pH of greater than 7.45 on an ABG sample, the disorder is termed metabolic alkalosis. This disorder is further described as "chloride resistant" or "chloride responsive," depending on the urine chloride concentration. Metabolic alkalosis results from either H^+ losses or gains of HCO_3^-, relative or actual. Relative gains of HCO_3^- occur when there is a disproportional loss of chloride, usually accompanying a sodium loss that alters electroneutrality leading to renal HCO_3^- retention. This disorder is the most common acid-base disturbance in hospitalized adults.

Vomiting or gastric suction is a common cause for metabolic alkalosis. The use of certain diuretics can cause metabolic alkalosis when they prompt the excretion of excess chloride ions in the urine. Various endocrine conditions, including primary aldosteronism, Bartter syndrome, Liddle syndrome, primary reninism, and hyperglucocorticoidism, are implicated as well.

Prehospital providers risk causing metabolic alkalosis when a patient with a previously compensated respiratory acidosis from hypercapnea or chronic obstructive pulmonary disease with an elevated P_{CO_2} level is placed on a ventilator and aggressively ventilated. Prior to ventilation, the chronically elevated P_{CO_2} level is compensated for with enhanced HCO_3^- retention by the kidneys to maintain a neutral pH. Following aggressive ventilation, the CO_2 level normalizes, creating a relative HCO_3^- excess, allowing a metabolic alkalosis to predominate.

The excessive administration of sodium HCO_3^- may cause an occasional, transient metabolic alkalosis. The extent of the injury is usually limited in most situations. The kidneys quickly begin excreting the excess HCO_3^-, resolving the misadventure. This mechanism may be impaired in patients with renal disease, causing more serious complications, including cell dysfunction or death.

Clinical Features

Patients with metabolic alkalosis demonstrate many significant clinical effects, often related to concomitant electrolyte abnormalities. Elevated blood pH increases hemoglobin affinity for oxygen molecules, inhibiting tissue oxygen extraction and leading to tissue hypoxia. Compensatory hypoventilation and hypercarbia further undermine tissue oxygenation. Expect P_{CO_2} levels to increase 0.7 mm Hg for every 1 mmol/L increase in HCO_3^-. Seizures, altered mental status, refractory and lethal arrhythmias, and weakness may occur. Alkalosis will decrease ionized calcium levels and sequester

potassium within cells (causing a transient hypokalemia), each causing additional symptoms.

Treatment

The treatment of metabolic alkalosis is directed at the identification and correction of the particular cause in a specific patient. Urgent treatment should occur when the HCO_3^- level exceeds 40 mmol/L or the pH exceeds 7.55. Many patients experiencing metabolic alkalosis have potentially massive hypovolemia from gastrointestinal- or renal-related fluid volume losses. These patients require volume resuscitation and electrolyte repletion with careful monitoring. Potassium, sodium, calcium, and chloride repletion are often required.

Specific management includes surgical management for pyloric stenosis, which causes protracted vomiting and massive GI fluid and H^+ losses. Other GI fluid and H^+ losses are controlled with treatment of emesis or the discontinuation of gastric suction devices. Diuretic discontinuation (may be temporary) or changing the type of diuretic is indicated when renal chloride losses are the cause of the alkalosis.

Several pharmacologic options exist for the treatment of severe metabolic alkalosis. Hydrochloric acid can be given IV to replete H^+ and correct chloride losses. Potassium chloride will replete potassium and also correct chloride losses. Acetazolamide (Diamox) is a diuretic and carbonic anhydrase inhibitor that can correct any fluid volume excess and promote the excretion of HCO_3^- in the urine. Chloride-responsive alkalosis is generally treated with the previously described medications. Chloride-resistant alkalosis often benefits from potassium chloride repletion, but also requires correction of the underlying condition to resolve the alkalosis. Certain endocrine disorders have specific treatment requirements that necessitate consultation with medical direction.

Metabolic Acidosis

Metabolic acidosis is demonstrated by a decreased serum pH (< 7.35) accompanied by a decreased HCO_3^- concentration (< 23 mmol/L). This disorder occurs through three possible mechanisms:

1. Kidneys may be unable to excrete enough of the 50 to 100 mEq of H^+ produced or absorbed each day.
2. An increased amount of H^+ is present because of exogenous loading or altered metabolism.
3. The kidneys or GI tract excrete too much HCO_3^-, causing an imbalance.

A myriad of situations cause metabolic acidosis. Cellular starvation states such as diabetic ketoacidosis, alcoholic ketoacidosis, and profound malnutrition each accumulate acids from altered metabolism and demonstrate an increased AG acidosis. GI HCO_3^- losses occur from diarrhea, fistulas, or lower GI suctioning, causing metabolic acidosis. Many toxic chemicals produce either an AG or non-AG metabolic acidosis following exposure or absorption.

Excess accumulation or impaired excretion of lactate leads to acidosis and an elevated AG. Lactic acidosis can be a result of exposure to various toxic substances, such as ethylene glycol, ethanol, epinephrine, cocaine, iron, propofol, salicylates, valproic acid, metformin (Glucophage), and numerous others. It can occur from inadequate tissue perfusion in various shock states, dysfunction of certain organs, nutritional deficiency, infection, malignancy, or diabetes. Other hereditary metabolic disorders, such as glucose-6-phosphatase deficiency, pyruvate carboxylase deficiency, oxidative phosphorylation deficiency, and methylmalonic aciduria, also cause lactic acidosis.

Renal Metabolic Acidosis

Kidney dysfunction is the cause of metabolic acidosis through a variety of mechanisms. Uremic states

from the accumulation of cellular waste products directly cause a metabolic acidosis. Inadequate renal ammonium (NH_4) production prevents excretion of sufficient H^+ leading to acidosis.

Type 1 (distal) **renal tubular acidosis (RTA)** impairs the kidney's ability to excrete H^+. This state is often characterized by plasma HCO_3^- levels of less than 15 mmol/L, hypokalemia, increased urine calcium levels, and kidney stones. Urine pH remains greater than 5.5 despite acidosis. This condition is relatively rare and may be hereditary, autoimmune, or linked to other diseases or chemicals.

Type 2 (proximal) RTA involves impaired HCO_3^- reabsorption translating into increased renal HCO_3^- excretion. It is characterized by an initial elevated urine pH until plasma HCO_3^- levels drop, then the urine pH drops significantly. Glucose, protein, and phosphate are increasingly excreted in the urine in addition to HCO_3^-. This condition is also rare. Causes included heredity, numerous medications, and a variety of medical conditions.

Type 4 (generalized or hyperkalemic) RTA results from impaired liberation of renin by the kidneys or altered synthesis, excretion, or response to aldosterone by the kidneys or adrenal glands. In addition to hyperkalemia, there is often an elevated urine sodium level (> 40 mmol/L) and hyperchloremia. Type 4 RTA is the most common manifestation of RTA. It is linked with toxicity to numerous medications and genetic disorders, and as a consequence to diabetes, HIV, systemic lupus erythematosus, and sickle cell anemia. Types 1, 2, and 4 RTA present with a metabolic acidosis without an elevated AG.

Finally, Type 3 RTA is a rare classification, with characteristics of Type 1 and Type 2, and is not clinically relevant.

Clinical Features

Metabolic acidosis is rarely a clinically isolated occurrence. Underlying pathologic conditions causing acidosis will predominantly shape the clinical status of a particular patient. Kussmaul respirations are characteristic of metabolic acidosis because a decreasing pH will stimulate respiratory centers, causing an increase in alveolar ventilation. Hypotension and hypovolemia are also characteristic of severe metabolic acidosis, demonstrating the progression of widespread cell, tissue, organ, and body system dysfunction. In response to acidosis, potassium ions shift out of the cell, moving excess H^+ into the cell, resulting in a pseudohyperkalemia even when there is an actual normal or decreased whole-body potassium presence.

Treatment

CCTPs should resist the temptation to treat every metabolic acidosis with IV sodium HCO_3^-. Certain conditions, such as RTA, hyperchloremic acidosis, and isolated GI HCO_3^- losses, are amenable to treatment with IV sodium HCO_3^-, but other causes of metabolic acidosis require a more specific approach. Sodium HCO_3^- is not generally indicated even in these circumstances unless the pH has fallen below 7.2.

Lactic acidosis requires correction of cellular metabolism not accomplished with sodium HCO_3^-. Improving cellular metabolism will cease production of excess H^+ and allow normal acid-base control mechanisms to restore a physiologic pH. HCO_3^- is ineffective in the treatment of lactic acidosis and is not recommended. Optimal tissue oxygen delivery and adequate perfusion are the primary goals of lactic acidosis treatment along with more specific management of potential underlying causes.

The various types of RTA are treated with agents such as sodium HCO_3^- or sodium citrate often over long periods of time. Calcium, potassium, and other electrolytes require careful monitoring and often repletion, depending on the particular type of RTA. Type 2 RTA often requires potassium repletion. Type

4 RTA often requires volume expansion, potassium wasting diuretics, or even mineralocorticoid replacement therapy in select situations.

Sodium HCO_3^- is not recommended for the treatment of diabetic ketoacidosis and has been shown to cause cerebral edema when administered to children with this condition. Diabetic ketoacidosis is best managed with fluid volume restoration, IV insulin, and electrolyte (especially potassium and sodium) correction.

Alcoholic ketoacidosis, another cellular starvation acidosis, is also not treated with IV sodium HCO_3^-, unless there is a profound, life-threatening acidosis (pH > 7.1). Alcoholic ketoacidosis is treated with IV fluids and carbohydrates to improve nutritional status and allow normal metabolic processes to resume. Potassium chloride in 5% dextrose and sodium chloride injection D_5NS and thiamine (to correct deficiencies and prevent Wernicke's encephalopathy) are generally the only medications needed for treatment.

Other causes of metabolic acidosis, such as uremia or exposure to toxic chemicals, require specialty consultation and often complex treatment. Critical care providers should seek medical consultation when transporting patients with these conditions.

Diagnosis and management of patients with metabolic alterations of acid-base status can challenge CCTPs. Clinical suspicion, focused investigation, and optimal treatment of these disorders will improve patient outcomes and minimize the adverse impact of many serious medical conditions. Providers should consider the potential and consequences of metabolic acid-base alterations during every critical care transport.

Flight Considerations

Critical care providers must take precautions or modify techniques when performing air-medical patient transport. Unpressurized or underpressurized aircraft place GI/GU patients at increased risk for complications related to transport. Careful assessment and simple interventions eliminate or minimize many adverse effects.

GU complications specifically related to air-medical transport are rare. Prolonged exposure to altitude will alter urinary pH. Pneumaturia (presence of gas within the bladder) can occur following a urinary tract infection with certain microorganisms, after manipulation of the genitourinary tract, and when a fistula develops between the digestive tract and bladder (causing bowel contents to contaminate the normally sterile bladder environment). Pneumaturia requires more specific interventions, often including an indwelling urine (Foley) catheter for bladder and urinary tract decompression. Unless contraindications are present, a catheter will eliminate the need for patients to void during transport, permit assessment of fluid volume status, and prevent complications associated with urinary retention. GI complications during air medical transport are much more common. Sequestered gases due to abdominal surgery, bowel obstruction, and abdominal trauma will significantly expand as cabin altitude increases. Ascending from sea level to 9,000′ will cause any sequestered gas to expand by 50%. In severe situations, this gas expansion can lead to respiratory compromise, severe discomfort, syncope, and vasovagal episodes.

Patients with any of the previously mentioned conditions should have an NG or OG tube placed prior to any increase in cabin altitude. Once these tubes are in place, they should be either vented to ambient air or connected to suction for transport. Colostomy patients should have their devices frequently monitored for excessive amounts of gas and either emptied or changed when this occurs. If at all possible, patients who have undergone abdominal surgery should wait 24 to 48 hours following surgery before being transported by air.

CCTPs should take certain steps to minimize personal GI symptoms associated with air medical transport. Drinking carbonated beverages, swallowing large amounts of air while eating, and consuming gas-forming foods all contribute to GI distress at altitude.

Summary

The GI and GU systems are complex pathways through the body that support critical functions—the digestion of food and the elimination of wastes, respectively. They withstand constant usage, leading to inevitable wear and tear. The many GI/GU pathologies that can occur require prompt recognition and treatment to preserve function. Because of the interactions of these systems with accessory organs and other systems, local problems can quickly evolve into systemic ones. Through awareness of the possible diseases, history taking, and proper assessment, many complications can be prevented or corrected at an early stage.

The CCTP is the connection between the patient and the tertiary care required. The continuity of care provided is a fundamental piece of the treatment and recovery of the critically ill patient with a GI/GU condition. When a problem arises during transport, it is the responsibility of the CCTP to correct it and prevent its recurrence. Being equipped with this knowledge provides the CCTP and the patient with the greatest likelihood for a safe, uneventful transfer.

Case Study

YOU AND YOUR CRITICAL CARE TEAM ARE DISPATCHED to the scene of an adolescent who is complaining of severe abdominal pain. Upon your arrival at the residence, you find a 17-year-old female lying on the bathroom floor. The patient's mother reports that her daughter has been complaining of stomach and shoulder pain for the past four days. At first she thought that her daughter was exaggerating because she did not want to go to school, but she became concerned when her daughter collapsed on the bathroom floor. You question the mother further and find out that the daughter had a "spell" yesterday morning, but the mother attributed it to her daughter taking diet pills and not eating enough. The patient denies having had a fever or vomiting. You question the patient further and are informed that she had a regular menstrual period last month and is due to start any day now. She denies being sexually active and states that she does not take contraceptives.

You perform your physical exam, which reveals a well-nourished female who appears to be in acute distress. The patient is lethargic, but will respond to your questions. Her pupils are equal round at 4 mm and reactive to light. Her airway is patent and clear, as evidenced by verbal communication. Breath sounds are present and clear to auscultation. Her respiration rate is 26 breaths/min and shallow. S1 and S2 heart tones are auscultated, and no murmurs, gallops, or friction rubs are noted. The radial pulse is 115 beats/min and strong. Her initial blood pressure is 92/40 mm Hg. Her skin is pale and diaphoretic. The abdomen is positive for rebound tenderness and is slightly distended. The patient has a positive Kehr's sign.

Your partner brings the stretcher to the bathroom doorway in preparation to load the patient in the hallway because the bathroom is very narrow. You and your partner prepare to assist the patient in moving to the stretcher. As the patient attempts to stand with assistance, she loses consciousness and is assisted to the ground by you and your partner. The patient regains consciousness shortly afterwards. Your critical care team initiates two large-bore IVs, places the patient on oxygen via nonrebreathing mask at 15 L/min, and prepares to transport the patient to the closest emergency department with an ETA of 15 minutes.

The patient's condition continues to deteriorate en route. Upon arrival at the emergency department,

the patient's condition has worsened; her blood pressure has dropped to 70/40 mm Hg, her pulse rate is 125 beats/min, and she is only responding to tactile stimulation. Blood and urine were collected and sent to the laboratory. An emergency transvaginal sonogram was requested.

The lab values are as follows:

- Urinalysis
  - Color, dark yellow
  - Appearance, clear
  - Specific gravity, 1.030
  - pH 5.3
  - Protein, none
  - Glucose, none
  - Ketones, none
  - Bilirubin, none
  - Urobilinogen, normal
  - Hemoglobin, none
  - Red blood cells, none
  - Nitrite, none
  - White blood cells, none
- Hematology tests
  - White blood cells, 7,725/μL
  - Red blood cells, 3.5×10^6/μL
  - Hemoglobin count, 7.5 g/dL
  - Hematocrit value, 22.5%
  - Platelets, 145,000/μL
- Electrolytes
  - Sodium, 138 mEq/L
  - Potassium, 4.6 mEq/L
  - Chloride, 114 mEq/L
  - Calcium (ionized), 9.9 mg/dL
- Arterial blood gas analysis
  - pH, 7.01
  - P_{CO_2}, 68 mm Hg
  - P_{O_2}, 38 mm Hg
  - Base excess, 13 mmol/L
  - HCO_3^-, 11.7%
  - O_2 saturation, 59%
  - O_2, 15 L/min 100%
- Other test
  - Human chorionic gonadotropin, 1,500 mIU/mL

- Transvaginal sonogram
  - The results of the sonogram revealed a right complex mass measuring 3 to 4 cm, minimal free fluid in the adnexa, and an empty sac. The findings were discussed with the radiologist, who stated that the appendix could not be well visualized.

1. What is the patient's diagnosis?
2. What treatment should be initiated?
3. What other diagnosis should be considered in this patient?

Analysis

Pregnant patients who present with an acute abdomen are considered a surgical emergency and require an appropriate diagnosis to avoid the risk of maternal and fetal mortality. Ectopic pregnancy and appendicitis are two possible causes of acute abdomen in a pregnant patient. CCTPs should not become complacent and look for a single diagnosis, but be observant for the possibility of concurrent causes of abdominal pain in the female patient, particularly during pregnancy.

The patient was transfused with 3 units of packed red blood cells and a culdocentesis was performed (aspiration of fluid from the space between the uterus and rectum), which revealed non-clotting blood in the cul-de-sac. A preoperative diagnosis of acute abdomen was made, and the patient was taken emergently to surgery for a laparotomy, which revealed a ruptured right fallopian tube. A saplingectomy was performed (removal of the fallopian tube), the blood and clots were aspirated from the abdominal cavity, and bleeding was localized and controlled. The patient was transferred to the recovery room postoperatively with stable vital signs and later transferred to the OB/GYN floor for further follow-up.

The patient made a full recovery from the ectopic pregnancy, and was discharged 2 days later. She was instructed to return for a follow-up in 1 week for a serum human chorionic gonadotropin test to confirm a decrease in human chorionic gonadotropin levels.

Prep Kit

Ready for Review

- Homeostasis depends on a number of metabolic processes involving the GI and GU systems, but these processes can be the target of a number of pathologic conditions. Assessment and management of GI and GU pathologies is inherently difficult because the signs and symptoms that accompany these may be obscure.
- The GI system consists of a specifically arranged network of organs and ducts devoted to the digestion of food and the extraction of its nutritional content.
- The alimentary canal contains numerous specialized cells and tissues. Four layers are seen almost continuously from the esophagus to the rectum: the mucosa, the submucosa, the muscularis externa, and the serosa.
- The alimentary canal maintains a chemical environment that is beneficial for the digestion of food, without altering the environment of the rest of the body.
- The alimentary canal consists of the mouth, pharynx, esophagus, stomach, small intestine, and large intestine; food travels through these structures and finally exits the body via the rectum.
- The renal system provides a path for waste to leave the body.

- The kidneys continuously filter blood, manage volume, maintain appropriate balances between acids and bases, and discard toxins and excesses by producing urine. The remainder of the urinary system—the ureters, urinary bladder, and urethra—provides for transport and storage of urine during its journey out of the body.
- The purpose of the male reproductive system is to generate sperm and provide a means for its delivery to a fertilizable egg in the female partner.
- The female reproductive system produces and develops eggs. In addition, the uterus of the female provides a home for a developing embryo during gestation.
- The common symptoms of GI abnormalities include abdominal pain, tenderness, and bleeding.
- GI bleeding can be classified into one of two categories based on the location of the bleeding: upper GI bleeding and lower GI bleeding.
- Endoscopy is the preferred method of locating the bleeding source.
- Peptic ulcers are the leading cause of upper GI bleeding, accounting for more than 50% of acute cases.
- Stress-related erosive syndrome is a frequent cause of peptic ulcers in critically ill patients, with an incidence of nearly 100%.
- Ulcers associated with severe burns are termed Curling's ulcers, and those accompanying episodes of increased intracranial pressure are Cushing's ulcers.
- Inflammation of the gastric mucosa, termed gastritis, is a common precursor to upper GI bleeding.
- Acute gastritis is characterized by a rapid onset of mucosal inflammation frequently accompanied by mild to severe upper GI bleeding.
- Autoimmune disorders targeting the GI system can cause chronic inflammation of mucosal lining and can also inhibit certain metabolic pathways crucial to digestion.
- Reactive gastritis is a chronic mucosal edema that results from recurring contact of the mucosa with antagonistic substances such as bile, pancreatic juice, or NSAIDs.
- Radiation exposure causes varying forms of gastritis depending on the amount of radiation involved.
- An esophageal varix results from the swelling of esophageal veins into the lumen of the esophagus.
- When portal hypertension occurs, venous blood will use alternate pathways for its return to the vena cava via the azygos system.
- In cirrhosis, buildup of fatty acids, along with chronic destruction of liver tissue and fibrosis, obstructs blood flow.
- Mallory-Weiss syndrome involves a longitudinal laceration of the esophageal mucosa as a result of repeated significant changes in local pressure, such as those seen in repeated vomiting.
- Lower GI bleeding is frequently the result of an exacerbation of a chronic condition.
- Diverticulosis is a common disease of the lower GI in the elderly.
- Diverticulitis, an inflammation of the diverticula, is frequently a result of infection from invading intestinal bacteria and is the most common cause of lower GI bleeding.
- Angiodysplasia is a malformation of submucosal blood vessels in the GI tract.
- Inflammatory bowel disease is a collective term covering two idiopathic colon pathologies that are together responsible for about 10% of the cases of lower GI bleeding: ulcerative colitis and Crohn's disease.
- Ulcerative colitis is an inflammation of the rectal mucosal and submucosal tissues.

- Crohn's disease is a less organized inflammation of the GI tract in which all layers of the mucosa may be affected.
- Radiation colitis occurs in 75% of patients who have received radiation doses of 40 Gy or more to the abdomen or pelvis.
- Symptoms of GI bleeding include melena, diffuse abdominal pain, emesis containing hematemesis, fever, complaints of frequent dizziness and syncope, diarrhea, dehydration, and cardiac arrhythmias.
- Symptoms of significant GI bleeding include hemodynamic instability, shock, large amounts of bright red blood in vomit, hematochezia, hypotension, tachycardia, diaphoresis, altered mental status, and a decreased level of consciousness.
- Fluctuations in the hematocrit value over time indicate active bleeding.
- Pressure ulcers can arise from prolonged pressure on body tissues, are commonly seen in patients confined to a bed, and are classified on a scale of stages 1 through 4.
- Endoscopy is capable of visualizing more than 90% of the upper GI tract with a 90% to 95% diagnosis rate.
- Colonoscopy allows visualization of the entire rectum and large intestine, up to the ileocecal junction.
- For an angiography, dye injected into blood vessels will leak into the lumen of the GI tract at the site of the bleeding.
- During acute GI bleeding, airway compromise occurs primarily by either of two ways: physical obstruction or mechanical obstruction.
- Any patient with acute GI bleeding should be designated NPO (nothing by mouth), and blood samples should be drawn concurrently with IV placement.
- Along with treating the immediate concerns of GI bleeding, other factors such as incontinence, diarrhea, and constipation need to be addressed.
- Treatments for endoscopic and pharmacologic refractory variceal hemorrhage include balloon inflation and shunt placement.
- The introduction of a transjugular intrahepatic portosystemic shunt into the systemic venous circulation results in a significant decrease in hepatic portal pressure and, therefore, a significant decrease in the pressure in the esophageal collateral veins.
- A mechanical obstruction is the result of a physical blockage of the intestinal lumen and can be classified into one of three categories: extrinsic, intrinsic, or intraluminal.
- Ileus is the lack of movement of the GI contents through the intestines in the absence of a mechanical obstruction.
- In a patient with an intestinal obstruction, the abdomen is tender and distended on palpation, typically with diffuse pain.
- Plain radiography can diagnose an intestinal obstruction by detecting abnormally high air volumes proximal to the obstruction site. A CT scan can be used to diagnose a bowel obstruction with exceptional specificity.
- After the stabilization of any life threats to the patient's airway, breathing, or cardiac functioning, initial treatment focuses on fluid resuscitation.
- An NG or OG tube may already be in place upon the CCTP's first encounter with the patient, particularly during interfacility transports.
- In general, an insult to the liver is either infectious or noninfectious. If the insult resolves within 6

months without any permanent function deficit, it is termed acute. When symptoms persist longer, chronic liver disease has developed.

- Hepatitis, an inflammation of the liver, is the physiological result of any liver disease.
- Fulminant hepatic failure is the result of a sudden significant insult to the liver.
- The leading cause of cirrhosis is infection with the hepatitis C virus (HCV), with alcoholic liver disease closely following.
- Inflammation of liver tissue results in damage to a variety of functional cells, including hepatocytes and Kupffer cells.
- Bilirubin that is normally conjugated by hepatocytes and excreted via bile begins to build up in the blood, resulting in jaundice.
- Symptoms of early acute hepatitis include general malaise, generalized fatigue, and fever and chills. Other symptoms include portal hypertension, melena, hematochezia, chronic shortness of breath, hypotension, tachycardia, and hair loss.
- Liver function is assessed by evaluating the presence of its synthesized products as well as the absence of its cellular enzymes in the blood. It is important to recognize the distinction between tests for liver function and markers of injury.
- Treatment of hepatitis focuses on prevention of further injury with a goal of preventing progression to cirrhosis.
- Blockage of the biliary tracts at any point will result in a backup of bile and, possibly, depending on the location of the obstruction, pancreatic enzymes.
- Gallstones in the gallbladder, cholelithiasis, are a fairly common condition that affects around 20 million Americans per year.
- Cholecystitis causes colicky pain in the right upper quadrant of the abdomen. Patients typically present with Charcot's triad, nausea and vomiting, clay-colored feces, and a positive Murphy's sign.
- Imaging and detecting techniques include transabdominal ultrasonography, endoscopic ultrasonography, hepatoiminodiacetic acid scanning, endoscopic retrograde cholangiopancreatography, and percutaneous transhepatic cholangiography.
- Immediate treatment of choledocholithiasis involves pain management once general treatment has been performed. Opiates should be avoided, because they can cause spasms of the biliary ducts at the ampulla of Vader.
- Inflammation of the pancreas, known as pancreatitis, can lead to significant impairment of gastrointestinal physiology depending on its level of severity and etiology.
- Upper abdominal pain is the primary symptom of pancreatitis. Symptoms include tenderness and guarding of the abdomen, tachycardia, nausea and vomiting, and a fever. Turner's sign, Cullen's sign, jaundice, hemodynamic instability, and shock may result from severe pancreatitis.
- Although elevated levels of serum amylase and serum lipase support a diagnosis of pancreatitis, they can result from a number of other conditions as well.
- A CT scan with contrast dye can provide a direct visual observation of pancreatic necrosis, peripancreatic abnormalities, abscesses, and overall size of the pancreas.
- General treatment of pancreatitis includes palliative care such as supplemental oxygen administration, IV placement, and ECG monitoring.
- Pain management is necessary and may take the form of IV narcotics or patient-controlled analgesia

devices.

- Significant decreases in renal perfusion pressure disrupt the elimination of waste from the bloodstream by lowering the glomerular filtration rate (GFR). When this situation develops in the absence of preexisting renal dysfunction, it is termed acute renal failure (ARF).
- Symptoms include dizziness, poor skin turgor, thirst, flat neck veins, dry mucous membranes, weight loss, orthostatic blood pressure changes, fever, edema, ascites, and lower back pain.
- A family history of renal disease indicates a predisposition to ARF when a precursory disease of ARF is present. The incidence of ARF is increased in patients with diabetes, hypertension, or lupus.
- The retention of wastes in the bloodstream that results from a decreased GFR provides an easy way to monitor for the existence and severity of ARF. Renal ultrasonography is the gold standard in assessing suspected postrenal ARF.
- Initial treatment of the patient with ARF involves maintaining the ABCs and a perfusing blood pressure. Once these basic elements are ensured, management focuses on increasing the GFR.
- A gradual decrease in renal function over a long time interval is known as chronic renal failure (CRF).
- Symptoms include azotemia, electrolyte imbalances, hyperkalemia, cardiac arrhythmias, congestive heart failure, edema, anemia, chronic fatigue, hyperparathyroidism, skeletal abnormalities, polyuria or anuria, metabolic acidosis, uremia, jaundice, and uremic frost phenomenon.
- The results of lab studies on CRF and ESRD are generally parallel to the results seen for ARF. The most important factor in determining whether the renal failure is acute or chronic is disease duration.
- The best treatment for chronic renal failure is prevention, as there is no definitive cure once it has progressed to clinically detectable signs. Once CRF is recognized, treatment focuses on slowing the progression.
- Bacterial flora that live symbiotically in the GI system can cause considerable damage when they are introduced into the urinary system. A urinary tract infection typically begins in the urethra, as this location is the most proximal to the external environment.
- In about 12% of the male population, the tunica vaginalis attachment is misaligned, allowing some degree of free testicular movement, known as the “bell clapper” deformity. These patients are susceptible to testicular torsion, a condition in which one or both of the testes rotate to the point of occluding their blood supply.
- Direct blunt trauma to the penis during penile erection can result in penile fracture. The fracture here is actually a rupture of one or more of the vascular spaces within the penis, mimicking the appearance of a long bone fracture.
- Priapism is a prolonged erection of the penis that can be painful and damaging to tissues in the immediate area. The two major classifications of priapism are arterial high-flow and veno-occlusive priapism.
- A simple NG tube can be used to administer food into the stomach or to remove food. For longer-term situations, a gastrostomy tube (G tube) or percutaneous endoscopic gastrostomy (PEG) tubes can be inserted
- Total parenteral nutrition is an alternative feeding method used when the GI tract is not functioning adequately. In TPN, all required nutrients are administered IV to the patient.
- When transporting a patient with a feeding tube, contact medical direction if the patient has vomiting, abdominal distention, or diarrhea.

- Straight catheters, often called intermittent catheters, are designed for temporary use and are frequently self-inserted by the patient.
- Indwelling catheters, also known as Foley catheters, provide a complete management of urine for bedridden or incapacitated patients, with minimal upkeep.
- When surgery or trauma makes urethral catheter introduction unfavorable, a suprapubic tube can be placed directly into the bladder through the abdominal wall by way of a surgically created stoma.
- Common complications of urine collection catheters include clogging, infection, pain, leakage, and dislodgement. Dislodgement is the largest concern during transport. Any signs of infection should be treated with antibiotics immediately.
- An ostomy is a surgically created opening of the GI tract through the abdomen that allows for waste removal.
- The patient with an ostomy should be monitored for signs of tissue necrosis and infection, which, if detected, may warrant treatments ranging from antibiotic therapy to surgical intervention.
- Jackson-Pratt drains are inserted to remove postoperative buildups of fluid and blood in the abdominal cavity. During liver transplant surgery, a T tube is placed to monitor bile drainage from the gallbladder.
- In-flight complications need to be considered for the numerous drainage systems that include closed bags containing air. Excess air should be vented from any drainage bag such as a colostomy or urostomy prior to flight in anticipation of changes in air pressure.
- Be sure to unclamp any feeding or drainage catheters prior to departure, and ensure that they remain unclamped for the duration of travel.
- Air transport should be postponed or avoided for any patient with a bowel obstruction if possible.
- Significant alterations of oxygen and carbon dioxide levels, electrolyte concentration, temperature, glucose levels, and acid-base status will impair cell, tissue, and organ function, eventually leading to death.
- The relationship of acids to bases within the body is the pH value, which represents the concentration of free hydrogen ions (H^+) present.
- The bicarbonate–carbonic acid buffer system is the principle extracellular buffer system that operates primarily in the lungs and kidneys, where carbonic anhydrase is present to stimulate the chemical reaction.
- The phosphate buffer system operates similar to the bicarbonate–carbonic acid buffer system in that it allows only small pH changes following large variations in the presence of free H^+.
- The concentration of free H^+ in extracellular fluid (pH) as well as other key variables can be obtained from an arterial blood gas (ABG) or venous blood gas (VBG) sample.
- Results from an ABG sample provide the CCTP with valuable information regarding the existence or type of acidosis or alkalosis.
- Total blood CO_2, which can be written as either TCO_2 or HCO_3^- in clinical practice, provides an indication of an acid-base abnormality on routine blood work.
- When an acidosis is suspected, its origin can be examined using the anion gap.
- When metabolic conditions create an excess of bicarbonate (HCO_3^-) accompanied by a pH greater than 7.45 on an ABG sample, the disorder is termed metabolic alkalosis.

- Patients with a metabolic alkalosis demonstrate many significant clinical effects, often related to concomitant electrolyte abnormalities.
- Specific management of metabolic alkalosis includes surgical management for pyloric stenosis, which causes protracted vomiting and massive GI fluid and H^+ losses.
- Metabolic acidosis is demonstrated by a decreased serum pH (< 7.35) accompanied by a decreased HCO_3^- concentration (< 23 mmol/L).
- Kidney dysfunction is the cause of metabolic acidosis through a variety of mechanisms.
- Metabolic acidosis is rarely a clinically isolated occurrence. Underlying pathologic conditions causing the acidosis predominantly shape the clinical status of a particular patient.
- CCTPs should resist the temptation to treat every case of metabolic acidosis with IV sodium HCO_3^-. Providers should consider the potential and consequences of metabolic acid-base alterations during every critical care transport.
- Critical care providers must take certain precautions or modify techniques when performing air-medical patient transport.
- Pregnant patients who present with an acute abdomen are considered a surgical emergency and require an appropriate diagnosis to avoid the risk of maternal and fetal mortality.

Vital Vocabulary

acute gastritis A type of gastritis characterized by a rapid onset of mucosal inflammation, frequently accompanied by mild to severe upper GI bleeding.

acute renal failure (ARF) Decreased renal function in the absence of preexisting renal disease. Classified into three categories: prerenal, intrarenal, and postrenal.

acute tubular necrosis Damage to the tubules of the nephron, preventing proper ion and fluid exchanges in the kidneys.

adhesions Bands of connective tissue that can distort the normal GI anatomy. They are the result of improper healing or scar tissue growth following surgery.

alcoholic ketoacidosis A type of acidosis characterized by a buildup of ketones in the blood and caused by a large intake of alcohol.

angiodysplasia Deformed submucosal blood vessels in the GI tract that are prone to bleeding.

angiography Radiologic observation of dye injected into the bloodstream for leakage.

ascites A buildup of fluid in the abdominal cavity that can impede lung expansion and put pressure on other organs.

aspartate aminotransferase/alanine aminotransferase (AST/ALT) ratio A ratio used as an indicator of liver damage; this ratio can determine if the elevation is due to a liver injury or injury elsewhere in the body.

azotemia A combined elevation of blood urea nitrogen and serum creatine levels often seen in acute renal failure.

azygos system A network of blood vessels that connects the superior and inferior vena cava; it also drains a portion of the esophageal venous blood.

bicarbonate–carbonic acid buffer system The principal extracellular buffer system, which operates

primarily in the lungs and kidneys, and by which CO_2 and H_2O are reversibly converted into H_2CO_3 (carbonic acid), which in turn is reversibly converted into H^+ and HCO_3^- (bicarbonate).

bilirubin A waste product of heme formed during erythrocyte metabolism. It is moved to the small intestine within bile and then converted into urobilinogen, resulting in brown pigmented feces.

buffer Any substance that can alternately bind or release H^+ depending on outside conditions.

Charcot's triad Fever, jaundice, and right upper quadrant abdominal pain suggestive of choledocholithiasis.

cholangitis An infective form of biliary tract obstruction in which white blood cell levels rise.

cholecystitis Inflammation of the gallbladder.

choledocholithiasis Gallstones in the biliary tract system, which put the person at high risk for developing a biliary tract obstruction.

cholelithiasis Gallstones in the gallbladder.

chronic renal failure (CRF) A gradual decrease in renal function resulting from irreversible damage to the nephrons. It is characterized by a glomerular filtration rate (GFR) of less than 30 mL/min, and will eventually progress to end-stage renal disease.

cirrhosis Irreversible structural changes to the liver that impair its proper functioning.

colonoscopy Similar to endoscopy, but used for the lower GI tract.

concentration gradient The natural tendency for substances to flow from an area of higher concentration to an area of lower concentration, within or outside the cell.

creatinine The metabolized form of creatine that is eliminated through the urine. The rate of creatinine clearance is calculated as follows: [(140 — age) × weight in kilograms], divided by [plasma creatinine level × 72].

Crohn's disease An inflammation of the GI tract in which all layers of the mucosa may be affected. It results in scattered ulcerations and fibroses throughout the large and small intestines.

diabetic ketoacidosis A form of acidosis in uncontrolled diabetes in which certain acids accumulate when insulin is not available.

diverticula Small pouches of tissue that develop as outcroppings of the large intestine, typically in the descending colon and sigmoid colon.

diverticulitis Inflammation of diverticula.

diverticulosis Development of diverticula that may then become inflamed or bleed.

end-stage renal disease (ESRD) A loss of proper kidney functioning, with renal replacement therapy becoming a requirement for survival.

endoscopy The method of choice for visualization of the GI tract; it allows for observation, diagnosis, and treatment of an insult to the GI tract.

enteroclysis Infusion of barium contrast dye into the GI tract to observe for obstruction.

esophageal varix Swelling of esophageal veins into the lumen of the esophagus.

fulminant hepatic failure A sudden and significant insult to the liver characterized by encephalopathy and a mortality rate of up to 90%.

gastritis Inflammation of the gastric mucosa that occurs when the equilibrium of offensive and defensive

mechanisms for the lining is altered.

glomerular filtration rate (GFR) A benchmark for comparison of nephron function, based on the amount of fluid filtered by the glomerulus per minute.

Helicobacter pylori A bacterium that causes most peptic ulcers.

hematemesis Coffee-ground emesis containing partially digested blood.

hematochezia Stool streaked with bright red blood, originating from the lower GI tract.

hemodialysis (HD) Use of vascular access through a fistula or AV shunt to access the blood directly. Solute separation occurs across an artificial semi-permeable membrane within the dialysis machine.

hepatic encephalopathy Encephalopathy secondary to hepatic disease.

hepatitis Inflammation of liver cells that can impede proper functioning of the liver and lead to chronic conditions such as cirrhosis.

hepatitis C virus (HCV) The virus that is the most common cause of cirrhosis and is especially pathogenic in causing hepatitis.

hepatoiminodiacetic acid (HIDA) scan Administration of a radiologically labeled chemical specific for bile incorporation to a patient; the path taken by the marker is observed through radiography to ascertain whether an obstruction is present.

hernia A protrusion of an organ from its tissue lining.

homeostasis Stability in the body's internal environment.

hyperchloremic acidosis A form of metabolic acidosis in which low bicarbonate (base) concentration occurs along with an increase in chloride concentration.

ileus A lack of movement of GI contents in the absence of an obstruction.

inflammatory bowel disease (IBD) Term covering two colon inflammation pathologies: ulcerative colitis and Crohn's disease.

intussusception A prolapse of the intestine into an adjacent segment.

Jackson-Pratt drain A surgical drain used to remove fluid buildup from the wound site during the postoperative healing process.

jejunostomy tube (J tube) A feeding tube placed through the abdominal wall into the jejunum.

lactic acidosis A form of acidosis caused by an excess accumulation or impaired excretion of lactate, leading to an elevated anion gap; can result from exposure to various toxic substances, inadequate tissue perfusion in various shock states, dysfunction of certain organs, nutritional deficiency, infection, malignancy, diabetes, or hereditary metabolic disorders.

ligament of Treitz A small ligament supporting the small intestine at the junction between the duodenum and jejunum. It serves as the dividing point between the upper and lower GI tract.

lithotripsy Use of external vibrations to break up gallstones.

Mallory-Weiss syndrome Longitudinal laceration of the esophagus, often following severe vomiting.

mass A tumor, aneurysm, or abscess.

melena Black, tarry stool containing partially digested blood, with bleeding originating from the upper GI tract.

metabolic acidosis A pathologic condition (blood pH < 7.35) resulting from the accumulation of acids in

the body caused by any number of systems in the body, including the gastrointestinal system, or major organ failure.

metabolic alkalosis A pathologic condition (blood pH > 7.45) resulting from the accumulation of bases in the body caused by any number of systems in the body, including the gastrointestinal system, or major organ failure.

Minnesota esophagogastric tamponade tube A tube that is placed to stop bleeding of esophageal varices. It is similar to the Sengstaken-Blakemore tube, but has a built-in suction catheter.

mixed acidosis A pathologic condition in which there is a low pH (< 7.35), an elevated P_{CO_2} level (> 45 mm Hg), and a low bicarbonate level (< 23 mmol/L), which occurs when there is both a respiratory and a metabolic cause present at the same time.

mixed alkalosis A pathologic condition in which there is an elevated pH (> 7.45), a low P_{CO_2} level (< 35 mm Hg), and an elevated bicarbonate level (> 29 mmol/L), which occurs when there is both a respiratory and a metabolic cause present at the same time.

mucosa The outermost layer of the alimentary canal. It consists of three sublayers: surface epithelium, lamina propria, and muscularis mucosae.

Murphy's sign Pain in the right upper abdomen on deep inspiration during palpation.

muscularis externa The third tissue layer of the alimentary canal. It contains two levels in most places: the circular layer and the longitudinal layer.

ostomy A surgically created opening through which feces can be voided in the absence of some or all of the large intestine or rectum.

pancreatitis Inflammation of the pancreas leading to tissue destruction, improper functioning of the pancreas, and chronic disease.

paracentesis A "tapping" of the abdomen with a needle to draw off ascites.

penile fracture A rupture of one of the blood-containing sacs in the penis, resulting in deformity and possible loss of function.

peptic ulcer An erosion of the mucosal lining of the GI tract.

percutaneous endoscopic gastrostomy (PEG) tube A feeding tube that is placed through the abdominal wall into the stomach.

peristalsis A general term applicable to any concerted and directional movement in the body such as the movements that push food or urine through the body.

peritoneal dialysis Use of a catheter to introduce dialysate solution into the abdomen using the peritoneum as a natural semipermeable membrane to separate solutes.

phosphate buffer system The buffer system that functions in the renal tubules and intracellular fluids to convert strong acids or bases into weak acids or bases so that there is only a minimal effect on overall pH.

point-of-care (POC) testing Laboratory testing that is performed at the patient's beside, so that results can be quickly obtained and can be considered while decisions are still being made about patient care.

portal hypertension An increase in vascular resistance through the hepatic portal system. It can cause high venous pressure in gastric and esophageal veins, leading to varices, among other problems.

pressure ulcer A sore on the skin arising from prolonged pressure, classified in four stages, with stage 4 being the most severe with tissue necrosis and muscle and bone involvement. All stages are painful and

prone to infection; commonly seen in patients confined to a bed.

priapism Prolonged, painful erection of the penis.

pyelonephritis An infection of the kidney, typically the result of a urinary tract infection that traveled up the ureter.

reactive gastritis A chronic mucosal edema that results from recurring contact of the mucosa with antagonistic substances such as bile, pancreatic juice, or NSAIDs.

renal tubular acidosis (RTA) A form of metabolic acidosis caused by dysfunction of the kidneys or renal system; presents without an elevated anion gap; characterized into Type 1, 2, or 4.

respiratory acidosis A pathologic condition (blood pH < 7.35) resulting from the accumulation of acids in the body caused by a breathing problem or insufficient function of the respiratory system.

respiratory alkalosis A pathologic condition (blood pH > 7.45) resulting from the accumulation of bases in the body caused by a breathing problem or insufficient function of the respiratory system.

scintigraphy An imaging technology that is similar to angiography, except that the red blood cells themselves are radiologically labeled to allow greater specificity.

Sengstaken-Blakemore tube A tube with an inflatable balloon at its end that is inserted into the GI tract and inflated to tamponade bleeding.

serosa A protective layer of connective tissue over most of the alimentary canal; also called the visceral peritoneum.

stress-related erosive syndrome A condition in which small, diffuse peptic ulcers appear in critically ill patients in the intensive care unit, including Cushing's ulcers from head injuries and Curling's ulcers from severe burns.

submucosa The layer of connective tissue below the mucosa. Blood vessels, lymph, and nerves reside here.

systemic inflammatory response syndrome An immune response to acute pancreatitis that significantly worsens the patient's prognosis by expanding the scope of tissue damage.

testicular torsion Twisting of a testicle about the spermatic cord to the point of ischemia and possibly necrosis.

third spacing An abnormal increase in the amount of vascular fluid that flows into the intestinal lumen; it can lead to dehydration, electrolyte imbalances, and hypovolemia.

total parenteral nutrition (TPN) The IV administration of all necessary nutrients in a patient whose GI tract does not function.

transjugular intrahepatic portosystemic shunt The placement of a shunt in the abdomen that bypasses much of the hepatic portal system, intended to decrease portal hypertension and its effects.

T tube A T-shaped tube used to drain bile from the gallbladder.

type A gastritis A form of gastritis in which the intrinsic factor secreted by mucosal parietal cells is attacked by autoantibodies, ultimately resulting in pernicious anemia.

type B gastritis A form of gastritis caused by *Helicobacter pylori* and in which the degree of inflammation varies in severity.

ulcerative colitis An inflammation of the rectal mucosal and submucosal tissues.

urinary tract infection (UTI) A common type of infection of the urinary tract that can progress to major

conditions if not treated.

volvulus A twisting of the intestine onto itself, usually causing strangulation.

Zollinger-Ellison syndrome A condition in which a tumor in the GI tract secretes large amounts of acids.

Endocrine Emergencies

Authors

Brian J. Williams, BS, NREMT-P, CCEMT-P

Contributing Authors:

Jane Bedford, RN, CCP

Bob Audet, NREMT-P

Objectives

1. Describe the anatomic structures of the endocrine system and their physiology (p 694–696).
2. Discuss the pathophysiology, assessment, and critical care transport management of conditions related to diabetes, including hypoglycemia, hyperglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic nonketotic syndrome (p 696–701).
3. Discuss the pathophysiology, assessment, and critical care transport management of pituitary disorders, including central diabetes insipidus, pituitary lesions, acromegaly, and gigantism (p 701–702).
4. Discuss the pathophysiology, assessment, and critical care transport management of adrenal abnormalities, including adrenal insufficiency, Addison's disease, Cushing's disease, pheochromocytoma, aldosteronism, and amyloidosis (p 702–706).
5. Discuss the pathophysiology, assessment, and critical care transport management of thyroid abnormalities, including hyperthyroidism, hypothyroidism, myxedema coma, thyrotoxicosis, Hashimoto's disease, and thyroid cancers (p 706–708).
6. Discuss the pathophysiology, assessment, and critical care transport management of lipid disorders, including metabolic syndrome (p 709).

Introduction

Patients with an endocrine disorder will often present with a multitude of signs and symptoms that require a thorough knowledge of history of present illness or injury, the patient's medical history, and a detailed patient assessment. The CCTP will need to consider disorders that involve the endocrine system when assessing a patient's condition. For example, adrenal insufficiency after cardiac surgery can easily be overlooked while other symptoms are present during the unstable postoperative period. If unrecognized, this condition may cause serious morbidity and can be fatal.

Anatomy and Physiology

As a CCTP student, you are likely already familiar with the components of the endocrine system, which are reviewed in **Figure 17-1. Figure 17-2** provides a review of substances secreted by the pituitary gland and their destinations in the body.

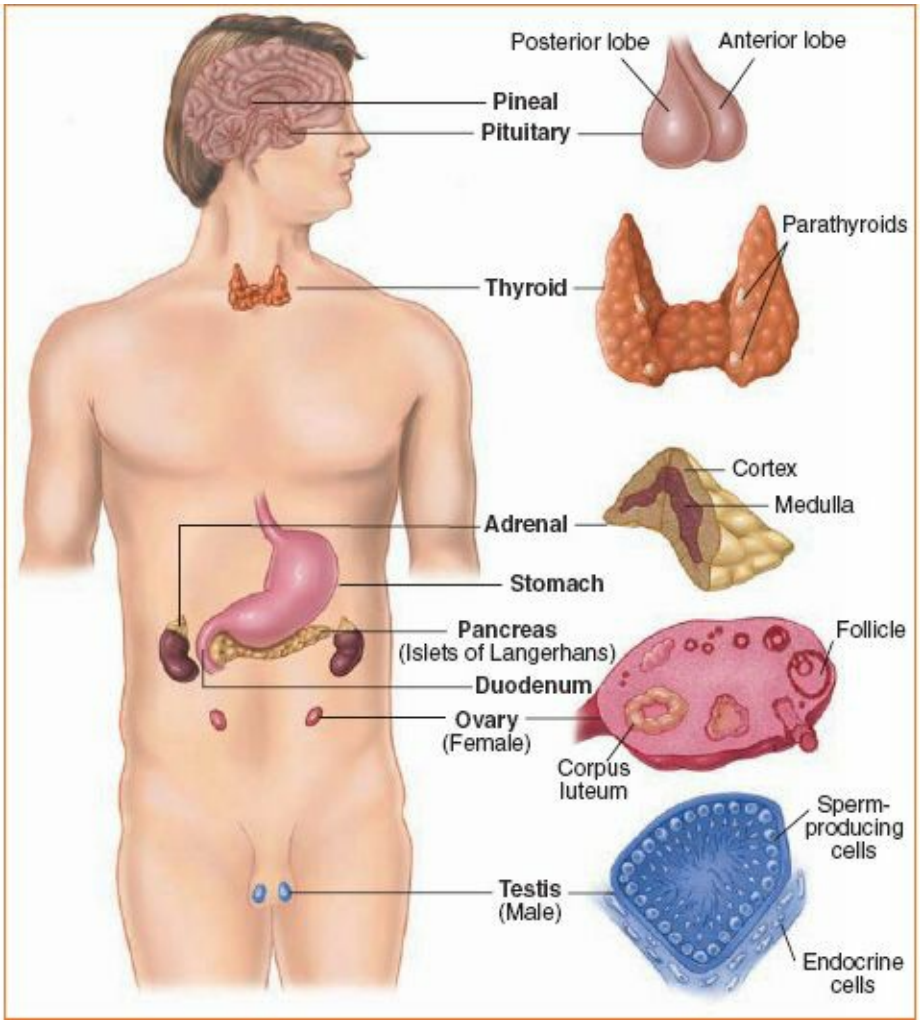

Figure 17-1 The endocrine system uses various glands to deliver chemical messages to organ systems throughout the body.

The Thyroid

The largest gland in the neck, situated in the anterior part of the neck below the skin and muscle layers, is the thyroid gland. It takes the shape of a butterfly, with the left and right thyroid lobes wrapping around the trachea. The function of the thyroid gland is to regulate the body's metabolism by secreting thyroxine when the body's metabolic rate decreases. Thyroxine, the body's major metabolic hormone, stimulates energy production in cells, which increases the rate at which cells consume oxygen and use carbohydrates, fats, and proteins. When the body gets cold, for example, the increased cellular metabolism creates heat. Iodine is an important component of thyroxine. Without the proper level of dietary iodine intake, thyroxine cannot be produced, and a person's physical and mental growth is diminished. The thyroid gland also secretes calcitonin, which helps maintain normal calcium levels in the blood. This hormone is secreted directly into the bloodstream when the thyroid detects high levels of calcium. Calcitonin travels to the bones, where it stimulates the bone-building cells to absorb the excess calcium. It also stimulates the kidneys to absorb and excrete excess calcium.

The location of the thyroid gland, the largest gland in the neck, is important. It is very vascular and if inadvertently nicked during an emergency cricothyrotomy, it will hemorrhage profusely.

The Adrenal Glands

Consisting of two parts, the adrenal glands produce hormones. The outer part is called the adrenal cortex, and the inner part is called the adrenal medulla **Figure 17-3**. Corticosteroids are hormones that are

created in the adrenal cortex. Corticosteroids regulate metabolism, the immune system, and sexual function; they also maintain the balance of salt and water within the body. The adrenal medulla produces catecholamines (the hormones epinephrine and norepinephrine). Catecholamines are involved in regulating autonomic functions, such as increasing the heart rate, respiratory rate, and blood pressure as needed when responding to stress.

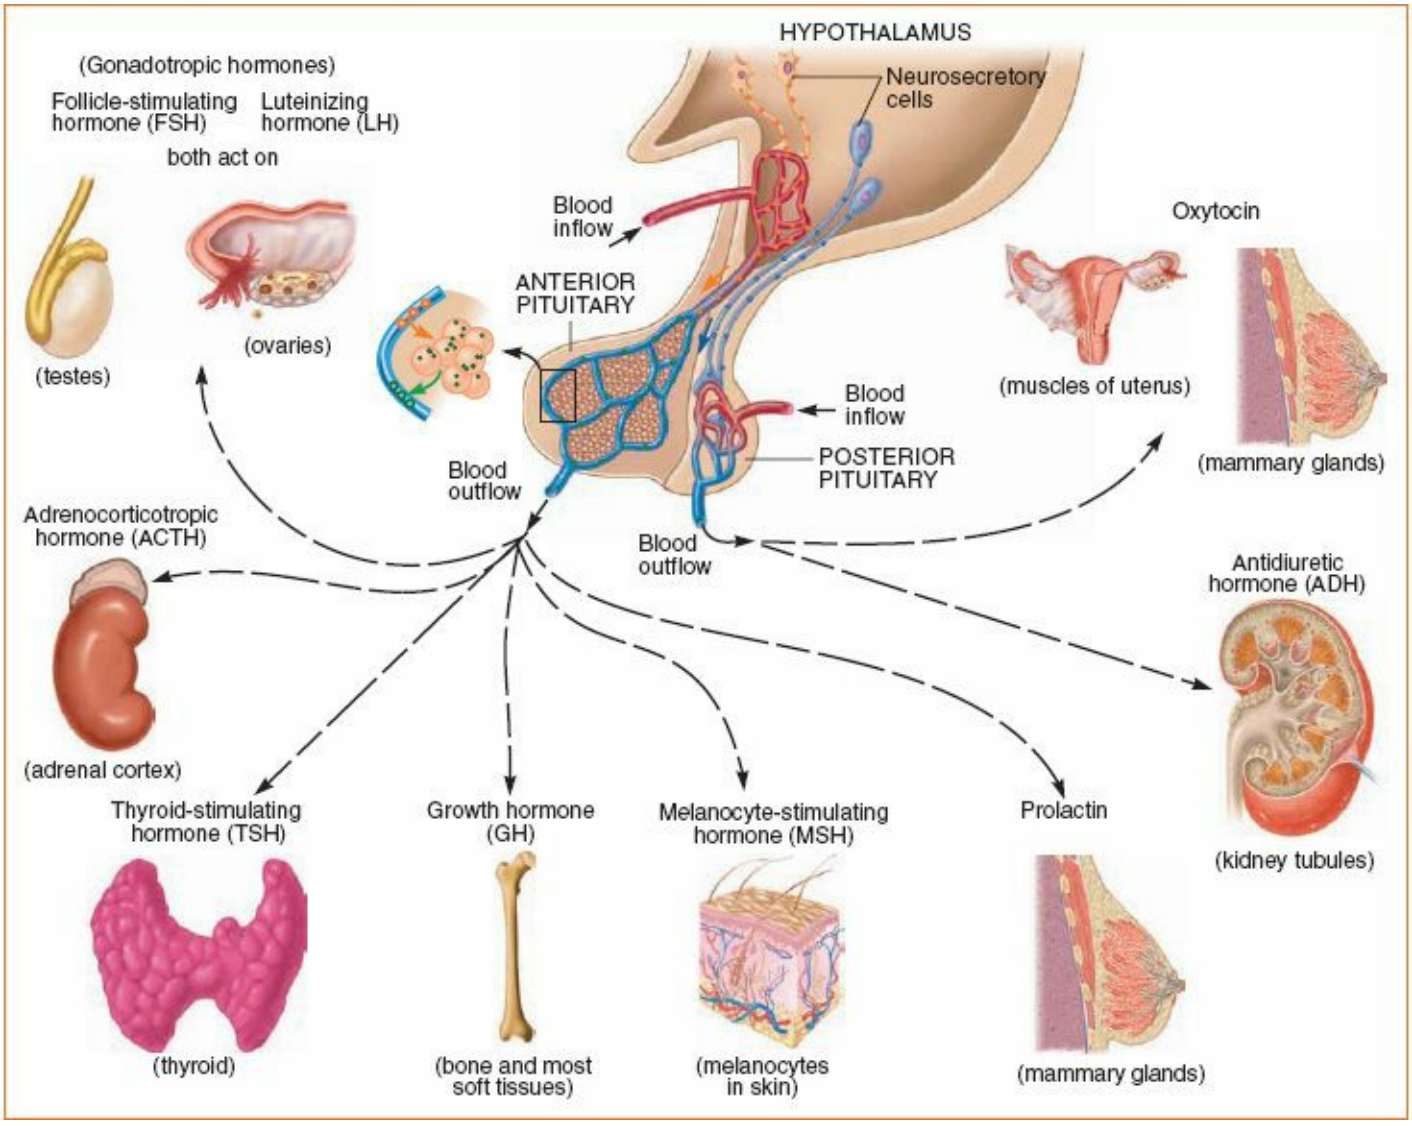

Figure 17-2 The pituitary gland secretes hormones from its two regions: the anterior pituitary lobe and the posterior pituitary lobe.

During times of stress, the hypothalamus secretes a hormone that stimulates the anterior pituitary to release adrenocorticotropic hormone (ACTH). ACTH targets the adrenal cortex, resulting in cortisol (a glucocorticoid) secretion. Cortisol stimulates most body cells to increase their energy production in response to increased stressors.

If the body experiences a drop in blood pressure or volume, a decrease in sodium level, or an increase in potassium level, the adrenal cortex is stimulated to secrete aldosterone (a mineralocorticoid). Aldosterone stimulates the kidneys to reabsorb sodium from the urine and excrete potassium by altering the osmotic gradient in the blood; this action increases both blood volume and blood pressure. Aldosterone also reduces the amount of salt and water lost through the sweat and salivary glands.

The body's reaction to physical or emotional stress is referred to as the "fight-or-flight" response. Following stimulation from the hypothalamus, the adrenal medulla secretes small amounts of norepinephrine and large amounts of epinephrine. Norepinephrine raises blood pressure by causing blood

vessels and skeletal muscles to constrict. Epinephrine stimulates sympathetic nervous system receptors throughout the body. In addition, epinephrine stimulates the liver to convert glycogen to glucose for use as energy in the cells. The action of both hormones results in increased levels of oxygen and glucose in the blood and faster circulation of blood to the brain, heart, and muscles. The body is then able to respond to the short-term emergency situation.

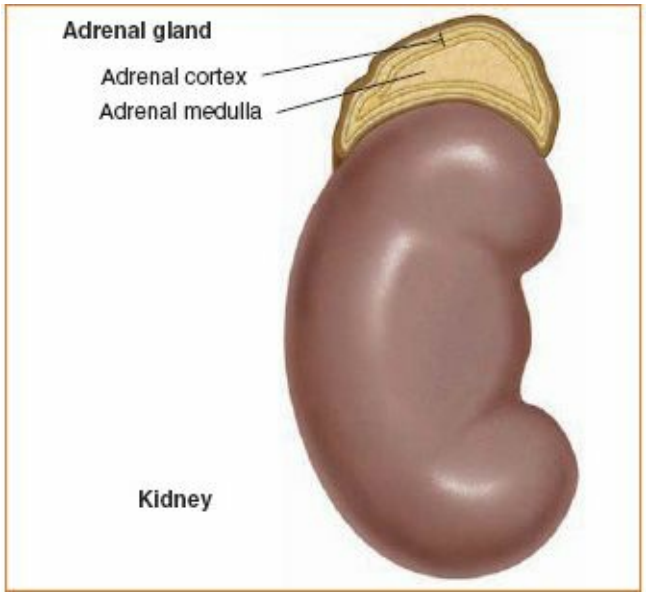

Figure 17-3 The adrenal glands, which sit on top of the kidney, consist of two parts: the adrenal cortex and the adrenal medulla.

Aldosterone

Aldosterone is the principal steroid hormone (mineralocorticoid family) that is produced in the zona glomerulosa (outer zone) of the adrenal cortex and acts primarily at the distal renal convoluted tube. When aldosterone is produced, its function is to increase the reabsorption of sodium and water and release potassium into the kidneys, thereby increasing circulating blood volume and blood pressure. Aldosterone is vital for the management of sodium in the kidneys, salivary glands, sweat glands, and colon.

Abnormal overproduction of aldosterone, resulting from either primary or secondary disorders, is common in the general population and is an important cause of morbidity and mortality.

Pancreas

The pancreas is a digestive gland that is considered an endocrine gland and an exocrine gland. It secretes digestive enzymes into the duodenum through the pancreatic duct. The exocrine component is responsible for the secretion of the digestive enzymes. The endocrine component comprises the islets of Langerhans. These cell groups within the pancreas act like “an organ within an organ.” The main hormones they secrete—glucagon and insulin—are responsible for the regulation of blood glucose levels **Figure 17-4**.

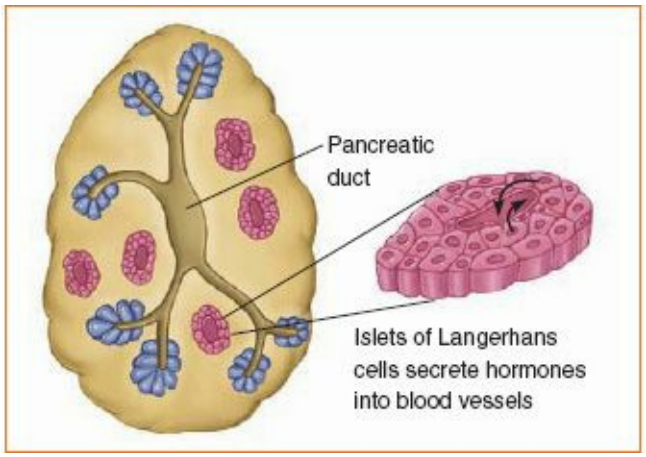

Figure 17-4 The islets of Langerhans secrete hormones into blood vessels.

When the body's blood glucose level falls, such as between meals, the hormone glucagon is secreted to raise the glucose level and bring the body's energy back to normal. When it enters the bloodstream, glucagon stimulates the liver to convert glycogen (a storage starch form of the sugar glucose made up of thousands of glucose units). The glucose is secreted into the bloodstream, where cells can use it for energy.

Insulin is responsible for the removal of glucose from the blood for storage as glycogen, fats, and protein. When blood glucose levels are elevated, the islets of Langerhans secrete insulin, which is carried by the bloodstream to the cells. The cells then take in more glucose to produce energy. Insulin also stimulates the liver to take in more glucose and store it as glycogen for later use by the body. Insulin is the only hormone that decreases the blood glucose levels. Insulin is essential in order for glucose to enter and nourish the cells. Once the blood glucose levels have returned to normal, the islets of Langerhans discontinue the secretion of insulin.

Diabetes

The term diabetes refers to a metabolic disorder in which the ability of the pancreas to metabolize simple carbohydrates (glucose) is impaired because of the lack of insulin or inadequate production of insulin. As mentioned, the pancreas is the primary blood glucose regulator. Digestive enzyme production and insulin and glucagon production take place in the islets of Langerhans. Beta cells in the islets of Langerhans produce insulin and amylin (65% to 80% of the islet cells), alpha cells release glucagon (15% to 20%), and delta cells produce somatostatin (3% to 10%). Insulin and glucagon are the hormones responsible for keeping the blood glucose level within normal ranges of 70 to 110 mg/dL. Diabetes, characterized by the passage of large quantities of urine containing glucose, can cause significant thirst and deterioration of body function.

Glucose that is not used immediately for energy is stored in the liver and muscles as glycogen, or converted by adipose tissue into fat. The liver releases glucose back into the bloodstream when the levels decrease and removes glucose when the levels are too elevated. Only glycogen in the liver can be converted back to glucose; the glycogen stored in muscle can be used only by the muscle for energy.

Insulin is secreted by the beta cells of the pancreas in response to blood glucose levels. After a meal, blood glucose levels rise, stimulating the pancreas to release insulin. The more glucose in the blood, the more insulin the pancreas releases. Insulin transports glucose into the cells via facilitated diffusion, where it is converted into energy. It also has an effect on many cells that play a part in absorbing the glucose, causing the blood glucose levels to return to normal.

Glucagon, which is secreted by the alpha cells, has the opposite effect. When blood glucose levels

are low, the pancreas releases more glucagon. The presence of glucagon stimulates the release of the glucose that is stored in liver cells, making energy available to the tissues between meals.

Diabetes mellitus results from an impairment of the body's ability to produce or use insulin. There are two major types of diabetes mellitus: type 1 and type 2.

Pathophysiology

Type 1 diabetes generally affects children and has historically been referred to as juvenile diabetes, although now patients are developing type 1 diabetes in adulthood as well. Type 1 diabetes has a hereditary predisposition. It is now believed, however, that environmental factors may be part of the cause—for example, an infection that triggers an autoimmune disorder (ie, antibodies destroy the islets of Langerhans).

In type 1 diabetes, most patients do not produce insulin. They require daily injections of supplementary, synthetic insulin throughout their lives to control blood glucose. In addition to daily replacement of insulin through injections or continuous infusion pump, and careful balancing of dietary intake of carbohydrates and simple sugars, physical activity must be in place to achieve good glucose control to avoid extreme highs and lows. This can be a particular challenge in young children, performance athletes, alcoholics, and patients with multiple medical problems.

The most common form of diabetes is **type 2 diabetes** (sometimes called adult-onset diabetes), in which blood glucose levels are elevated. Approximately 90% of all diabetics in the United States have type 2 diabetes, which typically develops later in life, usually when the patient is middle-aged, although the disease is becoming more common in younger people.

In many people with type 2 diabetes, the pancreas actually produces enough insulin; however, for reasons not fully understood, the body cannot effectively use it. This condition is known as **insulin resistance**. One possible explanation is that the insulin receptor cells located on the target cells have changed in some way and are no longer able to receive the insulin when it arrives at the target cell. Type 2 diabetes can also be caused by a deficiency in insulin production.

Hypoglycemia

Hypoglycemia in patients with diabetes is often the result of having taken too much medication, not having eaten enough food, unusual or unexpected physical activity, or high levels of alcohol consumption. The tissues of the central nervous system (including the brain) depend entirely on glucose as their source of energy, which is unlike other tissues, which can usually metabolize fat or protein in addition to glucose. If the blood glucose level drops dramatically, the brain is starved, and if hypoglycemia persists, cerebral dysfunction progresses very quickly to permanent brain damage.

Signs and Symptoms

Hypoglycemia

- Headache
- Altered mental status
- Memory loss
- Blurred or double vision
- Lack of coordination
- Slurred speech
- Stroke-like symptoms

- Seizure
- Hypertension
- Tachycardia
- Diaphoresis
- Chest pain
- Upper abdominal pain
- Tremor
- Anxiety
- Hostility
- Paranoia
- Hunger
- Coma

Normal blood glucose is approximately 70 to 110 mg/dL; hypoglycemia occurs when blood glucose drops to 45 mg/dL or less. Hypoglycemia can develop rapidly, from minutes to a few hours. It should be suspected in any patient with diabetes who presents with bizarre behavior, neurologic signs, or coma.

Of course, diabetics are not the only persons who are prone to episodes of hypoglycemia. Persons who are alcoholics, those who have ingested poisons or overdosed with drugs (notably aspirin), and those with certain cancers, liver disease, kidney disease, profound sepsis, and other conditions may also experience hypoglycemia.

Hyperglycemia and Diabetic Ketoacidosis

Hyperglycemia is one of the classic symptoms of diabetes mellitus and occurs when blood glucose levels exceed the normal range (70 to 110 mg/dL). In patients with a known history of hyperglycemia, physicians typically try to keep the glucose levels at less than 160 mg/dL. Hyperglycemia can be caused by excessive food intake, insufficient insulin dosages, infection or illness, injury, surgery, and emotional stress. Onset may be rapid (within minutes) or gradual (hours to days), depending on the cause. For example, excessive food intake may cause blood glucose levels to rise quickly, whereas an infection or illness will result in hyperglycemia over the course of several days. If left untreated, hyperglycemia in a patient with type 1 diabetes will progress to **diabetic ketoacidosis (DKA)**, a life-threatening condition that occurs when certain acids accumulate in the body because insulin is not available. Patients with this condition tend to be young—teenagers and young adults. In DKA, the deficiency of insulin prevents cells from taking up the extra glucose. Because the body cannot use glucose, it turns instead to other sources of energy—principally, fat. The metabolism of fat generates acids and ketones as waste products. (The ketones give the characteristic fruity odor to the breath of a patient with DKA.) Because glucose must be excreted in the urine in solution, the body loses excessive amounts of water and electrolytes (sodium and potassium). This may lead to disturbances in water balance and acid-base balance.

Special Populations

Pediatric patients with DKA can pose a greater management challenge than adult patients with DKA. Children are more susceptible to rapid shifts in fluid volume and osmolarity, and as such are at much greater risk for cerebral edema as a result of treatment. Although fluid administration is the mainstay of therapy for both children and adults with DKA, a more judicious approach must be used with the pediatric patient. The CCTP must meticulously monitor the inputs and outputs of the patient, and fluids

must be given in 20-mL/kg boluses with careful reassessment after each bolus. Most experts recommend a maximum of three boluses followed by one to one-and-one-half times maintenance fluids using either normal saline or one half normal saline based on age and electrolyte status. Additionally, insulin infusion should be between 0.05 and 0.1 U/kg/h, with a goal of lowering the glucose at a rate of about 50 mg/dL/h.

Meanwhile, glucose continues to accumulate in the blood. As the blood glucose level rises, the patient undergoes massive osmotic diuresis (passing large amounts of urine because of the high solute concentration of the blood). This diuresis, together with vomiting and the rapid, deep respirations will cause progressive dehydration and acidosis, ultimately leading to shock, coma, and death.

These processes usually progress slowly, during a period of 12 to 48 hours, with the patient's level of consciousness deteriorating only gradually.

Signs and Symptoms

Diabetic Ketoacidosis

- Fruity-smelling breath
- Polydipsia
- Polyuria
- Polyphagia
- Nausea and vomiting
- Abdominal pain
- Deep, rapid (Kussmaul) respirations
- Dehydration
- Hypotension
- Tachycardia
- Warm, dry skin and mucous membranes
- Confusion
- Gradual deterioration of consciousness

Hyperosmolar Hyperglycemic Nonketotic Syndrome

Hyperosmolar hyperglycemic nonketotic syndrome (HHNS) is a metabolic derangement that occurs principally in patients with type 2 diabetes. This condition is characterized by hyperglycemia, hyperosmolarity, and an absence of significant ketones. HHNS often develops in patients with diabetes who have some secondary illness that leads to reduced fluid intake. Although infection (in particular, pneumonia and urinary tract infection) is the most common cause, many other conditions can cause altered mentation or dehydration. In most cases, the secondary illness is not identified. Hyperglycemia and hyperosmolarity lead to osmotic diuresis and an osmotic shift of fluid to the intravascular space, resulting in further intracellular dehydration. Unlike patients with DKA, patients with HHNS do not experience ketoacidosis. Although most patients diagnosed as having HHNS have a known history of diabetes (usually type 2), approximately 30% do not have a prior diagnosis of diabetes. The stress response to any acute illness tends to increase hormones that favor elevated glucose levels; cortisol, catecholamines (epinephrine and norepinephrine), glucagon, and many others.

Signs and Symptoms

Hyperosmolar Hyperglycemic Nonketotic Syndrome

- Severe dehydration
- Drowsiness
- Lethargy
- Delirium
- Coma
- Focal or generalized seizures
- Visual disturbances
- Hemiparesis
- Sensory deficits
- Acute myocardial infarction

Assessment

Patients with diabetes mellitus may present with varied physical findings and vital signs on examination, depending on the current blood glucose level. The patient assessment, the patient's history of present illness or injury, and a thorough review of the patient's medical history will aid in determining if a diabetes-related problem is influencing the patient's vital signs and symptoms.

The assessment of the patient with hypoglycemia may reveal headache, altered mental status, memory loss, lack of coordination, strokelike symptoms, and possibly seizures. Hypertension, tachycardia, diaphoresis, chest pain, upper abdominal pain, and anxiety may be present as well because of the release of epinephrine from stimulation of the sympathetic nervous system.

It is important to rule out the possibility of hypoglycemia in patients presenting with signs of intoxication, including slurred speech, lack of coordination, paranoia, hostility, and aggressiveness. These signs may be the direct result of cerebral hypoxia, rather than alcohol or drugs.

Hyperglycemia and DKA typically present with the three Ps: polyuria, polydipsia, and polyphagia. **Polyuria** is a result of osmotic diuresis, **polydipsia** is caused by dehydration, and **polyphagia** is believed to be caused by the body's inefficient use of nutrients. Patients may also experience abdominal pain, which results in nausea and vomiting, thus increasing the degree of dehydration, causing hypotension; tachycardia; warm, dry skin; and dry mucous membranes. The two hallmark signs of DKA are deep, rapid (Kussmaul) respirations, which are the body's attempt to compensate for the resultant acidosis by "blowing off" carbon dioxide, and the fruity odor of ketones on the patient's breath.

Hyperosmolar HHNS presents similarly to DKA; however, it does not produce the two hallmark signs of DKA—Kussmaul respirations and fruity breath odors. Patients with HHNS typically present with severe dehydration and focal or global neurologic deficits, such as drowsiness and lethargy, delirium and coma, focal or generalized seizures, visual disturbances, hemiparesis, and sensory deficits. In addition, an acute myocardial infarction is frequently associated with HHNS. **Table 17-1** compares DKA with HHNS.

Laboratory Assessment

Testing for hypoglycemia or hyperglycemia is one of the limited testing procedures that a CCTP will be able to perform during transport, allowing for easy administration and/or titration of existing medications as a result of the biochemical analysis.

Because glucose is one of the three major energy sources for the body, it is important to routinely monitor the patient's blood glucose level during transport. Most commonly, this is accomplished via a

portable blood glucose monitor (glucometer) **Figure 17-5**, similar to the one the patient may use at home. The portable blood glucose monitor measures the glucose level in whole blood using either capillary or venous samples. Blood glucose testing performed in a laboratory measures the blood glucose level in the plasma, which is typically about 10 mg/dL higher than that in a whole blood sample.

It is important to read and understand the operator's manual prior to use because of variabilities in glucometer manufacturer specifications. Some glucometers will read "Lo" when a glucose reading below 20 mg/dL is detected, whereas others will display "Lo" when a reading below 30 mg/dL is detected. Inversely, the same is true with a "Hi" reading; some glucometers read "Hi" at 550 mg/dL, and some read "Hi" at 600 mg/dL, so it is important to know both the upper and lower ranges of the glucometer.

The normal lab value for glucose in whole blood in nonfasting adults and children is 70 to 110 mg/dL; in a neonate, blood glucose levels should be maintained above 65 mg/dL.

Arterial or venous blood gas monitoring should also be used in patients with DKA. Monitoring commonly reveals metabolic acidosis with a pH below 7.30, a bicarbonate level below 15 mEq/L, and a $Paco_2$ level below 30 mm Hg.

Laboratory testing for diabetics may also include a urine ketone test, which results in either a positive or a negative reading, depending on whether it detects ketones in the urine. Generally blood chemistries and blood testing for ketones is indicated to detect elevations in BUN and creatinine that may result from significant dehydration, detect electrolyte abnormalities (which can be profound), and to calculate anion gap which, when calculated in the presence of serum ketones, is used to guide ongoing insulin infusion therapy. The patient's creatinine and blood urea nitrogen levels may be elevated as well because the patient is dehydrated.

TABLE 17-1 Diabetic Ketoacidosis vs Hyperosmolar Hyperglycemic Nonketotic Syndrome

	Diabetic Ketoacidosis	**Hyperosmolar Hyperglycemic Nonketotic Syndrome**
Onset	Hours to days	Days to weeks
Cardiovascular	Tachycardia Hypotension	Tachycardia Hypotension
Respiratory	Kussmaul-type pattern Fruity odor	Normal to tachypnea Normal odor
Integumentary	Warm, dry Nonpyretic	Warm, dry Normal to pyrexia
Gastrointestinal	Polyphagia Polydipsia Polyuria	Polyphagia Polydipsia Polyuria
Urinalysis	Glucose present Ketones present	Glucose present Ketones absent
Blood chemistry	pH: < 7.30 Bicarbonate: < 15 mEq/L Glucose: > 300 mg/dL Sodium: normal Carbon dioxide: elevated	pH: normal Bicarbonate: normal Glucose: > 600 mg/dL Sodium: > 145 mEq/L Carbon dioxide: normal
	20-mL/kg bolus of isotonic crystalloid,	20-mL/kg bolus of isotonic crystalloid,

Treatment	repeated as needed IV insulin Continuous insulin infusion	repeated as needed IV insulin

Figure 17-5 A portable glucometer used in the critical care transport environment.

A diabetic patient may also have had a hemoglobin A1c, or glycohemoglobin, test completed prior to transport, although this test is typically not performed during an acute emergency. As a result of prolonged hyperglycemia, the red blood cells become saturated with glucose. A measurement is made using a percentage of saturation in an attempt to estimate the patient's blood glucose level during the previous 3 to 4 months. Typically, nondiabetic patients will have a hemoglobin A1c level between 4% and 6%. In diabetic patients, a measurement below 7.5% indicates good control, a measurement of 7.6% to 8.9% indicates fair control, and a measurement of 9.0% or more indicates poor control or no control of diabetes.

Management

Patients presenting with hypoglycemia should have the condition corrected prior to initiating transport. Standard treatment for hypoglycemia in adults is 50% dextrose; and in pediatric patients, 25% dextrose. However, the CCTP may be called on to transport a patient who remains hypoglycemic as a result of an intentional or unintentional insulin overdose. In these cases, a continuous dextrose infusion may be required. This may be accomplished by adding 50 g of 50% dextrose (two amps of D_{50}) to 1,000 mL of normal saline (making $D_{10}NS$) and titrating the infusion to the patient's blood glucose level.

As a result of profound dehydration in the hyperglycemic patient (with DKA and HHNS), fluid boluses with an isotonic saline solution should be initiated via an IV, intraosseous, or central line at a volume of 20 mL/kg, repeated as needed in an effort to stabilize the intravascular volume. After the intravascular volume has been normalized, short-acting insulin, such as a human insulin isophane suspension (Humulin N), should be administered at a dosage of 2 to 12 U IV, followed by a continuous insulin infusion of 2 to 10 U/h, in an attempt to decrease the blood glucose level to approximately 180 mg/dL. As the glucose is brought under control, the body begins to process the buildup of ketones that are the hallmark of DKA. The insulin infusion to treat DKA should be continued until there are no longer ketones present in the serum. For the CCTP, this may mean adding glucose to maintenance fluids and/or periodic administration of D_{50} in order to maintain glucose levels in the normal range while the insulin infusion is continued. In general, insulin drips should *not* be titrated based on glucose results in patients with DKA. During the hyperglycemic episode, the patient may become hypokalemic as well. An IV infusion of potassium should be initiated if the patient's serum potassium level is below 4.8 mEq/L via

laboratory studies. This infusion is typically accomplished by adding 40 mEq of potassium to 1,000 mL of normal saline and infusing at 5 to 10 mEq/h.

Patients being treated for hyperglycemic problems should have continuous cardiac monitoring for potential cardiac arrhythmias and hypokalemia. As with all patients the CCTP will encounter, definitive airway management and ventilatory assistance may be required. If there is a possibility of aspiration because of a decreased level of consciousness, insertion of a nasogastric tube should be considered. If urine output is desired during transport, an indwelling (Foley) catheter should be inserted as well.

Recent controversy has arisen with regard to the control of glucose levels in critically ill patients. Historically, continuous insulin infusions have been used in the intensive care unit to maintain an intensive control (81 to 108 mg/dL) of the glucose level as a means of reducing morbidity and mortality. In the March 26, 2009, issue of the *New England Journal of Medicine*, the Normoglycemia in Intensive Care Evaluation—Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study found that by utilizing a conventional control (below 180 mg/dL) of glucose, there was an increased likelihood of morbidity and mortality if intensive controls were utilized, as opposed to conventional controls.

Transport Management

Hypoglycemia

- Test for hypoglycemia/hyperglycemia.
- Administer a continuous dextrose infusion, if required, and titrate the infusion to the patient's blood glucose level.

Numerous studies in the cardiac surgery patient subset demonstrate decreased infections and better survival when intensive controls are utilized, and it would stand to reason that these values could be applied to the rest of the critically ill patient population (noncardiac surgery patients); however, as a result of the NICE-SUGAR study, this seems untrue. This is not to say that insulin infusions are unhelpful in noncardiac surgery patients, only that an as-of-yet unknown target value should be utilized. The NICE-SUGAR study sought to determine optimal glucose levels to improve outcomes in critically ill patients and found only that intensive controls were less than optimal. This should not be interpreted as a call for abandoning good glucose management practices for critically ill patients.

CCTPs can expect to see continuous insulin infusions in almost any patient admitted to an intensive care unit who subsequently requires transfer to another hospital. When insulin infusions are used in critically ill patients, there is an appreciable decrease in both mortality and morbidity. The controversy is as follows: (1) whether the increased survival results from the insulin infusion or the control of the blood glucose level and (2) what is the optimal blood glucose target for improved outcomes in critically ill patients.

To add to the controversy, most institutions have their own protocols for insulin infusions. All are very different, and the incidences of hypoglycemia between the various protocols vary widely. Research has shown that hypoglycemic episodes increase morbidity and mortality and may negate the benefits of the insulin infusion in some patient populations.

Nevertheless, the CCTP should understand that insulin infusion is a routine part of care, requiring vigilance in monitoring during transport, including frequent (hourly or more often) checks of blood glucose levels using a blood glucometer, and may require adjustments in the insulin infusion rate to maintain the blood glucose targets prescribed for that patient.

Transport Management

Hyperglycemia (DKA and HHNS)

- Replenish fluids via an IV, an intraosseous, or a central line.
- Administer short-acting insulin, such as Humulin, followed by a continuous insulin infusion.
- Administer sodium bicarbonate for acidosis.
- Administer an IV infusion of potassium if the patient becomes hypokalemic.
- Provide continuous cardiac monitoring.
- Provide airway management and ventilatory assistance if required.
- Insert an indwelling (Foley) catheter if urine output is desired.

TABLE 17-2 Common Medications Used to Treat Diabetes Mellitus

Medication Class	Examples
Sulfonylureas	Acetohexamide (Dymelor) Chlorpropamide (Diabinese) Tolbutamide (Orinase) Tolazamide (Tolinase) Glipizide (Glucotrol) Gliclazide (Glipizide) Glibenclamide (Glyburide) Gliquidone (Glurenorm) Glimepiride (Amaryl)
Biguanides	Metformin (Glucophage)
Thiazolidinediones	Rosiglitazone (Avandia) Pioglitazone (Actos)
Alpha-glucosidase inhibitors	Acarbose (Precose) Miglitol (Glyset)
Meglitinides	Repaglinide (Prandin) Nateglinide (Starlix)
Dipeptidyl peptidase IV (DPP-IV) inhibitors	Vildagliptin (Galvus) Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin (Ondero)
Carbohydrates	50% Dextrose in water 25% Dextrose in water 10% Dextrose in water
Pancreatic hormones	Glucagon (GlucaGen) Insulin Premixed insulin – Humulin 70/30

	– Novolin 70/30 – NovoLog 70/30 – Humulin 50/50 – Humalog mix 75/25
Rapid-acting insulin	Humalog mix NovoLog
Short-acting insulin	Humulin Novolin
Intermediate-acting insulin	Neutral Protamine Hagedorn Lente
Long-acting insulin	Ultralente Insulin glargine (Lantus)

Table 17-2 lists common medications used to treat diabetes mellitus.

Pituitary Disorders

When a patient is experiencing a pituitary disorder, the presenting signs and symptoms commonly mirror other disease processes, requiring you to obtain a thorough medical history and conduct a physical exam in order to narrow down the condition to a potential pituitary problem. Failure to recognize these disorders, although they are seldom life threatening, could have an impact on your patient's well being.

Pathophysiology

The pituitary gland, commonly referred to as the "master gland," secretes hormones that regulate the secretions of other endocrine glands. Located at the base of the brain, approximately the size of a grape, it is attached to the hypothalamus by a very thin piece of tissue. This gland is divided into the following two lobes: (1) the anterior pituitary, which produces and secretes six hormones (growth hormone, thyroid-stimulating hormone [TSH], ACTH, and three gonadotropic hormones); and (2) the posterior pituitary, which secretes two hormones (antidiuretic hormone and oxytocin) but does not produce them.

Central Diabetes Insipidus

Central diabetes insipidus occurs when the posterior part of the pituitary gland is damaged, which causes a lack of production of the antidiuretic hormone vasopressin. The damage may be caused by traumatic head injuries, neurosurgery, or genetic abnormalities. Because of the lack of antidiuretic hormone, patients frequently experience unregulated fluid losses, which leads to dehydration.

Signs and Symptoms

Central Diabetes Insipidus

- Polyuria
- Polydipsia
- Dehydration

Pituitary Lesions

Pituitary lesions can be classified into the following two types: functioning adenomas and nonfunctioning adenomas. **Nonfunctioning adenomas**, which account for 40% of pituitary lesions, are tumors that do not secrete hormones. With **functioning adenomas**, which make up the remaining 60% of pituitary tumors, overproduction of hormones can occur depending on the type of hormone the adenomas produce:

- ACTH-secreting adenomas, which are responsible for Cushing's disease
- Growth hormone-secreting adenomas, which are responsible for acromegaly and gigantism
- Prolactin-secreting adenomas, which are responsible for gynecologic problems

Acromegaly and Gigantism

Acromegaly is a syndrome that results from excessive growth hormone, secreted by the pituitary gland *after* the epiphyseal plate has closed. Commonly affecting middle-aged adults, acromegaly can result in disfigurement and premature death if left untreated. Because of the slow progression of the syndrome, definitive diagnosis often goes undiagnosed for many years, until enlargement appears in the hands, feet, and face. Acromegaly is often associated with gigantism.

Signs and Symptoms

Acromegaly and Gigantism

- Abnormally fast growth of bones, muscles, and internal organs

TABLE 17-3 Common Medications Used to Treat Acromegaly and Gigantism

Medication Class	Examples
Dopaminergic agonist	Bromocriptine (Parlodel)
Somatostatin analog	Octreotide (Sandostatin) Lanreotide (Somatuline)
Growth hormone receptor antagonist	Pegvisomant (Somavert)

Gigantism, on the other hand, results from excessive growth hormone secreted by the pituitary gland *before* the epiphyseal plate has closed.

Regardless of the onset (childhood or adulthood), both of these conditions are characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate. Acromegaly and gigantism are almost always caused by a benign pituitary tumor.

Assessment

The assessment of patients presenting with acromegaly or gigantism will follow the same assessment steps as other patients, ensuring that a detailed medical history and answers to questions about weight gain as well as excessive and rapid growth are obtained.

Laboratory Assessment

Patients presenting with acromegaly and gigantism typically present with elevated creatinine levels (> 1.2 mg/dL). Because acromegaly and gigantism are a result of excessive growth hormone production, growth hormone levels will be elevated (> 18 ng/mL).

Management

There are currently two medications that are used to treat acromegaly and gigantism. Bromocriptine (Parlodel), which is a dopaminergic agonist, is used to decrease growth hormone secretion. Octreotide (Sandostatin) and lanreotide (Somatuline), synthetic forms of the hormone somatostatin, stop growth hormone production entirely. A recent development of acromegaly and gigantism is the use of pegvisomant (Somavert), which is a growth hormone receptor antagonist. Pegvisomant is able to control acrogmegaly and gigantism in virtually all patients because of the blocking action of the endogenous growth hormone molecules.

Table 17-3 lists common medications used to treat acromegaly and gigantism.

Adrenal Abnormalities

There are many abnormalities of the adrenal glands. Some are hereditary (familial adrenal hypoplasia syndromes), others are steroid resistance and hypersensitivity abnormalities such as glucocorticoid resistance syndromes and states, and there are genetic disorders such as adrenal insufficiency as a result of x-linked adrenoleukodystrophy.

Pathophysiology

Conditions associated with **pseudo-Cushing's states** are a mixed group of disorders that are related to increased cortisol production. The physiologic conditions that cause increased cortisol production include surgery-associated stress, severe illness, emotional stress, intense aerobic exercise, and caloric restriction. Nonphysiologic conditions that may elevate cortisol production include chronic alcoholism and alcohol withdrawal syndrome, poorly controlled diabetes mellitus, and obesity.

Endocrine hypertension is a result of hormonal disorders that cause clinically significant hypertension. The most common causes of endocrine hypertension are excess production of mineralocorticoids, such as aldosterone; catecholamines, such as epinephrine, norepinephrine, and dopamine; and glucocorticoids, such as cortisol. The cause of endocrine hypertension often relates to excess hormone produced by a tumor. Endocrine hypertension can be treated with surgery or antihypertensive therapy.

Adrenal Insufficiency

Underproduction of cortisol and aldosterone caused by decreased functioning of the adrenal cortex is called **adrenal insufficiency (AI)**. When at least 90% of the adrenal cortex has been damaged, AI occurs. A function of cortisol is to help the body respond to stress, including stress caused by surgery, illness, or infection. The hormone also aids in maintaining normal blood pressure and cardiovascular functions and regulating the metabolism of proteins, carbohydrates, and fats. AI may affect the adrenal gland (idiopathic adrenal insufficiency) or other glands (polyendocrine deficiency syndrome).

Primary causes of adrenal insufficiency include:

- Autoimmune disorders (such as with Hashimoto's disease)
- Illness or increased stress Genetic disorders
- Renal injuries
- Radiation therapy
- Surgery Infections
- Pituitary and hypothalamic lesions

Men and women of all ages are equally affected by AI. Causes of permanent AI include Addison's

disease, congenital adrenal hyperplasia, and complete surgical removal of the pituitary gland or the adrenal glands. Temporary AI can be caused by physical stress, infections, surgery, or failure to take corrective medication as required.

In the patient with chronic AI, signs and symptoms of **Addisonian crisis** may appear suddenly as a result of an increased period of stress, trauma, surgery, or severe infection. The primary clinical manifestation of Addisonian crisis is shock. Other symptoms include weakness, altered mental status, hyperthermia, and severe pain in the lower back, legs, or abdomen. Severe vomiting and diarrhea may precipitate dehydration in these patients. The ACTH stimulation test is the most specific test for diagnosing AI. The test measures blood cortisol levels (normal range, 10 to 60 ng/L). Undiagnosed, AI is a potentially fatal disease that usually results in death from hypotension or cardiac arrhythmias as a result of hyperkalemia. Acute AI may present in postsurgical or trauma patients. One study showed that as many as 5% of general surgical patients were affected by postoperative AI.

Signs and Symptoms

Addisonian Crisis

- Shock
- Weakness
- Altered mental status
- Hyperthermia
- Severe pain in the lower back, legs, or abdomen
- Severe vomiting and diarrhea
- Dehydration

Patients with moderate or severe traumatic brain injury present with some form of AI in approximately 50% of injury cases. Patients with traumatic brain injury receiving high-dose pentobarbital or propofol as well as patients with vasopressors used to manage lower blood pressures should be carefully monitored for AI.

Addison's Disease

Addison's disease is a chronic hormonal or endocrine disorder that occurs in patients of all age groups, caused by a deficiency in cortisol and/or aldosterone. Addison's disease is characterized by weakness, fatigue, hypotension, unexplained weight loss, and darkening of the skin **Figure 17-6**. Although other AI conditions are acute, Addison's disease is chronic.

Most cases of Addison's disease are caused by the slow destruction of the adrenal cortex. Addison's disease affects about 1 in 100,000 people.

Treatment of Addison's disease is the same as that of acute AI conditions. Prognosis is good for well-managed adult-onset Addison's disease, with a normal average mortality rate; however, recent studies show that young patients with Addison's disease are at risk for premature death. In patients diagnosed at a young age, Addison's disease is still a potentially lethal condition, with excess mortality in acute adrenal failure, infection, and sudden death.

Figure 17-6 The hand of a patient with Addison's disease (right) compared with the hand of a healthy subject (left).

Signs and Symptoms

Addison's Disease

- Weakness
- Fatigue
- Hypotension
- Unexplained weight loss
- Darkening of the skin

Cushing's Syndrome

Cushing's syndrome, also known as hypercortisolism, is caused by prolonged exposure to elevated levels of cortisol in the body. The syndrome is relatively rare and affects persons between 20 and 50 years old. Risk factors for Cushing's syndrome are obesity, poorly controlled type 2 diabetes, and hypertension. Patients taking glucocorticoids, such as prednisone for inflammatory diseases, are also at risk for developing Cushing's syndrome.

Regardless of the cause, excess cortisol causes characteristic changes in many body systems. The metabolism of carbohydrates, protein, and fat is disturbed, causing hyperglycemia. Protein synthesis is impaired so that body proteins are broken down, which leads to loss of muscle fibers and muscle weakness. Bones become weaker and more susceptible to fracture. Other common signs and symptoms include the following:

- Weakness and fatigue
- Depression and mood swings
- Increased thirst and urination
- Weight gain, especially on the abdomen, face ("moon face") **Figure 17-7**, neck, and upper back ("buffalo hump") **Figure 17-8**
- Thinning of the skin, with easy bruising and pink or purple stretch marks (striae) on the abdomen, thighs, breasts, and shoulders

Signs and Symptoms

Cushing's Syndrome

- Hyperglycemia
- Weakness and fatigue
- Depression and mood swings
- Increased thirst and urination
- Weight gain (especially on the abdomen, face, neck, and upper back)
- Thinning of the skin; easy bruising and pink or purple stretch marks on the abdomen, thighs, breasts, and shoulders
- Increased acne and facial hair growth; in women, scalp hair loss and cessation of menstrual periods
- Darkening of skin on the neck
- Obesity and poor growth in height in children

Figure 17-7 Weight gain in the face as a result of Cushing's syndrome.

Figure 17-8 Weight gain in the upper part of the back as a result of Cushing's syndrome.

- In women increased acne, facial hair growth, scalp hair loss, and cessation of menstrual periods
- Darkening of skin (acanthosis) on the neck
- Obesity and poor growth in height in children

Pheochromocytoma

A **pheochromocytoma** is a catecholamine-producing benign tumor of chromaffin cells, located in the center of the adrenal gland, which can occur either sporadically or chronically as a result of genetic risk factors. The catecholamines produced include epinephrine, norepinephrine, and occasionally dopamine. This catecholamine release causes stimulation of alpha-adrenergic receptors, resulting in hypertension, increased cardiac contractility, glycogenolysis, gluconeogenesis, and intestinal relaxation. Stimulation of the beta-adrenergic receptors results in an increase in heart rate and contractility. Although the majority of the pheochromocytomas are found in the adrenal glands, pheochromocytoma can be found anywhere there is chromaffin tissue. Of pheochromocytomas, 97% are in the abdomen, 2% are in the thorax, and the remaining 1% are in other body areas.

Investigation of sustained hypertension leads to a diagnosis of pheochromocytomas in 0.05% to 0.2% of patients. Pheochromocytoma can be corrected in about 90% of cases if identified. If left untreated, fatal events such as catecholamine-induced malignant hypertension, heart failure, myocardial infarction, stroke, or ventricular arrhythmias occur.

Definitive treatment of pheochromocytoma is surgery to remove the tumor. Patients with pheochromocytoma should be treated with appropriate preoperative medical management to block the effects of released catecholamines.

Patients can experience a hypertensive crisis as a result of the rapid increase in catecholamines released from the tumor. Patients may present with a hypertensive crisis in varying ways, such as severe headaches or diaphoresis, visual disturbances, palpitations, epistaxis, acute myocardial infarction, congestive heart failure, or cerebrovascular accidents. Antihypertensive therapy must begin immediately. Treatment of a hypertensive crisis as a result of pheochromocytoma should include phentolamine. The dosage is an IV bolus of 2.5 to 5 mg at 1 mg/min. Because of the short half-time of phentolamine, this dose can be repeated every 5 minutes until hypertension is adequately controlled (decreasing the systolic blood pressure by no more than 20% to 25%). A continuous infusion of phentolamine (100 mg of phentolamine in 500 mL of 5% dextrose in water) titrated to the patient's blood pressure may be preferred to bolus dosing.

Some patients remain hypertensive immediately following surgery, although the majority present with hypotension that requires treatment with fluids. Hypoglycemia is another complication after surgery that is prevented by infusion of 5% dextrose started immediately after tumor removal and continuing for several hours thereafter. Post-operative hypoglycemia is transient, whereas hypotension may continue for several days or more after surgery.

Signs and Symptoms

Pheochromocytoma

- Hypertension
- Increased heart rate
- Severe headache
- Diaphoresis
- Visual disturbances
- Palpitations
- Chest pain
- Upper abdominal pain
- Epistaxis

- Anxiety
- Acute myocardial infarction
- Congestive heart failure
- Cerebrovascular accident

Transport Management

Pheochromocytoma

- Administer an IV bolus or a continuous infusion of phentolamine.

The long-term prognosis of patients after pheochromocytoma excision is excellent; however, nearly half of these patients will experience resultant life-long hypertension.

Aldosteronism

Aldosteronism is a syndrome of high blood pressure and low blood potassium levels caused by an excess of aldosterone. There are two main types of aldosteronism, primary and secondary.

Primary aldosteronism is usually caused by a tumor of a single adrenal gland that overproduces aldosterone. This is also known as Conn's syndrome. More than 95% of the cases are benign. Rarely, however, these tumors may be malignant. **Secondary aldosteronism** results from other conditions not associated with the adrenal gland. It can be caused by obstructive renal artery disease, renal vasoconstriction, and edematous disorders, and occurs as a result of reduced renal blood flow. The reduced blood flow stimulates hypersecretion of aldosterone.

Aldosteronism is suspected in patients with hypertension and low blood potassium levels, because aldosterone's normal function is to increase sodium and fluid in the bloodstream and potassium excretion in the kidney. Elevated aldosterone levels can be measured via blood or urine chemistry. A special blood test called plasma renin activity is measured to distinguish between primary aldosteronism (low plasma renin activity) and secondary aldosteronism (high plasma renin activity). Once blood chemistry testing is completed, a computed tomo-graphic (CT) scan of the abdomen may be performed to confirm the location of the disease. Surgery is the treatment for aldosteronism if the primary cause is a single adenoma. When the cause does not lie within the adrenal gland, treatment is to correct the underlying condition that led to the elevated aldosterone levels.

Signs and Symptoms

Aldosteronism

- Hypertension
- Low blood potassium levels
- Alkalosis
- Muscular weakness
- Polyuria
- Polydipsia
- Edema
- Heart failure

- Hepatic cirrhosis

Amyloidosis

Amyloidosis is a group of diseases that result from abnormal deposits of the protein amyloid in various tissues of the body. This protein can be deposited in a localized area or it may affect tissues throughout the body in a systemic fashion. Systemic amyloidosis can cause serious changes in virtually any organ of the body and can cause the affected organs to fail.

Signs and Symptoms

Amyloidosis

- Pedal edema
- Weight loss
- Dyspnea
- Weakness
- Diarrhea
- Fatigue
- Cardiac arrhythmias

Primary amyloidosis is the most common form of amyloidosis and affects the heart, kidneys, tongue, nerves, and intestines. Primary amyloidosis is associated with multiple myeloma, a form of bone marrow cancer, in a minority of cases. Primary amyloidosis is classified as an apolipoprotein.

Secondary amyloidosis occurs as a result of another illness, such as multiple myeloma, chronic infections, or chronic inflammatory diseases. Secondary amyloidosis is classified as an amyloid A protein. The disease primarily affects the kidneys, spleen, liver, and lymph nodes, although other organs may be involved. Treatment of the underlying disease may help stop this form of amyloidosis. There is no known cure for amyloidosis. Therapies are directed at managing symptoms and limiting the production of amyloid protein.

Assessment

Patients with adrenal abnormalities may present with varied physical findings and vital signs on examination. The patient assessment, history of present illness or injury, and thorough review of medical history will aid in determining whether adrenal abnormalities are influencing the patient's vital signs and symptoms. It is important to emphasize the need to be aware of the possibility of adrenal complications to aid in the correct diagnosis. Treatment of adrenal abnormalities could easily escape recognition and, thus, contribute to needless increased morbidity and mortality.

In addition to the medical history and physical exam, a diagnosis of Cushing's syndrome or Cushing's disease requires laboratory studies demonstrating high levels of blood cortisol.

The assessment of the patient with pheochromocytoma may reveal hypertension and other symptoms associated with catecholamine release, such as tachycardia, diaphoresis, chest pain, upper abdominal pain, and anxiety.

Primary aldosteronism typically presents with hypokalemia, alkalosis, muscular weakness, polyuria, polydipsia, and hypertension.

Secondary aldosteronism is commonly associated with edematous states, heart failure, hepatic cirrhosis, and malignant hypertension.

Signs and symptoms of amyloidosis depend on the organ system affected and include pedal edema, weight loss, dypsnea, weakness, diarrhea, fatigue, and cardiac arrhythmias.

Laboratory Assessment

Laboratory testing is required to definitively diagnose these underlying health factors and will vary with the disease process.

TABLE 17-4 Common Medications Used to Treat Adrenal Conditions

Medication Class	Examples
Adrenal Insufficiency Synthetic glucocorticoids	Fludrocortisone acetate (Florinef), taken once a day
Cushing's Syndrome Synthetic cortisol	Ketoconazole (Nizoral), mitotane (Lysodren), metyrapone (Metopirone), prednisone, hydrocortisone, dexamethasone (Dosages depend on the cause of the syndrome and the treatment plan).
Pheochromocytoma Antihypertensives	Phentolamine: IV bolus of 2.5 to 5 mg at 1 mg/min; sodium nitroprusside (preparation similar to phentolamine) at 0.5 to 10.0 μg/kg/min (stop if no results are seen after 10 min)
Aldosteronism	Treatment for primary aldosteronism depends on the underlying cause
Amyloidosis	Treatment is directed at managing symptoms and limiting the production of amyloid protein; it includes melphalan (Alkeran or Alkeran IV), a chemotherapy agent, and dexamethasone; new drugs being tested for use in amyloidosis include bortezomib (Velcade), thalidomide (Thalomid), and lenalidomide (Revlimid)

The ACTH stimulation test, along with the cortisol test, is the most specific combination of tests for diagnosing Addison's disease. In these tests, a synthetic form of ACTH is injected, then blood and urine cortisol are measured before and after the injection is given. A healthy patient will exhibit a rise in blood and urine cortisol levels after an injection of ACTH, but patients with adrenal insufficiency will have less of an increase, or no increase. The normal range for cortisol levels in adults is 5 to 25 μg/dL. The normal range for aldosterone levels in adults is 2 to 9 ng/dL.

No increase in blood and urine cortisol levels indicates that the pituitary gland is the origin of the condition, whereas a delayed increase indicates that the hypothalamus is the origin of the condition. More specifically, patients with primary adrenal insufficiency have high ACTH levels but do not produce cortisol. Patients with secondary adrenal insufficiency have decreased cortisol responses but absent or delayed ACTH responses.

Unlike adults, children are more likely to have absolute adrenal insufficiency, defined by a basal cortisol level of less than 18 μg/dL and a peak ACTH-stimulated cortisol concentration of less than 18 μg/dL. Patients at risk of inadequate cortisol or aldosterone production in the setting of shock include children with purpura fulminans and Waterhouse-Friderichsen syndrome, children who previously received corticosteroid therapies for chronic illness, and children with pituitary or adrenal insufficiency.

Management

Treatment of adrenal diseases usually involves replacing, or substituting, the hormones that the adrenal glands are not making and varies depending on the cause of the condition and the clinical presentation and severity of symptoms.

The initial treatment of an acute adrenal crisis is the correction of hypovolemic shock via fluid resuscitation. Large volumes of an isotonic crystalloid (500 to 1,000 mL) solution should be given by IV or intraosseous routes. For a patient diagnosed with glucocorticoid deficiency, IV dexamethasone sodium phosphate or hydrocortisone sodium succinate may be administered. Dexamethasone has a long duration of action and does not interfere with serum or urinary steroid testing; therefore, it is preferable.

Table 17-4 lists common medications used to treat adrenal conditions. Although treatment of the patient with pituitary disorders in the acute setting is rare, the CCTP should appreciate the impact that these disease processes have on the patient's day-today life, and should keep a high index of suspicion when confronted with the patient who may be presenting with these signs and symptoms.

Thyroid Abnormalities

As a CCTP, you will seldom be called upon to transport a patient with a life-threatening condition as a result of a thyroid abnormality. However, with a high index of suspicion and available laboratory studies, you should be in a position to appreciate the long-term outlook of the patient's care in relation to your care of the patient's concurrent medical problems.

Pathophysiology

The thyroid gland, as a primary controller of the body's metabolism, produces the hormones T3 (triiodothyronine) and T4 (thyroxine). These hormones cause an increase in organ function in all organs to which they are exposed.

Hypothyroidism

Hypothyroidism is caused by a deficiency of T3 and T4, both of which are secreted by the thyroid gland. Because of the decrease in the production, the body's organ function slows, causing the patient to feel a decrease in body temperature, to have gradual weight gain, and to have an increased risk for acute MI and CVA. In the critical care patient, a good history will help with the diagnosis of hypothyroidism.

Signs and Symptoms

Hypothyroidism

- Decrease in body temperature
- Gradual weight gain
- Lethargy
- Constipation
- Muscle aches and weakness
- Joint pain, stiffness, or swelling
- Puffy face
- Pale, dry skin
- Brittle fingernails and hair
- Hoarse voice

- Depression

Hyperthyroidism

Hyperthyroidism is caused by an increased production of T3 and T4. Because of the increase in the body's metabolism as a result, patients with hyperthyroidism experience an increase in body temperature and gradual weight loss, even if they are eating the same amounts of food. Other side effects of hyperthyroidism are increased and/or irregular heart rate, sweating, and irritability.

Signs and Symptoms

Hyperthyroidism

- Increase in body temperature
- Gradual weight loss
- Increased and/or irregular heart rate
- Hypertension
- Sweating
- Irritability

Thyrotoxicosis

Thyrotoxicosis, also known as a thyroid storm, is caused by hyperthyroidism and can be classified as either acute or chronic. This is an acute condition in the presence of infection or stress, and presents with a worsening of the symptoms of hyperthyroidism. Something as simple as a laceration can cause the patient with hyperthyroidism to experience thyro-toxicosis. Many diseases and conditions can exacerbate this condition, including the following:

- Graves disease (accounts for 85% of all cases of hyperthyroidism)
- Growth abnormalities of the thyroid gland
- Tumors of the testes or ovaries
- Inflammation of the thyroid (as a result of viral infections or other causes)
- Overmedication with supplemental thyroid hormones
- Ingestion of excessive iodine
- Trauma to the thyroid

Myxedema Coma

Myxedema coma is a rare, life-threatening clinical condition in patients with long-standing, severe, untreated hypothyroidism. Most commonly seen in elderly female patients, myxedema coma has an extremely high mortality rate if left untreated. The three key features of myxedema coma are as follows:

- Altered mental status and lethargy (including lengthy sleeping patterns)
- Failure of the thermoregulatory system (hypothermia or the absence of fever despite infectious disease)
- A precipitating event (such as cold exposure, infection, drugs [diuretics, tranquillizers, sedatives, or analgesics], trauma, stroke, heart failure, or gastrointestinal bleeding)

Signs and Symptoms

Myxedema Coma

- Hypothermia
- Auditory and visual hallucinations
- Seizures
- Unresponsiveness

A person who initially presents with myxedema coma is usually hypothermic and may be experiencing both auditory and visual hallucinations, seizures, and unresponsiveness.

Hashimoto's Disease

Hashimoto's disease, also known as chronic lymphocytic thyroiditis, occurs when the immune system attacks the patient's thyroid gland. As a result of inflammation, Hashimoto's disease is the leading cause of hypothyroidism, most commonly affecting women between the ages of 30 and 50 years.

Thyroid Cancer

Thyroid cancer is a cancer that starts in the thyroid gland. The four main types are as follows.

- Papillary and/or mixed papillary/follicular (incidence, approximately 78%)
- Follicular and/or Hurthle cell (incidence, approximately 17%)
- Medullary (incidence, approximately 4%)
- Anaplastic (incidence, approximately 1%)

Most thyroid cancers are treatable with surgical removal of either the affected tissue or the entire thyroid gland.

Assessment of the Patient With Suspected Thyroid-Related Illness

A patient with a thyroid-related condition may present with general weakness, fever, altered mental status, abdominal pain, and lethargy (hypothyroidism), or heart-related complications that include rapid heart rate, congestive heart failure, and atrial fibrillation (hyperthyroidism). In cases of hyperthyroidism, thyrotoxicosis may occur.

Although hypothyroid emergencies are rare, they are medically urgent and require aggressive evaluation and treatment.

Abnormal vital signs in the patient will commonly be more pronounced with the hyperthyroid patient; these include tachycardia and hypertension.

The physical exam may reveal thyroid enlargement (goiter) **Figure 17-9**.

Laboratory Assessment

Laboratory tests that evaluate thyroid function include serum TSH, T3, and T4.

Serum TSH measures the amount of TSH in the blood. The normal range is 0.4 to 4.2 mIU/mL for persons with no symptoms of abnormal thyroid function. However, persons without signs or symptoms of hypothyroidism who have a TSH value greater than 2.0 mIU/mL but normal T4 levels may experience hypothyroidism in the future. This condition is called subclinical hypothyroidism (mildly underactive thyroid) or early-stage hypothyroidism. The condition of anyone with a TSH value greater than 2.0 mIU/mL should be followed very closely by a doctor. Patients being treated for a thyroid disorder should

have a TSH level between 0.5 and 3.0 mIU/mL. Low levels of TSH indicate possible hyperthyroidism or pituitary gland failure, and values above normal indicate thyroid gland failure or a pituitary gland tumor.

TABLE 17-5 Common Laboratory Studies for Thyroid-Related Conditions

Laboratory Study	Normal Range	Causes of Low Levels	Causes of High Levels
TSH	0.4–4.2 mIU/L	Hyperthyroidism, or pituitary gland failure	Thyroid gland failure, or pituitary gland tumor
T3	60–180 ng/dL	Hypothyroidism	Hyperthyroidism
Total T4	5.5–12.5 µg/dL	Hypothyroidism	Hyperthyroidism
Free T4	0.9–2.3 ng/dL	Hypothyroidism	Hyperthyroidism
RT3U	24%–37%	Hypothyroidism	Hyperthyroidism
Triglycerides	< 160 mg/dL	Clinically irrelevant with respect to thyroid disorders	Possible hypothyrodisim
Radioactive iodine uptake	8%–25%	Hypothyroidism	Hyperthyroidism
Glucose tolerance test	Fasting: 70–1,100 mg/dL	Clinically irrelevant with respect to thyroid disorders	Hyperthyroidism
Thyroglobulin antibody	< 2 IU/mL	Clinically irrelevant with respect to thyroid disorders	Hyperthyroidism

Abbreviations: RT3U, triiodothyronine reuptake; T3, triiodothyronine; T4, thyroxine; TSH, thyroid-stimulating hormone.

Figure 17-9 Thyroid enlargement.

Table 17-5 indicates common laboratory testing for thyroid-related conditions.

Management

Treatment of thyroid conditions varies depending on the cause of the condition and the severity of symptoms. As with most conditions discussed in this chapter, transport management is mainly supportive.

Hyperthyroidism is usually treated with antithyroid medications, radioactive iodine (which destroys the thyroid and stops the excess production of hormones), or surgery to remove the thyroid. Beta-blockers such as propranolol are indicated to treat the resultant tachycardia, and anxiety may be treated with diazepam, lorazepam, or midazolam until the hyperthyroidism can be controlled. If the thyroid must be removed with radiation or surgery, replacement thyroid hormones must be taken for the rest of the person's life.

TABLE 17-6 Common Medications Used to Treat Thyroid Conditions

Medication

Class	Examples
Antithyroid medications	Methimazole (Tapezole) or propylthioracil (PTU)
Thyroid hormone	Levothyroxine (L-Thyroxin, Levolet, Levo-T, Levothroid, Levoxyl, Novothyrox, Synthroid, Thyro-Tabs, or Unithroid), liothyronine (Cytomel), or liotrix (Euthroid or Thyrolar)
Radioactive iodine	N/A
Beta-blockers	Acebutolol (Sectral), atenolol (Tenormin), betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), carvedilol (Coreg), labetalol (Normodyne or Trandate), metoprolol (Lopressor or Toprol-XL), nadolol (Corgard), nebivolol (Bystolic), penbutolol (Levatol), pindolol (Visken), propranolol (Inderal), sotalol (Betapace), or timolol (Blocadren)

Hypothyroidism is normally treated with hormone replacement therapy. Complications may be related to replacement of thyroid hormones. If too little hormone is given, symptoms of under-active thyroid can occur, including fatigue, increased cholesterol levels, mild weight gain, depression, and slowing of mental and physical activity. If too much hormone is given, the symptoms of hyperthyroidism will recur.

Table 17-6 lists common medications used to treat thyroid conditions.

Lipid Disorders

Lipid disorders cause a change in the production or use of cholesterol. They also may cause a change in the way cholesterol is circulated or processed in the body. As a result, patients with lipid disorders experience very high total cholesterol levels, very low high-density lipoprotein, or "good," cholesterol levels, or high triglyceride levels.

A lipid disorder increases the patient's risk for atherosclerosis and heart disease, but is rarely a true medical emergency.

Pathophysiology

Metabolic Syndrome

Metabolic syndrome is a group of symptoms that together may lead to coronary artery disease, stroke, and type 2 diabetes. Although the syndrome is not widely understood, patients display the risk factors and predisposition for lipid disorders and, consequently, heart disease.

Assessment

Patients with lipid disorder or metabolic syndrome may present with very few abnormal physical findings and vital signs on examination. Laboratory testing is required to definitively diagnose these underlying health factors.

Laboratory Assessment

Tests used to diagnose a lipid disorder may include total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein, or "bad," cholesterol, triglycerides, or very low-density lipoprotein cholesterol.

The desirable value for total cholesterol is less than 200 mg/dL. A borderline high value is 200 to

239 mg/dL. The normal value for high-density lipoprotein cholesterol is greater than 40 mg/dL. The normal value for low-density lipoprotein cholesterol is less than 160 mg/dL. The normal value for triglycerides is less than 160 mg/dL. Finally, the normal range for very low-density lipoprotein cholesterol is 2 to 38 mg/dL.

Management

Lipid disorders are normally managed as a component of the patient's long-term healthy lifestyle and by a physician. The patient's emergency conditions (cardiac/respiratory) are managed based on presentation.

TABLE 17-7 Common Medications Used to Treat Lipid Disorders

Medication Class	Examples
Antihyperlipidemic	Colestipol (Colestid), colesevelam hydrochloride (WelChol), gemfibrozil (Lopid), fluvastatin (Lescol or Lescol XL), or omega-3 polyunsaturated fatty acids (Lovaza)
Cholesterol absorption inhibitors	Ezetimibe (Zetia) or ezetimibe and simvastatin (Vytorin)
Fibrates	Fenofibrate (Tricor, Antara, or Lofibra)
Statins	Lovastatin (Mevacor), simvastatin (Zocor), fluvastatin (Lescol), pravastatin (Pravachol), atorvastatin (Lipitor), or rosuvastatin (Crestor)
Calcium channel blockers	Amlodipine and atorvastatin (Caduet)

Table 17-7 lists common medications used to treat lipid disorders.

Flight Considerations

The management of patients experiencing endocrine-related disorders requires the same management in flight as during ground transport, with no special management considerations when flying at altitude.

Summary

While endocrine disorders are not a common cause for a critical care transport, an understanding of endocrine-related conditions and their pathophysiology will help the CCTP manage these complex patients. As always, it is important to ensure appropriate blood glucose levels. An understanding of adrenal insufficiency in particular can help prevent patient death.

Case Study

YOU ARE JUST FINISHING UP YOUR DINNER after a relatively quiet shift when your dispatch center advises that you are being dispatched to Pondera Medical Center, approximately 95 miles away. The patient has been diagnosed with DKA and requires transport to your base hospital, Northern Rockies Medical Center, for further treatment in the intensive care unit. You and your partner, an EMT, depart for the rural hospital.

Once you arrive, you are met by the attending physician. He advises you that your patient is a 28-year-old, 84-kg man who had been complaining of general malaise and increasing thirst for the past 3 to 4 days. The patient's family called 9-1-1 this morning when they found him minimally responsive. He was subsequently transported to Pondera Medical Center via BLS ambulance with a Glasgow Coma Scale score of 8 (eye score, 2; verbal score, 2; and motor score, 4). Upon arrival, the patient's score had increased to 12 (eye score, 3; verbal score, 3; and motor score, 6) and he was able to answer some questions appropriately but with difficulty. According to the family members, the patient is generally healthy, and no medical problems, takes no medications, and has no allergies. They tell you that it seems like he has been drinking "a lot" of water over the past couple of days and has had to urinate excessively.

Treatment in the emergency department included oxygen via nonrebreathing mask at 15 L/min; a bedside glucose test that revealed high levels of glucose; laboratory studies including a complete blood cell count and comprehensive metabolic panel; a portable chest radiograph that showed the lungs were clear bilaterally; and an electrocardiogram that was unremarkable. The patient has a 14-gauge IV in his left forearm, currently running normal saline to keep the vein open, an 18-gauge saline lock in his right forearm, and an indwelling (Foley) catheter, with approximately 1,300-mL urine output in the last 75 minutes. The patient has received two boluses of normal saline, with each bolus based on 20 mL/kg, and 10 U of short-acting insulin, which decreased the blood glucose level to 580 mg/dL on recheck.

Vital signs included the following: blood pressure, 89/42 mm Hg; heart rate, 132 beats/min; sinus tachycardia with no ectopy; clear respirations, 36 breaths/min with a Kussmaul respiration pattern; and oxygen saturation as measured by pulse oximetry, 96% with oxygen therapy. Laboratory studies revealed the following abnormalities: glucose, 789 mg/dL; blood urea nitrogen, 60 mg/dL; creatinine, 2.0 mg/dL; blood urea nitrogen to creatinine ratio, 30:1, chlorine, 116 mEq/L; potassium, 5.5 mEq/L; and sodium, 151 mEq/L. A urinalysis was positive for ketones and glucose. Arterial blood gas readings showed metabolic alkalosis with a pH of 7.24; $Paco_2$, 19 mm Hg; bicarbonate, 4 mEq/L; and base excess, 1.

As your partner is securing the patient onto the cot for the return transport, you contact your base hospital physician to advise of the patient's status, obtain any additional orders, and give an estimated time of arrival. The receiving intensivist has requested that a continuous insulin infusion be initiated, with the blood glucose level titrated to a target decrease of 50 mg/dL/h.

Once en route back to Northern Rockies Medical Center, you prepare an insulin infusion by adding 100 U of insulin to a 100-mL bag of normal saline and begin the infusion at 8.4 U/h, based upon 0.1 U/kg/h. Because of the patient's altered mental status, you elect to administer 8 mg of ondansetron IV as prophylaxis against vomiting and insert a 16F nasogastric tube in the left nare. After approximately 20 minutes, you recheck the patient's blood glucose level using your glucometer and obtain a reading of 550 mg/dL. On the basis of this reading, you increase the infusion rate to 16.8 U/h and continue the transport. Once you arrive at Northern Rockies Medical Center, the patient is taken directly to the intensive care unit for continuing treatment.

1. How was the diagnosis of DKA determined?
2. Why was the patient given 3,360 mL of normal saline?
3. What are the potential problems that you may experience while en route with this patient?

Analysis

Because of your critical care training, you are able to recognize that this patient is experiencing DKA based on the presence of Kussmaul respirations, an elevated blood glucose reading, and arterial blood gas abnormalities. Symptoms of DKA include an elevated blood glucose level, acidosis, and an altered mental status. Signs include polydipsia, polyphagia, polyuria, and Kussmaul respirations.

This patient was given 3,360 mL of normal saline (20 mL/kg) in an attempt to hydrate the patient because of excessive urination; the lost fluids were demonstrated by tachycardia and hypotension. Short-acting insulin was administered in an attempt to decrease the blood glucose level. It is imperative not to decrease glucose levels too quickly in cases of diabetic ketoacidosis because of the possibility of cerebral edema. In an attempt to gradually decrease the glucose level, a continuous infusion of insulin was initiated, allowing the CCTP to accurately titrate the amount of insulin based on glucose level. Ondansetron was given prophylactically to minimize the risk of aspiration resulting from decreased mental status.

This patient has the potential to experience several problems en route. The ground transport was 95 miles; with the patient's decreased level of consciousness, aspiration must be considered. Insertion of a nasogastric tube minimizes this risk, but the CCTP must still recognize the possibility. With any patient presenting with an altered mental status in the transport environment, CCTPs need to be aware of the possible need to perform definitive airway management, which is often difficult in the confined spaces of an ambulance. Furthermore, with continued administration of insulin, the possibility of inadvertent hypoglycemia may develop. Hypoglycemia can be recognized via vigilant monitoring of the patient's blood glucose level and subsequently corrected by discontinuing the insulin infusion and following local protocols regarding hypoglycemia.

Prep Kit

Ready for Review

- CCTPs should be familiar with the endocrine system and its function.
- The thyroid gland secretes thyroxine to regulate the body's metabolism and calcitonin to maintain normal calcium levels in the blood.
- The adrenal glands consist of the adrenal cortex, which produces corticosteroids, and the adrenal medulla, which produces catecholamines (the hormones epinephrine and norepinephrine).
- During times of stress, adrenocorticotropic hormone causes the adrenal cortex to secrete cortisol, which stimulates body cells to increase their energy production.
- The adrenal cortex secretes aldosterone if blood pressure or volume drops, sodium level decreases, or potassium level increases. The function of aldosterone is to increase the reabsorption of sodium and water and release potassium into the kidneys, increasing circulating blood volume and thus increasing blood pressure.
- During the "fight-or-flight" response, the adrenal medulla secretes small amounts of norepinephrine and large amounts of epinephrine to enable the body to respond to a short-term emergency.
- The pancreas is both an endocrine and an exocrine gland. The exocrine component secretes digestive enzymes; the endocrine component comprises the islets of Langerhans.
- The main hormones secreted by the pancreas are glucagon and insulin, which regulate blood glucose levels. Insulin is the only hormone that decreases blood glucose levels. Insulin is essential for glucose to enter and nourish the cells.
- Diabetes is a metabolic disorder in which the body's ability to metabolize glucose is impaired as a result of insufficient production or inadequate utilization of insulin.
- There are two major types of diabetes mellitus: type 1 and type 2. Type 1 diabetes generally strikes children, whereas type 2 diabetes commonly occurs in adults.

- Most patients with type 1 diabetes do not produce insulin. In patients with type 2 diabetes, the pancreas produces enough insulin, but the body is not able to use it. This is known as insulin resistance. Type 2 diabetes can also be caused by a deficiency in insulin production.
- Hypoglycemia, a drop in blood glucose level, can develop rapidly in patients with diabetes and in alcoholics, those who have ingested a poison or certain drugs, and patients with other diseases such as cancer, liver disease, or kidney disease. If hypoglycemia persists, it can cause permanent brain damage.
- Hyperglycemia, an increase in blood glucose levels above normal range, can have rapid or gradual onset. If left untreated, hyperglycemia will progress to DKA, a life-threatening condition.
- Patients with DKA tend to be young—teenagers and young adults. The processes of DKA usually progress slowly—over a period of 12 to 48 hours—and can lead to dehydration and shock.
- Hyperosmolar hyperglycemic nonketotic syndrome occurs principally in patients with type 2 diabetes. It is characterized by hyperglycemia, hyperosmolarity, and an absence of significant ketones.
- Signs of hypoglycemia may mimic those of intoxication. Patients presenting with signs of intoxication, such as slurred speech and lack of coordination, should be checked for hypoglycemia because hypoglycemia can cause cerebral dysfunction.
- Hyperglycemia and DKA typically present with the three Ps: polyuria, polydipsia, and polyphagia. The two hallmark signs of DKA are Kussmaul respirations and fruity breath odor.
- Signs of HHNS are similar to those of DKA, except that patients with HHNS do not present with Kussmaul respirations or fruity breath odor.
- CCTPs may test for hypoglycemia or hyperglycemia during transport. Knowledge of the glucometer being used is important for understanding the readings.
- Insulin infusions are routinely used in critically ill patients. The CCTP should check the patient's blood glucose levels frequently using a blood glucometer and adjust the insulin infusion rate to maintain the blood glucose targets prescribed for the patient.
- Signs and symptoms of pituitary disorders commonly mirror other disease processes; obtaining a thorough medical history and physical exam results are important to finding the cause of the problem.
- The pituitary gland is divided into two lobes: the anterior pituitary and the posterior pituitary. The anterior pituitary produces and secretes six hormones; the posterior pituitary secretes two hormones, which it does not produce.
- Central diabetes insipidus, caused by damage to the posterior of the pituitary gland, is characterized by polyuria and polydipsia, which lead to dehydration.
- Pituitary lesions are classified into two types: nonfunctioning adenomas and functioning adenomas. Nonfunctioning adenomas do not secrete hormones; with functioning adenomas, overproduction of hormones may occur.
- Acromegaly results from excessive growth hormone secreted by the pituitary gland after the epiphyseal plate has closed. Gigantism results from excessive growth hormone secreted by the pituitary gland before the epiphyseal plate has closed. Both conditions are characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate. Both conditions are usually caused by a benign pituitary tumor.
- Acromegaly and gigantism are managed with medications.
- Abnormalities of the adrenal glands may be hereditary, corticosteroid resistance and hypersensitivity abnormalities, or genetic disorders.

- Pseudo-Cushing's states are a mixed group of disorders related to increased cortisol production. They may be caused by physiological conditions, such as severe illness or intense aerobic exercise, or nonphysiological conditions, such as chronic alcoholism and obesity.
- Endocrine hypertension is a result of hormonal disorders that cause clinically significant hypertension. Endocrine hypertension is often related to excess hormones produced by a tumor.
- Adrenal insufficiency is underproduction of cortisol and aldosterone caused by a decreased function of the adrenal cortex. Adrenal insufficiency may be temporary or permanent, and it affects men and women of all ages equally.
- In patients with chronic AI, signs and symptoms of Addisonian crisis may appear suddenly as a result of an increased period of stress, trauma, surgery, or severe infection. If undiagnosed, AI is potentially fatal.
- Addison's disease is a chronic disorder caused by a deficiency in cortisol and/or aldosterone. It occurs in all age groups. Young patients with Addison's disease are at risk for premature death.
- Cushing's syndrome is caused by prolonged exposure to elevated levels of cortisol in the body. It is relatively rare and affects patients aged 20 to 50 years. Excess cortisol affects many body systems, leading to hyperglycemia, muscle weakness, and bone weakness among other signs and symptoms.
- A pheochromocytoma is a catecholamine-producing benign tumor of chromaffin cells. Of pheochromocytomas, 97% are in the abdomen, 2% are in the thorax, and the remaining 1% are in other body areas. Most pheochromocytomas can be corrected if identified. If untreated, they can be fatal. Treatment is surgery to remove the tumor.
- There are two types of aldosteronism, a syndrome of high blood pressure and low blood potassium levels caused by an excess of aldosterone: primary and secondary.
- Primary aldosteronism, also known as Conn's syndrome, is caused by a tumor; most cases are benign. Secondary aldosteronism occurs as a result of reduced renal blood flow, which stimulates hypersecretion of aldosterone. A low plasma renin activity blood test indicates primary aldosteronism; high plasma renin activity indicates secondary aldosteronism. Treatment is surgery or treatment of the underlying condition.
- Amyloidosis results from abnormal deposits of the protein amyloid in various tissues of the body. Primary amyloidosis is the most common form; secondary amyloidosis occurs as the result of another illness. There is no cure for amyloidosis; treatments focus on managing the symptoms and limiting production of amyloid protein.
- Transport of patients with a life-threatening disorder resulting from a thyroid abnormality is rare. Transport management for patients with thyroid conditions is mainly supportive.
- The thyroid gland is the primary controller of the body's metabolism; it produces the hormones T3 and T4.
- Hypothyroidism is caused by a deficiency of the hormones T3 and T4. Patients with hypothyroidism are at increased risk for acute myocardial infarction and cerebrovascular accident.
- Hyperthyroidism is caused by increased production of the hormones T3 and T4. Thyrotoxicosis is caused by hyperthyroidism, and is classified as acute or chronic.
- Myxedema coma is a rare, life-threatening clinical condition in patients with long-standing severe untreated hypothyroidism. It occurs most often in elderly female patients and is fatal if untreated.
- Hashimoto's disease, the leading cause of hypothyroidism, occurs when the immune system attacks the patient's thyroid gland. It most commonly affects women aged 30 to 50 years.

- There are four main types of thyroid cancer: papillary and/or mixed papillary/follicular, follicular and/or Hurthe cell, medullary, and anaplastic. Most thyroid cancers are treatable with surgery.
- Laboratory tests that evaluate thyroid function are serum thyroid-stimulating hormone, T3, and T4.
- Lipid disorders cause a change in the production or use of cholesterol. They rarely cause a true medical emergency.
- Metabolic syndrome is a group of symptoms that together may lead to coronary artery disease, stroke, and type 2 diabetes. Laboratory testing is necessary to diagnose lipid disorders and metabolic syndrome.
- Lipid disorders are managed by lifestyle adaptations and medications.

Vital Vocabulary

acromegaly A syndrome that results from excessive growth hormone secreted by the pituitary gland after the epiphyseal plate has closed; characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate.

Addisonian crisis The sudden appearance of symptoms, especially shock, in a patient with chronic adrenal insufficiency; may appear suddenly as a result of an increased period of stress, trauma, surgery, or severe infection; other symptoms include weakness, altered mental status, hyperthermia, and severe pain in the lower back, legs, or abdomen.

Addison's disease A chronic hormonal or endocrine disorder caused by a deficiency of cortisol and/or aldosterone and characterized by weakness, fatigue, hypotension, unexplained weight loss, and darkening of the skin.

adrenal insufficiency (AI) Underproduction of cortisol and aldosterone caused by a decreased function of the adrenal cortex; occurs when at least 90% of the adrenal cortex has been damaged.

aldosterone One of the two main hormones responsible for adjustments to the final composition of urine; it increases the rate of active resorption of sodium and chloride ions into the blood and decreases the resorption of potassium.

aldosteronism A syndrome of high blood pressure and low blood potassium levels caused by an excess of aldosterone; there are two main types (primary and secondary).

amyloidosis A group of diseases that result from abnormal deposits of the protein amyloid in various tissues of the body; can occur in a localized area or may be systemic.

central diabetes insipidus A result of damage to the posterior part of the pituitary gland, which causes a lack of the hormone vasopressin, an anti-diuretic hormone, to be produced; because of the lack of anti-diuretic hormone, patients frequently experience polyuria and polydipsia.

Cushing's syndrome A condition caused by an excess of cortisol production by the adrenal glands or by excessive use of cortisol or other similar steroid (glucocorticoid) hormones.

diabetic ketoacidosis (DKA) A form of acidosis in uncontrolled diabetes in which certain acids accumulate when insulin is not available.

endocrine hypertension Significant high blood pressure caused by a hormonal disorder; often related to excess hormone produced by a tumor.

functioning adenoma A type of pituitary lesion in which overproduction of hormones occurs.

gigantism A syndrome that results from excessive growth hormone, secreted by the pituitary gland before

the epiphyseal plate has closed; characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate.

Hashimoto's disease A condition that occurs when the immune system attacks the patient's thyroid gland. The leading cause of hypothyroidism; also known as chronic lymphocytic thyroiditis.

hyperosmolar hyperglycemic nonketotic syndrome (HHNS) A metabolic derangement that occurs principally in patients with type 2 diabetes, and is characterized by hyperglycemia, hyperosmolarity, and absence of significant ketosis.

hyperthyroidism A condition caused by an increased production of T3 (triiodothyronine) and T4 (thyroxine) from the thyroid gland, resulting in an increase in the body's organ function, and characterized by an increase in body temperature, gradual weight loss, increased and/or irregular heart rate, sweating, and irritability.

hypothyroidism A condition caused by a deficiency of T3 (triiodothyronine) and T4 (thyroxine) from the thyroid gland, resulting in a slowing of the body's organ function, and characterized by a decrease in body temperature, gradual weight gain, and increased risk for acute myocardial infarction and cerebrovascular accident.

insulin resistance A condition in which the pancreas produces enough insulin but the body cannot effectively use it.

lipid disorders A group of disorders that cause a change in the production or use of cholesterol and that also may cause a change in the way cholesterol is circulated or processed in the body.

metabolic syndrome A group of symptoms that together may lead to coronary artery disease, stroke, and type 2 diabetes; usually related to predisposition to a lipid disorder.

myxedema coma A rare, life-threatening condition that can occur in patients who have severe, untreated hypothyroidism, and which is characterized by altered mental status and lethargy, failure of the thermoregulatory system, and a precipitating event; may be accompanied by auditory and visual hallucinations, seizures, or unresponsiveness.

nonfunctioning adenoma A type of pituitary lesion in which the tumor does not secrete any hormones.

pheochromocytoma A catecholamine-producing benign tumor of chromaffin cells located in the center of the adrenal gland, which can occur either sporadically or chronically as a result of genetic risk factors; causes stimulation of alpha-adrenergic and beta-adrenergic receptors, resulting in hypertension, increased cardiac contractility, glycogenolysis, gluconeogenesis, intestinal relaxation, and increased heart rate.

polydipsia Excessive thirst, resulting in excessive intake of fluid.

polyphagia Excessive desire to eat, resulting in overconsumption of food.

polyuria Frequent and plentiful urination.

primary aldosteronism A type of aldosteronism usually caused by a tumor of a single adrenal gland that overproduces aldosterone; also known as Conn's syndrome.

primary amyloidosis The most common form of amyloidosis, affecting the heart, kidneys, tongue, nerves, and intestines; classified as apolipoprotein.

pseudo-Cushing's state A condition in which a person has higher cortisol levels from a cause other than actual Cushing's syndrome; these causes include depression, alcoholism, malnutrition, and panic attack.

secondary aldosteronism A type of aldosteronism that occurs as a result of reduced renal blood flow,

which stimulates hypersecretion of aldosterone; can be caused by obstructive renal artery disease, renal vasoconstriction, and edematous disorders.

secondary amyloidosis A form of amyloidosis that occurs as a result of another illness, and which primarily affects the kidneys, spleen, liver, and lymph nodes; classified as amyloid A protein.

thyrotoxicosis An excess of thyroid hormones resulting in a hypermetabolic crisis, including tachycardia over 140 beats/min, hyperthermia (sometimes > 103.9°F), coma with agitation, nausea, vomiting, diarrhea, unexplained jaundice, and pulmonary edema, marked by an elevated thyroxine level; also called thyroid storm.

type 1 diabetes The type of diabetic disease that usually starts in childhood and requires daily injections of supplemental synthetic insulin to control blood glucose; sometimes called juvenile or juvenile-onset diabetes.

type 2 diabetes The type of diabetic disease that usually starts later in life and often can be controlled through diet and oral medications; sometimes called adult-onset diabetes.

Environmental Emergencies

Authors

Jonathan Hockman, NREMT-P, EMT-P, EMSIC

Andrew Bartkus, RN, MSN, CEN, CCRN, CFRN, NREMT-P, FP-C

Objectives

1. Discuss risk factors for environmental emergencies (p 718).
2. Describe the process of thermoregulation, including the concepts of thermogenesis and thermolysis (p 718).
3. Explain the process of heat transfer, including radiation, conduction, convection, evaporation, and absorption (p 719).
4. Discuss signs, symptoms, and transport management of heat cramps (p 721).
5. Discuss signs, symptoms, and transport management of heat syncope (p 722).
6. Discuss signs, symptoms, and transport management of heat exhaustion (p 722–723).
7. Discuss signs, symptoms, and transport management of heat stroke (p 723–724).
8. Discuss signs, symptoms, and transport management of frostbite (p 725–726).
9. Discuss signs, symptoms, and transport management of hypothermia (p 726–727).
10. Discuss signs, symptoms, and transport management of drowning and submersion (p 727–728).
11. Discuss signs, symptoms, and transport management of diving injuries (p 728).
12. Explain the purpose of hyperbaric therapy and when it might be used (p 729–730).
13. Discuss signs, symptoms, and transport management of altitude illness (p 730–731).
14. List flight considerations relating to environmental emergencies (p 731).

Introduction

Environmental emergencies are medical conditions caused or worsened by the weather, terrain, or unique atmospheric conditions. People may experience severe illness from environmental conditions in a vast array of locations and situations. Heat, cold, submersion, and decompression illnesses can occur in remote wilderness locations, major urban metropolitan areas, and any place in between. People in harsh environmental conditions frequently survive environmental extremes far better than at-risk people (such as elderly, homeless, and chemically dependent people). The list of potential scenarios creating an environmental emergency is seemingly endless, regardless of geographic region.

A CCTP is often involved with patients with environmental emergencies during the critical care transport between facilities. Many preexisting medical and lifestyle factors predispose patients to critical illness created or exacerbated by environmental stressors. The challenge to CCTPs is to recognize the patients who are more susceptible to environmental exposure in unexpected conditions. To provide patients with the optimal chance for recovery, it is essential that CCTPs continue or initiate many critical interventions during patient transport.

Risk Factors

Risk factors that predispose people to environmental emergencies include extremes of age (young and

old), taking certain medications, and being in a poor state of health. Specifically, environmental factors can be worsened in people with diabetes, cardiovascular disease, restrictive lung disease, thyroid disease, and even psychiatric illnesses.

Thermoregulation

The body's ability to acclimatize, to adjust to a changing environment, is part of the homeostatic process. **Thermoregulation** refers to the body's natural ability to ensure and maintain a balance between heat production (**thermogenesis**) and heat elimination (**thermolysis**). The **hypothalamus** is located in the most inferior portion of the diencephalon, making up the portion of the brain between the cerebrum and the brain stem. Through the **hypothalamo-hypophyseal portal system**, the hypothalamus sends a releasing or inhibiting factor to the pituitary gland. The interrelationship between the glands is referred to as the **hypothalamic-pituitary axis**. The result is an increase or decrease in metabolism throughout the body. The hypothalamus serves as the "master thermostat" by using negative feedback control. A rise in the core body temperature elicits signals to shut off thermogenesis pathways and increase heat loss mechanisms; a fall in the core body temperature prompts heat production and limits thermolysis mechanisms. In the preoptic area of the hypothalamus, heat-sensitive neurons increase firing when the body senses an increase in temperature. In the posterior hypothalamus, signals from the preoptic area are combined with signals from the remainder of the body to cause a compensating heat loss to restore the temperature back to a tolerable range. This negative feedback system of the hypothalamus cannot work properly without a network of complementary detectors that are sensitive to temperature changes. Cold sensors are located predominantly in the skin, spinal cord, and other areas that are sensitive to the cold end of the temperature spectrum. They respond to excess cooling by transmitting neural action potentials to the hypothalamus; these halt the heat-reducing signals. The goal is to maintain a constant core body temperature within a degree of 98.6°F (37°C).

The negative feedback system has three major components:

- Temperature receptors
- Effector organ systems
- Integrator or controller

The majority of temperature receptors are found in the papillary layer of the dermis throughout widespread areas of the body. These exteroceptors respond to external stimuli affecting the skin directly. Areas of nerves, or spots, respond to hot or cold stimuli, with cold spots being more numerous. Receptors are nerve endings that act as transducers, converting one form of energy into nerve impulses, sent along afferent nerves, including the lateral spinothalamic tract, to the diencephalon. The expression of this neural processing is to stimulate motor nerves and peripheral pathways to use effectors. The result is for muscles to contract or relax, blood vessels to constrict or dilate, and glands to secrete hormones. These impulses are coordinated as necessary by the specific integrator or controller against information already stored (such as the "normal" body temperature of 98.6°F [37°C]). This hypothalamic thermostat reduces excesses in body heat. Three major mechanisms have a part:

- Blood vessels in the skin dilate, resulting in eight times as much heat transfer to the skin's surface.
- Perspiration is increased at a ratio of 10 times the normal perspiration for each degree of temperature increase.
- Increases in muscle activity, including shivering, are inhibited.

In response to cold, the three main regulatory processes to increase body heat include the following:

- Stimulation of the posterior hypothalamus to cause a constriction of blood vessels

- Hypothalamic stimulation of the primary motor center in the posterior hypothalamus that stimulates the brain stem, spinal cord, and motor neurons to ultimately cause muscle activity, including shivering
- The hypothalamic stimulation of piloerector muscles causing minimal production of heat and the visible sign of "goose flesh" and the body hair to "stand on end"

Basal Metabolic Rate

At rest, the body's chief source of heat production is the metabolism of nutrients. The heat produced at rest from normal metabolic reactions, including breathing, circulation, and digestion, is referred to as the **basal metabolic rate (BMR)**. It is a calculation of the number of calories metabolized per square inch of body surface area per hour and can be thought of as the minimal requirement to sit still all day long. Calculation of the BMR requires fairly sophisticated laboratory equipment. A BMR provides useful information in specialized clinical settings, such as studies in endocrinology and metabolism. The average BMR of a 70-kg adult is around 60 to 70 kcal/h. A brisk walk can produce 300 kcal/h. The BMR can be greatly affected by age, sex, stress, hormones, and body surface area. As the ratio of body surface area to body volume increases, heat loss increases, so that the shorter of two persons of the same weight will lose heat at a faster rate; this is most relevant to pediatric patients, who have a very high surface area to body volume ratio and are most susceptible to heat loss.

Heat Transfer

Heat produced by metabolism and glycogen breakdown is used to warm the body and maintain the core body temperature. Excess heat must be eliminated. Usually this elimination is accomplished through the temperature gradient between the body and the immediate surrounding environment **Figure 18-1**. The body transfers heat to the surrounding environment through four primary mechanisms:

- **Radiation**—the transfer of heat through electromagnetic waves
- **Conduction**—the transfer of heat through direct contact with a cooler object
- **Convection**—the loss of heat carried away from the body by currents of air or water
- **Evaporation**—the loss of heat carried away as liquid converts to gas

If the surrounding environment is hotter than the body, the body gains heat through **absorption**. Convection and radiation cease as ambient temperatures reach or exceed skin temperatures. Furthermore, the humidity of the immediate environment can affect thermoregulation as well. A healthy adult can sweat up to about 1 L/h (although not for very long), but if the humidity in the surrounding air is more than 75% to 80%, the evaporative process is impaired.

When dealing with a cold environment, the body shifts to thermogenesis. This process is mainly controlled by increases in BMR and physical exertion. The sympathetic nervous system increases muscle tone and initiates shivering to produce more kilocalories per hour for the immediate needs of the body. The thyroid is stimulated to meet longer heat-production needs. The hypothalamus stimulates peripheral vasoconstriction, sweating stops, and blood is shunted toward the core.

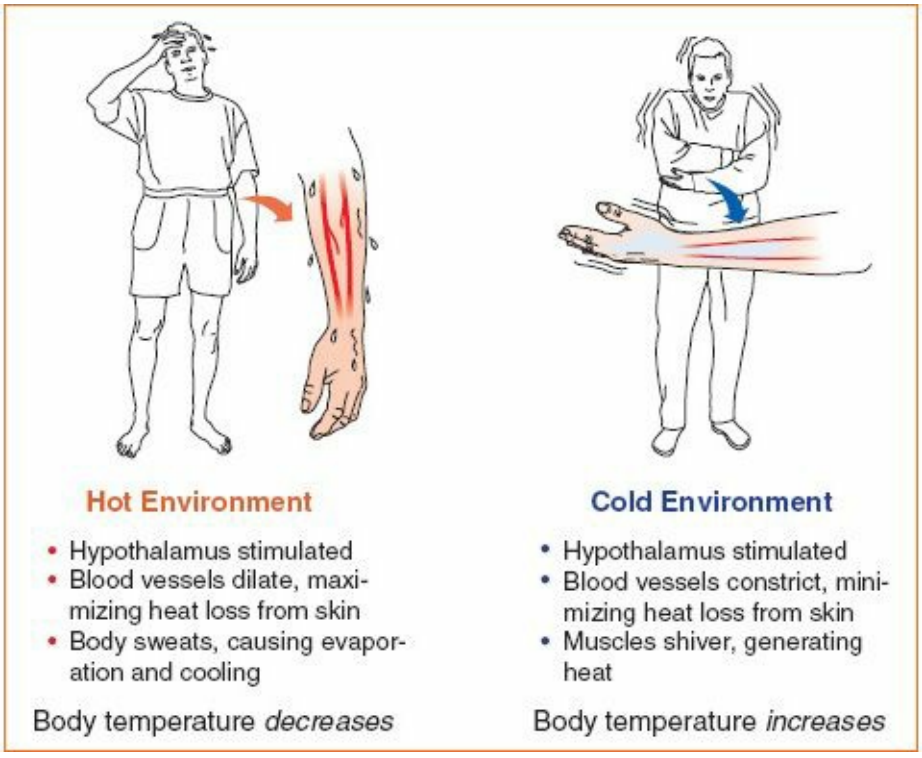

Figure 18-1 The hypothalamus notes a rise or fall in core body temperature and elicits responses to regulate it.

In very cold temperatures, a fair amount of heat is lost through the process of respiration. When cold air is inhaled, it is warmed by the body and then exhaled, causing heat to be lost.

Expecting the Unexpected

A patient need not be found in the desert or plucked from a snow bank to have a "temperature emergency." For example, patients with a spinal cord injury may have a disruption in the negative feedback loop and, therefore, a disruption of thermoregulation. CCTPs must be cognizant of these patients' inability to self-regulate body temperature and take the necessary external steps to maintain warmth or prevent overheating.

Heat Emergencies

Heat illness occurs when there is an increase in core body temperature as a result of inadequate thermolysis. A patient's general state of health, age, certain medications **Table 18-1**, amount of clothing, mobility, and surroundings all have a role in the effects of heat on the body, **Table 18-2**. According to the US Centers for Disease Control and Prevention, more people die of heat-related illness than in all natural disasters (such as floods, hurricanes, tornadoes, lightning, and earthquakes) combined. The United States averages more than 300 heat-related deaths each year. CCTPs in all geographic regions should be prepared to transport patients experiencing heat-related illnesses.

TABLE 18-1 Substances Contributing to Heat Illness

Alcohol
Alpha-agonists
Amphetamines

Anticholinergic medications (such as atropine sulfate, scopolamine, benztropine mesylate, belladonna, and synthetic alkaloids)
Antihistamines
Antiparkinsonian agents
Antipsychotics (such as haloperidol)
Beta-blockers
Calcium channel blockers
Cocaine
Diuretics (such as furosemide, hydrochlorothiazide, and bumetanide)
Heroin
Laxatives
Lithium
Lysergic acid diethylamide
Monoamine oxidase inhibitors
Phencyclidine hydrochloride
Phenothiazines (such as prochlorperazine, chlorpromazine, and promethazine)
Sympathomimetic medicines (such as amphetamines, epinephrine, ephedrine, cocaine, and norepinephrine)
Thyroid agonists (such as levothyroxine)
Tricyclic antidepressants (such as amitriptyline, imipramine, nortriptyline, and protriptyline)

Medications can cause or contribute to heat illness through a variety of possible mechanisms. Medications that depress the central nervous system, such as alcohol and barbiturates, impair a person's ability to properly dissipate heat generated within the body. Many central nervous system depressant medications can cause heat illness or hypothermia.

Stimulant medications promote increased muscle activity and metabolism, causing increased thermogenesis. Cocaine, amphetamines, and other sympathomimetic medications lead to hyperthermia through this mechanism. The increase in heat production cannot be compensated for by increased heat dissipation, leading to hyperthermia.

Any medication that interferes with cardiovascular performance will undermine the body's ability to dissipate heat. Beta-blockers, calcium channel blockers, and diuretics each interfere with heat loss, causing or worsening hyperthermia. Diuretics further complicate heat illness by limiting the fluid volume available for evaporative cooling (sweating).

Medications that impair sweating, such as antihistamines, tricyclic antidepressants, and other anticholinergics, compromise this essential thermoregulatory mechanism, another factor leading to heat illness. Other specific medication-related causes of hyperthermia or heat illness include neuroleptic malignant syndrome and malignant hyperthermia, discussed further in Chapter 20.

TABLE 18-2 Factors That Predispose to Heat Illness

Factors That Increase Internal Heat Production	Factors That Interfere With Heat Dissipation
Physical exertion	High ambient temperature
Response to infection (fever)	High humidity
Hyperthyroidism	Obesity (insulation effect, and less efficient dissipation)
Agitated and tremulous states (such as Parkinson disease, psychosis, mania, drug withdrawal—opiate and alcohol)	Impaired vasodilatation
Drug overdoses (such as sympathomimetics, cocaine, caffeine, lysergic acid diethylamide, phencyclidine hydrochloride, methamphetamine, and Ecstasy)	Diabetes
	Alcoholism
	Drugs: diuretics, tranquilizers, beta-blockers, antihistamines, and phenothiazines
	Impaired ability to sweat (as in cystic fibrosis, skin diseases, and healed burns)
	Heavy or tight clothing
Factors That Increase Heat Absorption	**Factors That Impair the Body's Response to Heat Stress**
Confined, unventilated, hot living quarters	Dehydration
Working in hot conditions (such as in bakeries, steel mills, and construction sites)	Prior heat stroke
Being in parked automobiles in the summer	Hypokalemia
	Cardiovascular disease
	Previous stroke or other central nervous system lesion

If thermoregulation mechanisms fail or become taxed beyond limits, the core body temperature will rise dramatically and quickly. The core body temperature can rise to 106°F (41.1°C) or more in less than 15 minutes. Older persons are particularly at risk. As a result of underlying illness and other metabolic changes they do not acclimatize well. They perspire less, feel thirst more slowly, have difficulty swallowing, and have decreased mobility (making it more difficult just to reach a glass of water). They are also more apt to be taking medications that can alter or impede thermoregulation.

Among the young and healthy, children exposed to hot environments are most vulnerable to heat stressors. Compared with adults, children have higher rates of metabolism and do not dissipate heat as well. Infants and young children are completely dependent on others to provide the proper thermal environment. Excessive blankets or bedding, prolonged confinement in hot vehicles, and other lapses in

environmental control place infants and young children at serious risk for heat-related injury.

Heat illness and heat stroke are the third leading cause of death of high school athletes in the United States; adolescent athletes are at high risk for heat-related illness. Older children may elect to continue strenuous activities in hot or humid environments without understanding the risks or symptoms of heat-related illness or the importance of adequate hydration.

Heat Cramps

Heat cramps are involuntary muscle pains, usually in the abdomen, lower extremities, or both, as a result of profuse sweating and loss of sodium. These events usually afflict healthy persons who are overexerting their bodies in a hot environment. Generally, people recognize the problem and instinctively move to a cooler place and replenish lost fluids. However, if the person has lost a lot of sweat and drinks only water, the sodium loss has not been resolved, and cramps may ensue. In addition, a person may attempt to quench thirst by drinking excessive amounts of water in a very short time, leading to **water intoxication**. Heat cramps are a result of a water-sodium imbalance and are often not accompanied by hyperthermia. If a patient also has some degree of heat exhaustion, heat stroke, or significant hyperthermia, additional cooling measures may be required.

Treatment

The treatment for heat cramps is largely supportive. The patient should be removed from the hot environment, lie supine if he or she feels faint, and be instructed to drink a salt-containing liquid or electrolyte drink (if not at risk for aspiration) **Figure 18-2**. As the patient's salt balance is restored, the symptoms will abate. If symptoms continue, the underlying cause should be sought, and the patient should be rapidly transported to the emergency department. It is unlikely that patients will require critical care transport for heat cramps unless there is a significant degree of hyponatremia or the heat cramps are accompanied by some form of hyperthermia. Significant heat cramps, refractory to oral electrolyte replacement, may be managed with the administration of 1 to 2 L of IV normal saline. CCTPs should use caution when administering IV fluids to correct presumed hyponatremia without adequate patient evaluation or laboratory studies.

Severe hyponatremia requires very specific management depending on the cause. It is essential that CCTPs avoid rapid correction of an abnormal sodium level in any patient with chronic hyponatremia. Devastating neurologic injury associated with central pontine myelinolysis occurs when patients with chronic hyponatremia have their sodium level rapidly corrected or inadvertently overcorrected.

Water Intoxication

The normal process of homeostasis provides for the body to balance intake against output. In general, an average adult takes in about 1,000 mL of fluid throughout an average day. Water intoxication or poisoning can result when the normal balance of electrolytes in the body is pushed outside of safe limits by overconsumption of free water. Normal, healthy (physically and nutritionally) people need not be overly concerned about accidentally consuming too much water. Nearly all deaths related to water intoxication from healthy people have resulted from water drinking contests or in people attempting to correct dehydration when they consume more than 5 to 10 L of water in a short period.

Figure 18-2 Give the patient with heat cramps one or two glasses of a salt-containing solution if he or she is not nauseated and there is no risk of aspiration.

Human kidneys can excrete up to 15 to 20 L of free water each day or up to 1 L per hour. When a euvolemic patient (one with normal blood volume) consumes or receives more free water (without sodium) than the kidneys are able to excrete, water intoxication and hyponatremia begin. In addition to the populations previously described, individuals consuming only water during prolonged endurance activities, such as marathons and hiking, are also at high risk for water intoxication.

Signs and Symptoms

Heat Cramps

- Involuntary muscle pain, usually in the abdomen or lower extremities
- Profuse sweating

Differential Diagnosis

Heat Cramps

- Heat exhaustion
- Heat stroke
- Musculoskeletal trauma (such as sprains or strains)
- Electrolyte abnormality
- Autoimmune disease
- Medication side effect or medication withdrawal symptoms

Transport Management

Heat Cramps

- Remove the patient from the hot environment.
- Place the patient in a supine position.

- If there is no risk of aspiration, give the patient a drink containing salt.
- Consider administering 1 to 2 L of IV normal saline; use caution if there is any possibility of chronic hyponatremia.

Heat Syncope

Heat syncope is an episode of collapse or near collapse that typically occurs in a nonacclimatized person. It is often seen at outdoor events where crowds are standing for long periods. Heat syncope is also common in outdoor settings when a person stands suddenly after sitting or lying on the ground for an extended period. It is thought that peripheral vasodilation, possibly exacerbated by some degree of dehydration, is the likely cause. Treatment is aimed at placing the patient in the recovery position and allowing fluid intake. If the patient does not recover quickly, heat exhaustion or heat stroke should be suspected.

Signs and Symptoms

Heat Syncope

- Postural hypotension from vasodilation
- Volume depletion
- Syncopal episode
- Subjective or documented hyperthermia

Differential Diagnosis

Heat Syncope

- Heat exhaustion
- Heat stroke
- Vasovagal syncope
- Cardiovascular dysfunction
- Psychogenic syncope
- Seizure
- Dehydration
- Pseudosyncope

Transport Management

Heat Syncope

- Place the patient in the recovery position.
- Provide fluids.
- Remove the patient from the hot environment.
- Manage the ABCs as clinically indicated.

Heat Exhaustion

Heat exhaustion is a clinical syndrome representing a moderate form of heat illness on the continuum to heat stroke. Two classic forms of the syndrome are recognized: water-depleted and sodium-depleted. Water-depleted exhaustion primarily occurs in elderly people. Age-related immobility, decreased thirst sensitivity, and medications that contribute to dehydration are suspected culprits.

This condition may also occur in active younger workers and in athletes who do not adequately replenish fluids during activities in a hot environment. Sodium-depleted exhaustion results from excessive losses of sodium from sweating and may take hours to days to develop. When a person loses sweat but replenishes only with water, the lost sodium is not replaced. A closely related condition is **exertional hyponatremia**, which shares many characteristics with (nonexertional) water intoxication. This condition occurs with prolonged exertional activity, usually, but not always, in a warm or hot environment coupled with excessive hypotonic fluid intake and begins with nausea, vomiting, mental status changes, and can eventually lead to cerebral edema and seizure.

Symptoms of heat exhaustion include headache, fatigue, dizziness, nausea, vomiting, and abdominal cramps. Transient syncope may also be present in heat exhaustion, but any significant alteration in neurologic status would be considered heat stroke. Profuse sweating and pale, clammy skin are generally seen. Heart rate and respirations are typically elevated. Tachypnea may lead to signs of hyperventilation syndrome: carpopedal spasm, perioral numbness, and a lowered end-tidal carbon dioxide ($ETCO_2$) level. In heat exhaustion, the patient's core temperature typically ranges from 100.4°F (38°C) to 104°F (40°C), although it is also possible for core temperatures to remain normal. The blood pressure may be low owing to peripheral pooling or volume depletion. Orthostatic hypotension will generally be present. The patient may report having darker, brown urine, which may suggest rhabdomyolysis. CCTPs may find it helpful to consider heat exhaustion as a fluid and electrolyte disorder caused by a hot environment or strenuous activity rather than a disruption of a person's thermoregulatory ability. If left untreated, heat exhaustion may completely compromise a patient's thermoregulatory ability and may progress into heat stroke.

Signs and Symptoms

Heat Exhaustion

- Headache
- Fatigue
- Dizziness
- Nausea
- Vomiting
- Abdominal cramps
- Profuse sweating
- Pale, clammy skin
- Elevated heart rate and respirations
- Carpopedal spasm
- Perioral numbness
- Lowered $ETCO_2$ level
- Normal or elevated skin temperature
- Low blood pressure

- Darker, brown urine

Differential Diagnosis

Heat Exhaustion

- Summer flu
- Heat stroke

Transport Management

Heat Exhaustion

- Move the patient to a cooler environment.
- Remove excess clothing.
- Place the patient in a supine position with the legs elevated.
- Rehydrate the patient with sports drinks if nausea is not present.
- Obtain blood samples for electrolyte analysis, and initiate IV administration of normal saline.
- Consider IV fluids with approval from medical control. Cooling a patient may redistribute fluids within the body, improving intravascular volume.
- Administer fluid based on blood pressure and heart rate.
- Monitor the electrocardiogram (ECG), vital signs, temperature, and $ETCO_2$.
- Consider external cooling measures, such as evaporative cooling.
- Exercise caution when using ice packs or ice water immersion.
- Care for patients receiving specialized cooling techniques, such as cooling blankets; cold water peritoneal, rectal, thoracic, or gastric lavage; cold IV fluids; or cold humidified oxygen, as directed.
- Avoid giving antipyretic medications, which may cause severe complications in patients with heat exhaustion.
- Consider benzodiazepine medications for patients with withdrawal symptoms, excessive shivering, or excessive muscle activity.

Treatment

Treatment of heat exhaustion is aimed at repairing the derangement. Move the patient to a cooler environment, remove excess clothing, and place the patient supine with the legs elevated. Rehydration should be undertaken. Oral rehydration with sport drinks may be appropriate if nausea is not present.

Obtain blood samples for electrolyte analysis and consider IV fluids with approval from medical control for patients who appear volume-depleted. As cooling occurs, fluids distributed throughout the body may return to the intravascular space, improving intravascular fluid volume. Administer fluid based on blood pressure, heart rate, and urine output.

Closely monitor the ECG for signs of electrolyte-induced arrhythmia. Rhabdomyolysis may release excess potassium from the destruction of muscle tissue. Hyperkalemia may result in tall, peaked T waves on the ECG. Exertional hyponatremia may lead to a relative increase in calcium. Heat illness can cause mutliple electrolyte disturbances, including hyponatremia and hypocalcemia, which may result in

electrocardiographic changes. Finally, monitor vital signs, temperature, and $ETCO_2$.

External cooling measures may be taken in patients with an elevated body temperature, but the patient should not be chilled excessively, which can result in shivering and thermogenesis. External cooling is easily accomplished by sponging or spraying the patient with water and fanning gently to promote evaporation. Evaporation will not likely take place if the relative humidity is high (> 80%). Rubbing alcohol should not be used to sponge a patient. Ice packs may cause localized vasoconstriction, restricting heat transfer and removal.

CCTPs may be requested to transport patients who are receiving additional aggressive cooling techniques. Cold water may be lavaged into peritoneal, rectal, gastric, and thoracic cavities of patients with severe heat exhaustion or heat stroke. In addition, many health care facilities have commercial cooling blankets to assist with the management of hyperthermic patients. Cold IV fluids and cold humidified oxygen are also potentially helpful for patients with severe heat exhaustion or heat stroke.

Heat Stroke

Heat stroke is the least common but most deadly of the heat illnesses. It is defined as a severe disturbance in the body's thermoregulation, resulting in altered mental status and a core body temperature of more than 104°F (40°C). It is a profound emergency, with mortality as high as 80% in untreated patients. Death occurs in as many as 10% of treated patients. The "critical thermal maximum" is reached as the core body temperature exceeds 109.4°F (43°C). When this occurs, cellular respiration becomes impaired, cell membranes have increased permeability, protein denaturing begins, and tissue necrosis results.

Two distinct syndromes have been identified: classic and exertional **Table 18-3**. Classic (or passive) heat stroke usually occurs during heat waves. It is most likely to be seen in persons who are very old, very young, or bedridden. Patients with chronic illnesses (such as diabetes and heart disease), people taking certain medications (such as anticholinergics, diuretics, and beta-blockers), and people with alcoholism are more susceptible. As high environmental temperatures elicit thermolysis, the previously mentioned conditions impair heat loss and the core body temperature continues to rise unchecked. In exertional heat stroke, a younger healthy person is exposed to high heat and humidity during a period of strenuous activity. As the ambient temperature reaches that of the body, radiation and convection are interrupted and thermolysis is no longer effective. Evaporative cooling through sweating may be further impaired when the relative humidity is more than 75%. If the person continues the activity in these conditions, heat will continue to generate without a mechanism for removal, resulting in an increase in the core body temperature to more than tolerable levels. In addition to the heat emergency, patients may also have depleted glucose and electrolytes. Their conditions may have progressed to rhabdomyolysis or acute renal failure.

TABLE 18-3 Classic vs Exertional Heat Stroke

Characteristic	Classic Heat Stroke	Exertional Heat Stroke
Age	Older	Younger
General health	Chronic diseases or schizophrenia	Healthy person
Medications	Beta-blockers, diuretics, or anticholinergics	Often none; consider stimulant abuse
Activity	Very little to bedridden	Strenuous
Sweating	Absent	Present

Skin	Hot, red, and dry	Moist and pale
Blood glucose level	Normal	Hypoglycemic
Rhabdomyolysis	Rare	Common
Acute renal failure	Rare	Common

Both types of heat stroke present with similar signs and symptoms. The earliest signs of the altered mental status are irritability, bizarre behavior, combativeness, and hallucinations. These symptoms often mislead bystanders who commonly think the problem is related to substance abuse or behavior rather than the environment. Other presenting signs may lead responders into suspecting stroke or head injury. The diagnostic sign of heat stroke is a markedly elevated core body temperature. Tachycardia, tachypnea with a n $ETCO_2$ less than 20 mm Hg, and dry, red skin are common. The blood pressure may be normal or decreased depending on the degree of dehydration. Other central nervous system disturbances may be seen as tremor, seizure, constricted pupils, and decerebrate or decorticate posturing. Heat stroke is an easy diagnosis to miss. CCTPs must keep the possibility of heat stroke constantly in mind during heat waves, when dealing with the presentation of coma of unknown origin and with cases of the summer flu.

Signs and Symptoms

Heat Stroke

- Altered mental status
- Confusion
- Irritability
- Bizarre behavior
- Combativeness
- Hallucinations
- Elevated core body temperature
- Tachycardia
- Tachypnea with $ETCO_2$ less than 20 mm Hg
- Dry, red skin
- Normal or decreased blood pressure
- Tremors
- Seizure
- Constricted pupils
- Decerebrate or decorticate posturing

Differential Diagnosis

Heat Stroke

- Intracranial hemorrhage
- Ischemic stroke
- Diabetic ketoacidosis

- Malignant hyperthermia
- Neuroleptic malignant syndrome
- Sympathomimetic toxicity
- Salicylate toxicity
- Phencyclidine toxicity
- Encephalopathy
- Withdrawal syndrome

Transport Management

Heat Stroke

- Evaluate the ABCs.
- Administer supplemental oxygen.
- Consider endotracheal intubation.
- Remove the patient's clothing.
- Move the patient to a cooler environment.
- Sponge or spray water over the patient.
- Fan the patient.
- Place ice packs at the nape of the neck, armpits, and groin.
- Initiate an IV line of normal saline, and obtain blood samples for glucose and electrolyte analysis.
- Contact medical control, and consult a physician regarding the use of lactated Ringer's solution.
- Watch closely for developing signs of pulmonary edema.
- Closely monitor the ECG, vital signs, and $ETCO_2$.
- Be prepared to treat a seizure with common antiepileptic drugs (such as diazepam).

Expecting the Unexpected

A heat emergency can occur in any season of the year, especially in elderly people who have difficulty acclimatizing and often have inadequate hydration and take multiple medications, which affect the negative feedback loops in thermoregulation. CCTPs should give particular attention to signs of poor skin turgor and lack of sweating during transport of elderly people with an elevated temperature.

Fever and other conditions may mimic heat stroke and, therefore, increase the challenge for clinicians. The patient's history may provide important clues. For example, a recent complaint of cough or dyspnea, an obvious skin rash, a change in urine color, or intermittent shaking "chills" are more likely to be associated with infection rather than an environmental cause. Pyrogens (proteins excreted in the body's fight of an infection) act on the hypothalamus to increase the body temperature. Fever in children may result in seizure. Fever is most often treated with antipyretics. These measures can prove dangerous in treating heat-related illness.

Anticholinergic and organophosphate exposure and poisoning can also cause hot, red, dry skin; mental status changes; and tachycardia. These agents usually cause dilated pupils, whereas a heat emergency generally results in pupil constriction. In addition, **neuroleptic malignant syndrome**, caused by some antiemetic and antipsychotic medications, and **malignant hyperthermia** may occur with common anesthesia agents (most notably succinylcholine) and may present with hyperthermia, a hyperdynamic state, and altered mentation.

Treatment of Heat Stroke

Treatment of heat stroke is focused on regaining control of the core body temperature. CCTPs should evaluate the ABCs, administer oxygen, and consider controlling the airway. Immediate attempts to decrease the core body temperature begin with removing the patient's clothing and moving him or her to a cooled environment.

Two main methods for rapid cooling are evaporative cooling and ice water immersion. For obvious reasons, ice water immersion, although shown by research to be the superior method, has limited usefulness in the transport environment. Evaporative cooling can be easily started and continued during transport by sponging or spraying water over the patient and fanning to promote the evaporation. Using rubbing alcohol and covering the patient with water-soaked sheets need to be avoided because they can promote thermogenesis. Placement of commercial ice packs at the nape of the neck, armpits, and groin further promotes cooling. In high humidity, evaporation will be restricted. Cooling should be continued until the rectal temperature falls below 102°F (38.8°C). Cooling promotes peripheral vasoconstriction and may raise the blood pressure.

Treatment also includes the following:

- Initiate an IV line of normal saline, and obtain blood samples for glucose and electrolyte analysis.
- Contact medical control, and consult a physician about the use of lactated Ringer's solution.
- Watch closely for developing signs of pulmonary edema.
- Closely monitor ECG, vital signs, and $ETCO_2$, and be prepared to treat a seizure with a benzodiazepine; keep a close eye on the ECG for indications of hyperkalemia and arrhythmia.

The patient should be monitored for changes in central venous pressure, pulmonary wedge pressure, systemic vascular resistance, and cardiac index. If rhabdomyolysis is present, treatment includes aggressive hydration and administration of normal saline. Closely monitor the patient's fluid status and contact medical control for further medications (such as mannitol and sodium bicarbonate) if the patient's condition continues to deteriorate. Additional efforts, such as dialysis, may be needed for elevated potassium or uremia.

Cold Emergencies

Most cold-related injuries are localized to exposed body parts, especially the face, where there are fewer cold receptors in the skin compared with areas of the body covered by clothing. The tip of the nose, ear lobes, fingers, and toes, where peripheral circulation is weakest and body temperature is the lowest, are most susceptible.

Frostbite

Frostbite is classified as **superficial frostbite** (frostnip) and **deep frostbite** depending on the extent of tissue involvement. Frostbite is a mild form of cold injury and comes on slowly and generally without a lot of pain. People with frostbite tend to be unaware of the occurrence. This condition is easily treated by placement of a warm hand over the chilled ear, nose, or fingers. The return of warmth to the affected part is noted by some degree of redness and tingling. Capillary leakage may result in localized edema. The surrounding tissue may appear white and waxy **Figure 18-3**. A burning or stinging sensation may result during warming and may persist for weeks following the event.

Deeper frostbite involves the freezing of tissues exposed to temperatures below the freezing point (32°F [0°C]). Subjected to the low, freezing temperature, the fluid within cells becomes ice crystals, which damage the cells. This condition is further complicated by the "sludge" effect of cooled blood,

resulting in increased viscosity, poor flow, capillary leakage, poor perfusion, thrombus, and ischemia. Frozen tissues appear hard and cold, are without sensation, and take on a yellow-white or mottled blue-white appearance. The most serious complication of frostbite is seen with gradual thawing or refreezing. When tissues thaw slowly, partial refreezing may occur. Because the newer ice crystals formed are larger, they cause greater tissue damage. During thawing, as circulation returns, the area becomes purple and excruciatingly painful. Gangrene, a result of permanent cell death, may set in within a few days, requiring amputation **Figure 18-4**.

Figure 18-3 Frostbitten parts are hard and usually waxy to the touch.

Figure 18-4 Gangrene can occur when tissue is frozen and chemical changes occur in the cells.

Signs and Symptoms

Frostbite

- Hard, cold, waxy, and yellow-white or mottled blue-white skin

Differential Diagnosis

Frostbite

- Arterial occlusion

- Hypoxia or cyanosis
- Dermal exposure to corrosive chemicals
- Vasospasm

Transport Management

Frostbite

- Place a warm hand over the chilled ear, nose, or fingers.
- Do not warm, rub, or massage the area.
- If transport time is less than 1 hour, leave the part frozen.
- If transport time is more than 1 hour or longer, contact medical control to discuss field warming.
- If medical control advises field warming:
  - Immerse the affected tissue completely in water between 95°F and 104°F (35°C and 40°C). Monitor the water temperature.
  - Establish an IV line, and administer pain medication.
  - Dry the part thoroughly once it has thawed.
  - Apply a dressing.
- Take great care to prevent refreezing.

Treatment

Treatment of deep frostbite depends on two factors:

- The distance to the receiving hospital
- The degree of thawing before arrival at the hospital

If the part is still frozen or the transport time is reasonable (< 1 hour), the part should be left frozen. The part should be padded excessively to protect it from further injury. Warming should not be attempted during transport because rapid warming is difficult. The patient should not rub or massage the area because the ice crystals in the cells would lacerate delicate tissues. If the tissue is partially thawed or transport will exceed 1 hour, medical control should be contacted for advice on field warming. The affected tissue should be immersed completely in water between 95°F and 104°F (35°C and 40°C). An IV line should be established for the administration of pain control medication (such as morphine or fentanyl). The water temperature should be monitored to maintain it in the therapeutic range. This treatment procedure typically takes 30 minutes or more. The patient should not smoke during this procedure because nicotine causes vasoconstriction that would further interfere with the thawing process. Once circulation has returned and the part is thawed, it should be dried thoroughly and a dry dressing should be applied to further protect the tissues during transport. The tissues should not be allowed to refreeze.

Hypothermia

Hypothermia is defined as a decrease in core body temperature below 95°F (35°C). Hypothermia may be a result of impaired thermogenesis, excessive thermolysis, or excess environmental cold stress. Any environmental temperature below an individual's physiologic core body temperature can result in hypothermia. Hypothermia may occur in any season. Alcohol use has been identified as a factor

contributing to hypothermia. Hypothyroidism, liver disease, and malnutrition may further contribute to a predisposition to hypothermia. Trauma is the most important other factor contributing to hypothermia. Additionally, hypovolemia and hypotension interfere with normal thermoregulation.

Mild hypothermia is a core body temperature between 90°F and 95°F (32.2°C and 35°C). At these temperatures, the body usually compensates with increased thermogenesis and interrupted thermolysis. Shivering is in full force, and the "umbles" (stumbles, mumbles, fumbles, and grumbles) are present. The heart rate, blood pressure, and cardiac output may rise. These processes continue until the core body temperature returns to normal or glycogen stores are exhausted. If left unchecked, more serious conditions will result.

Severe hypothermia begins as the core body temperature drops below 90°F (32.2°C). At these temperatures, the body reacts by slowing things down. This slowed metabolism decreases thermogenesis, and the heart rate, blood pressure, and cardiac output decrease. As peripheral vasoconstriction occurs to shunt warm blood in the core, the volume receptors interpret the change as an increase in blood volume and stimulate the kidneys to produce more urine (cold diuresis). There is a simultaneous shift of fluids from the intravascular to the extravascular space, which increases the viscosity of blood. As the cold continues, the heart rate plummets. Shivering ceases at a body temperature less than 91°F (32.7°C). Tracheobronchial secretions increase and bronchospasm may occur. At a core body temperature of less than 90°F (32.2°C), hypoventilation is profound.

Bradycardia and cardiac arrhythmia, in particular atrial arrhythmias, may be seen. An Osborn or J wave may be seen on the ECG tracing **Figure 18-5**. Abnormal cardiac conduction and hypothermia-induced arrhythmias may lead to ventricular fibrillation, especially as the core body temperature falls below 82.5°F (28°C). Repeated defibrillation is not recommended until the patient has been warmed to a core body temperature of more than 86°F (30°C).

Special Populations

Elderly patients are more susceptible to hypothermia. Even in warm weather or inside a heated transport unit, older patients are susceptible to significant heat losses. Monitoring temperature is as important in the older population as in neonates.

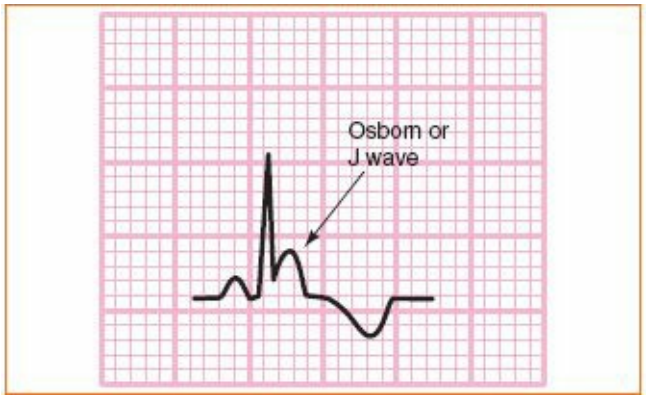

Figure 18-5 Osborn or J wave.

Many of the usual ACLS medications will not be effective for patients with severe hypothermia. American Heart Association guidelines recommend administering ACLS medications at greater intervals for patients with moderate hypothermia (86°F to 93.2°F [30°C to 34°C]). ACLS medications should be withheld for patients with severe hypothermia (< 86°F [30°C]) until the core body temperature has been

increased to more than 86°F (30°C). In general, atropine and cardiac pacing are ineffective for hypothermia-induced bradycardia. Lidocaine is also ineffective for preventing or treating hypothermia-induced ventricular arrhythmias. There is some limited evidence in animal studies that bretylium may be beneficial for preventing ventricular fibrillation in patients with hypothermia, but this practice is not currently recommended by American Heart Association guidelines.

Treatment

Treatment is based on warming the patient, which involves removing cold, wet clothing; drying and moving the patient to a warmed environment; and further passive or active warming of the truncal area. Active warming may include an infusion of warmed IV fluid (102°F to 105°F [38.8°C to 48.5°C]); warm, humid oxygen delivery; and a peritoneal lavage of a potassium chloride-free solution.

Expecting the Unexpected

Hypothermia can occur in any season of the year, especially in elderly people who have difficulty acclimatizing and are often prescribed multiple medications that affect the negative feedback loops of thermoregulation. CCTPs should pay particular attention during transport of elderly people. The transport environment creates numerous opportunities to cause or worsen preexisting hypothermia. Even brief episodes of exposure to cold temperatures while moving to or from a transport vehicle can significantly undermine rewarming efforts. Even when the ambient temperature is room temperature, young or elderly patients can be hypothermic. Although CCTPs may be sweating on a hot summer day, a patient may be too cold. It is essential that CCTPs sacrifice personal comfort by creating an adequately warm environment for the resuscitation or transportation of patients with hypothermia.

Signs and Symptoms

Hypothermia

- Decrease in core body temperature to less than 95°F (35°C)
- Shivering or lack of shivering
- Stumbling, mumbling, fumbling, and grumbling
- Increased or decreased heart rate
- Increased or decreased blood pressure
- Increased or decreased cardiac output
- Cardiac arrhythmias
- Osborn or J wave on the ECG

Differential Diagnosis

Hypothermia

- Drowning
- Profound shock
- Cardiac arrest
- Toxic chemical exposure
- Overdose

Transport Management

Hypothermia

- Remove cold, wet clothing.
- Dry the patient.
- Move the patient to a warmed environment.
- Consider warmed IV fluid, humidified oxygen, and peritoneal lavage of a potassium chloride-free solution.

Drowning

Drowning has been identified as the second leading cause of injury-related death among people between 1 and 15 years old. The term "near-drowning" was abandoned following the 2002 meeting of the first World Congress on Drowning. Experts narrowed the 33 former definitions of drowning to one definition that includes any process of respiratory impairment caused by submersion or immersion in liquid. Initial rescue should be conducted by specially trained personnel. CCTPs should never expose themselves or their crews to unwarranted hazards.

Transport Management

Drowning

- Provide spinal stabilization for patients witnessed to have dived into the water and when alcohol use is suspected.
- Provide supplemental oxygen.
- Perform endotracheal intubation.
- Provide positive end-expiratory pressure.
- Consider inserting a nasogastric tube to decompress the stomach.
- Consider administering a beta-2-adrenergic agonist to treat bronchospasm and tracheobronchial irritation.

Treatment

Treatment begins with spinal stabilization of patients witnessed diving into the water and when alcohol use is suspected. Ventilation should be assisted with supplemental oxygen as soon as possible, and advanced airway management where necessary. Widespread atelectasis and pulmonary shunt may be present in a drowning victim. The use of 10 cm H_2O of positive end-expiratory pressure, through the use of a commercially made additive valve designed for this purpose, may aid in keeping alveoli open and driving fluid into the interstitial or capillary spaces. A nasogastric tube may be used, after airway control, to decompress the stomach. Bronchospasm and tracheobronchial irritation may be treated with a beta-2-adrenergic agonist. Acute respiratory distress syndrome is a common complication of submersion incidents. Chemical or bacterial pneumonitis and renal failure are also complications that can occur days after resuscitation.

Diving Injuries and Decompression Sickness

Diving injury associated with recreational and professional scuba diving activities can result regardless of diver experience. All divers are subject to pressure effects. For each 33′ of depth, the pressure on the body increases by 1 atmo, or 14.7 lb/in^2. The most common effect is on nitrogen within the body. Nitrogen dissolves from gas inhaled into fatty tissues. Nitrogen readily displaces oxygen in the brain, resulting in feelings of euphoria and disorientation known as **nitrogen narcosis**. Nitrogen gas bubbles also expand rapidly on ascent, causing excruciating pain when trapped in body cavities such as joints or in the folds of the intestinal tract (the "bends") **Figure 18-6**. In addition to the bends, patients with decompression sickness may experience respiratory disturbances (the "chokes"), discussed later, neurologic impairment (the "staggers"), and skin sensation abnormalities (the "creeps" or "skin bends").

Barotrauma may occur during either ascent or descent, depending on the situation. Gases stored in confined spaces within the body may either expand or contract during changes in elevation. As a patient travels to a higher elevation, trapped gases attempt to expand, causing increased pressure within a particular body cavity. As a patient descends, the pressure of the outside environment exceeds the pressure of various gases within the body, resulting in inward pressure. The patient's lungs, ears, and gastrointestinal tract are prone to injury from barotrauma. Indwelling devices with inflated balloons, such as endotracheal tubes and laryngeal mask airways (LMAs), are also affected by changes in altitude. CCTPs should closely monitor these devices during ascent and descent. Rapid ascent is also responsible for **pulmonary overpressurization syndrome (POPS)**, in which gases in the lungs expand rapidly as the pressure decreases and pneumothorax or mediastinal or subcutaneous emphysema result. Simply holding one's breath during the last 6′ of the ascent is sufficient to cause these injuries. Arterial gas embolism may result, in which air bubbles escape from ruptured alveoli and enter pulmonary capillaries, travel through the pulmonary veins to the heart, and if they end up in the coronary arteries or cerebral vasculature, result in acute myocardial infarction or stroke. The vast majority proceed to cerebral arteries, resulting in a stroke.

Figure 18-6 Decompression sickness affects divers who ascend to the surface too quickly.

Transport Management

Diving Injuries

- Provide rapid transport.
- Provide oxygenation.
- Do not use positive end-expiratory pressure or continuous positive airway pressure (CPAP).

- Consider hyperbaric therapy.

Treatment for Decompression Sickness

Treatment in the prehospital setting includes rapid transport and oxygenation. Providers should administer 100% oxygen to promote nitrogen washout from the lungs. Positive end-expiratory pressure and CPAP should not be used for patients with diving injuries or decompression sickness unless necessary to maintain oxygenation.

A valuable resource for dealing with dive-related injuries is the Divers Alert Network (DAN), which provides a 24-hour hotline (919-684-8111). Hyperbaric oxygen therapy (HBOT) is often necessary to minimize the morbidity and mortality from decompression sickness. The DAN can guide CCTPs through a variety of complex decisions about treatment, transport, and patient disposition.

CCTPs should closely monitor patients with decompression sickness, even if they begin to show improvement or recovery. Relapses of symptoms are possible and may be associated with an overall deterioration of the patient's condition.

The use of a pure Trendelenburg or the combination of a head-down with left lateral decubitus (Durante) position is not currently recommended owing to increases in intracranial pressure. Patients should be transported in a supine position at the lowest cabin altitude pressure possible. Depending on the topography of a transport route, even ground ambulance transport may subject patients to increased physiologic stressors and worsen their condition.

Figure 18-7 A hyperbaric chamber, usually a small room, is pressurized to more than atmospheric pressure and used in the treatment of decompression sickness and air embolism.

Other potential interventions for treatment or during transport may include the following: (1) aspirin for prevention of thrombus formation, (2) management of tension or simple pneumothorax with a thoracostomy (chest) tube, (3) aggressive IV fluid resuscitation, and (4) ACLS protocols for profound cardiopulmonary dysfunction. Patients with decompression sickness are likely to require analgesics, sedatives or anxiolytics, and antiemetics during transport. The patients may also have other concerns, such as trauma or hypothermia, that require additional resuscitative measures. Severe manifestations of decompression illness are likely to require transport for HBOT.

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy is generally accomplished by placement of the patient in a specially constructed chamber designed to withstand internal pressures well in excess of normal atmospheric pressures. The chamber is filled with compressed air to a desired level, typically expressed as

atmospheres or feet of seawater. The patient receives pure or blended oxygen via mask or endotracheal tube **Figure 18-7**. Hyperbaric chambers can be in a fixed location or portable so they can be in proximity to high-risk diving activities. Chambers are configured to handle one patient or multiple patients. In larger chambers, a trained medical provider typically accompanies the patient into the chamber to monitor equipment and intervene if the patient's condition begins to deteriorate.

Most patients will receive 100% inspired oxygen while undergoing HBOT. In addition to saturating blood hemoglobin, oxygen under greater than atmospheric pressure becomes dissolved into the circulating plasma. HBOT has a number of interesting benefits to a variety of patients. Localized vasoconstriction from hyperoxygenation decreases tissue edema following crush injuries, burns, and other types of trauma. This vasoconstriction is offset by improved blood flow at the capillary level. HBOT also creates oxygen-free radicals and alters other components of a patient's inflammatory response, leading to improved wound healing and improvement of a pathologic inflammatory response. In specific situations, nitrogen and helium can be blended into the inspired oxygen.

TABLE 18-4 Indications for Hyperbaric Oxygen Therapy

Air or gas embolism
Carbon monoxide poisoning
Carbon monoxide poisoning complicated by cyanide poisoning
Clostridal myositis and myonecrosis (gas gangrene)
Crush injury, compartment syndrome, and other acute traumatic ischemias
Decompression sickness
Enhancement of healing in selected problem wounds
Exceptional blood loss (anemia)
Intracranial abscess
Necrotizing soft-tissue infections
Osteomyelitis (refractory)
Delayed radiation injury (soft-tissue and bony necrosis)
Skin grafts and flaps (compromised)
Thermal burns

Source: Reprinted with permission from the Undersea and Hyperbaric Medical Society (http://www.uhms.org).

The indications for HBOT have been established by the Committee on Hyperbaric Oxygenation of the Undersea and Hyperbaric Medical Society **Table 18-4**. HBOT facilities in North America and the Caribbean can be identified by contacting Duke University at 919-684-8111 or the DAN. The Undersea and Hyperbaric Medical Society also maintains a database of US and international hyperbaric chambers. With the wide variety of indications for HBOT, it is quite possible that hyperbaric chambers can be found in locations not typically associated with underwater activities. "Treatment tables" are used to determine the length of HBOT and treatment steps. These tables take into account the depth, time of dive,

decompression stops, and previous dives performed. A hyperbaric specialist can recommend which table to use. Patients with severe illness often require several HBOT treatments. HBOT may prove beneficial even several days or longer in select situations, such as carbon monoxide poisoning. Any time HBOT is considered, CCTPs or medical providers should seek specialty consultation with a provider experienced with hyperbaric medicine.

Transport to these special facilities often requires air medical flight. In cases of barotrauma, the flight should be planned to take place at low-level altitude (lowest altitude safely possible) or in a pressurized aircraft cabin set to 1 atm or ata. The sending medical providers, in conjunction with CCTPs, must carefully weigh the risks and potential benefits to a patient when selecting the appropriate transport vehicle for a patient requiring transport for HBOT. The DAN recommends that cabin altitude not exceed 800′ for aircraft transport of patients with decompression sickness. This altitude limit may not always be possible owing to terrain or topography, weather, aircraft limitations, or other factors.

Controversies

Although many training materials may not reflect the evolution of the ideal position for an injured diver, the trends have shifted over the years. Currently, certain observations have suggested that use of the Trendelenburg position may not provide the best in patient care. These findings include the limitations for resuscitation, increased cephalic venous volumes, and compromised subsequent middle ear equalization that occur in a head-down position, as well as the difficulty in distinguishing cerebral arterial gas embolism from cerebral decompression sickness. Likewise, significant arterial gas embolism most likely occurs in decompression sickness through the arterialization of venous bubbles. In the Trendelenburg position, venous return is increased, sending the bubbles back to the heart. Finally, studies show that brain function recovery time is longer for patients who are placed in a head-down position.

Ultimately, although there may be some occasional benefit to placing specific patients in a head-down position, many practitioners prefer keeping most patients supine.

Flight Considerations

According to DAN, if air evacuation is used, cabin pressure must remain near sea level and the aircraft should not go above 800′ unless the captain is required to do so for safety precautions. The diver should be placed in the lateral recumbent position, or the recovery position, with the patient on his or her side, the head supported at a low angle, and the upper leg bent at the knee. Gravity will help to keep the patient's airway clear. Other experts recommend that patients be transported in a supine position. Additional discussion of this subject is found in the controversies box.

Altitude Illness

Extremes of altitude pose life-threatening hazards for experienced mountain climbers pushing the limits of human exploration on remote peaks throughout the world. Scores of other people have similar, potentially catastrophic effects of altitude when they travel from lower elevations to higher elevations in the course of everyday life. People with preexisting medical problems, extremes of age, sedentary lifestyles, and poor health choices are at increased risk of altitude-related illness following even modest changes in elevation. The severity of altitude-related illness can range from mild symptoms, such as imperceptible tachypnea or sleep disturbances, to life-threatening manifestations, such as pulmonary edema, cerebral

edema, and hypoxia.

High altitude can also affect the body negatively, usually from a lack of acclimatization. Hypoxia from low atmospheric pressure is the main culprit in altitude sickness.

Altitude sickness is most commonly associated with mountain climbing and alpine skiing and is often called acute mountain sickness. Acute mountain sickness can occur at altitude changes of 3,000′ to 6,000′, but generally occurs at elevations above 8,000′ or higher. The Lake Louise criteria are useful for identifying acute mountain sickness. In the setting of a recent gain in altitude, these criteria include the presence of at least two of the following signs (crackles or wheezing in at least one lung field, central cyanosis, tachypnea, and tachycardia) and at least two of the following symptoms (dyspnea at rest, cough, weakness or decreased exercise performance, and chest tightness or congestion). More serious problems, **high-altitude pulmonary edema (HAPE)** and **high-altitude cerebral edema (HACE)** are likely at higher elevations.

HAPE is a noncardiogenic form of pulmonary edema that develops within 24 to 72 hours of reaching higher altitudes. Patients may demonstrate a variety of symptoms, including cough, respiratory distress, chest tightness, fatigue, and fever. The presence of fever may mislead clinicians and delay diagnosis.

The pathophysiologic features of HAPE are poorly understood. Pulmonary hypertension from alveolar hypoxia, localized inflammation, and capillary or arterial thromboses are implicated in patients with HAPE. People who make frequent changes in altitude are at increased risk of HAPE.

HACE should be considered a life-threatening emergency and should prompt immediate descent when recognized. Any patient who has recently experienced a significant gain in altitude and who now has mental status changes or ataxia should be evaluated for HACE. Either of the previously mentioned symptoms is presumed to be HACE if a particular person already has signs or symptoms of acute mountain sickness. If ataxia *and* mental status changes are present, HACE is presumed even if other signs or symptoms of acute mountain sickness are not present.

HACE is thought to be a result of cerebral vasodilation from hypoxia, although the precise mechanism has not been identified. Cerebral edema results from this enhanced blood flow, leading to the previously mentioned mental status changes and ataxia.

Once HACE is recognized, immediate descent should be initiated. Patients should receive supplemental oxygen during descent. Dexamethasone should be administered to patients with HACE. Diuretic medications are not indicated and have the potential to produce harmful alterations in fluid volume.

Signs and Symptoms

Altitude Illness

- Hypoxia
- Fatigue
- Weakness
- Near-syncope
- Headache
- Dyspnea
- Cough
- Pulmonary edema
- Chest tightness
- Tachycardia

Differential Diagnosis

Altitude Illness

- Any other possible cause of respiratory distress (such as asthma, chronic obstructive pulmonary disease, pneumonia, and bronchitis)
- Any other possible cause of altered mental status or ataxia (such as stroke, toxic exposure, encephalitis, and traumatic brain injury)
- Unrelated cardiovascular dysfunction (such as cardiogenic shock, cardiogenic pulmonary edema, and acute myocardial infarction)
- Unrelated gastrointestinal condition (such as gastroenteritis, gastritis, and pancreatitis)
- Labyrinthitis
- Electrolyte or hematologic abnormality

Transport Management

Altitude Illness

- Provide oxygenation.
- Evacuate the patient and begin descent.
- Consider hyperbaric therapy.

Rapid descent is the preferred treatment for HAPE. Patients should also receive supplemental oxygen during the descent. Nifedipine, salmeterol, and portable hyperbaric bags are effective and should be used if available for the management of HAPE. CPAP may also play a role in the management of these patients.

Flight Considerations

Patients with various altitude-related illnesses pose a significant challenge for CCTPs. It is quite conceivable that CCTPs may be asked to perform a rescue or evacuation function from a remote area with a high elevation. These locations are particularly hazardous for ground transport vehicles and aircraft. When requested to perform a rescue or evacuation mission, CCTPs should carefully consider safety issues, such as training and experience of the personnel, capabilities of the particular transport vehicle, and weather and environmental concerns, as well as the severity of illness and capabilities of a potential patient. Numerous emergency responders have been killed or severely injured while attempting rescue or evacuation of a patient from mountainous terrain.

During the transport, CCTPs must minimize the impact of environmental conditions on the patient. For patients with altitude-related illnesses, CCTPs must balance capabilities and safety concerns related to a particular transport vehicle with the patient's clinical needs. Ideally, descent should occur rapidly for patients with severe manifestations of altitude illness. Rapid or prompt descent may not be possible when weather, topography, and terrain complicate the transport.

Patients with altitude illness may have other issues, such as hypothermia, dehydration, trauma, or a preexisting medical condition that requires additional interventions. CCTPs must balance the needs for

warmth, privacy, and protection against patient care needs such as exposure, thorough assessment, and patient access for monitoring or procedures. It may be advisable in many situations to defer a thorough visual assessment or invasive interventions in the interest of keeping a patient clothed, covered, and warm during extreme environmental conditions.

Prolonged evacuation of a patient with altitude illness may also exceed the supplies, equipment, and capabilities of a particular transport team. When performing such transports, CCTPs should be mindful of critical supplies, such as oxygen, that may become rapidly depleted. Monitoring equipment, ventilator, and infusion pump batteries may not have the longevity to continue functioning during prolonged evacuation or transportation from remote locations.

Summary

Patients with conditions related to environmental emergencies can pose a significant challenge to CCTPs. These conditions are often difficult to diagnose and manage while in the transport environment, and there is a risk of further deterioration in a patient's condition during movement from one location or facility to another. CCTPs need to keep these conditions in mind when dealing with patients in a coma or those who have collapsed suddenly as a result of unknown causes. Knowing the risk factors that predispose a patient to environmental emergencies can aid in recognizing these conditions early in the patient encounter.

Case Study

YOU HAVE JUST ARRIVED FOR YOUR REGULARLY SCHEDULED ROTOR-WING SHIFT , when your dispatch center advises that you are being dispatched to the Rocky Mountain Rural Clinic, situated at 8,200′ above sea level, for a patient diagnosed as having probable HAPE. The patient needs to be transported to Mercy Hospital for HBOT. After your flight team (the pilot, flight nurse, and you, a critical care paramedic) completes the safety briefing, you depart for the rural clinic.

On arrival, your flight team is met by the attending physician. She advises you that the patient is a 42-year-old, 106-kg man who had been climbing in the local national park for the past 2 or 3 days with three other people when he started to complain of fatigue and severe dyspnea. The party began its descent from approximately 12,000′, which took approximately 9 hours, and then drove a vehicle to the local clinic. On arrival, the patient's dyspnea was mildly resolved; however, he had a decreasing level of consciousness.

Treatment in the clinic included oxygen via nonrebreathing mask at 15 L/min to treat central cyanosis, a chest x-ray that showed patchy bilateral infiltrates, and an ECG that indicated a right-sided heart strain pattern. The patient has an IV line with an 18-gauge needle in his left wrist running normal saline to keep the vein open; he also has an indwelling urinary catheter, with minimal urine output. Medications that were given included 10 mg of nifedipine (Procardia) by mouth and 80 mg of furosemide (Lasix) IV. The patient is presently resting but in moderate distress and has a Glasgow Coma Scale score of 13 (eye opening score, 3; verbal score, 4; and motor score, 6). Vital signs are a blood pressure of 142/81 mm Hg, a heart rate of 132 beats/min, sinus tachycardia with no ectopy, respirations of 28 breaths/min with rales bilaterally, and an Sp_{O_2} of 86% despite aggressive oxygen therapy. After a positive Allen test result, an arterial line was inserted into the right radial artery. Arterial blood gas readings show acute respiratory alkalosis with a pH of 7.49; Pa_{CO_2}, 30 mm Hg; Pa_{O_2}, 88 mm Hg; $H_{CO^-_3}$, 22 mEq/L; and base excess, 1. All available laboratory values are unremarkable.

As you are preparing to secure the patient onto your litter for the flight, he coughs up a small amount of blood-tinged sputum. Rather than electively intubating your patient for the flight, you decide to apply CPAP in an effort to decrease the patient's work of breathing. CPAP is applied initially at 5 cm H_2O, which seems to have no effect. You subsequently titrate the CPAP up to 7.5 cm H_2O, which decreases his

work of breathing and decreases his anxiety level. Your partner contacts your base hospital physician to advise of the patient's status, obtain any additional orders, and give an estimated time of arrival. The base hospital physician requests that 8 mg of dexamethasone (Decadron) and 250 mg of acetazolamide (Diamox) be administered en route. As your partner transfers the patient's IV to your pump and calibrates the arterial line to your monitor, you speak to the pilot and advise him that owing to the patient's condition, it is imperative to fly at a lower altitude to minimize the effects of altitude on the patient.

Once airborne, 8 mg of dexamethasone and 250 mg of acetazolamide are given IV, and all hemodynamic parameters are monitored throughout the 48-minute flight. Once you arrive at the Mercy Hospital helipad, the patient is taken directly to the hyperbaric chamber for definitive treatment.

1. How was the diagnosis of HAPE determined?
2. Why was the patient given nifedipine, furosemide, dexamethasone, and acetazolamide?
3. What are the potential problems that you may experience en route with this patient?

Analysis

Because of your critical care training, you are able to recognize that this patient is experiencing severe HAPE based on the Lake Louise acute mountain sickness criteria, which, in the setting of a recent gain in altitude, include the presence of at least two of the following signs (crackles or wheezing in at least one lung field, central cyanosis, tachypnea, and tachycardia) and at least two of the following symptoms (dyspnea at rest, cough, weakness or decreased exercise performance, and chest tightness or congestion).

Although you realize that HAPE usually resolves with descent from altitude, this patient was experiencing a severe case that did not resolve, and, in fact, the patient's condition appeared to be deteriorating.

Nifedipine is given in cases of HAPE in an effort to promote vasodilation of the pulmonary vessels, and furosemide is given to promote diuresis. Acetazolamide is given in cases of HAPE to increase the amount of bicarbonate excreted in the urine, making the blood slightly acidic, which, in turn, stimulates ventilation, increasing the amount of oxygen in the bloodstream. Dexamethasone is given to treat pulmonary edema and to minimize cerebral edema.

This patient has the potential to experience several problems en route. Owing to the 48-minute flight to the receiving hospital and the fact that the patient is receiving CPAP, the potential to run out of oxygen is a risk; however, by performing a thorough pre-flight of your aircraft, oxygen cylinders that are almost depleted should have been noted and replaced before your mission. In any patient with an altered mental status in the flight environment, CCTPs need to be aware of the possible need to perform definitive airway management, which is often difficult in the confined space of a helicopter. Finally, this patient was experiencing an acute case of HAPE, and, depending on the altitude required during the flight, his pulmonary edema could progressively worsen. Good communication between the crew and the pilot will help to minimize the effects of pressurization, thus minimizing complications en route.

Prep Kit

Ready for Review

- Very young and very old people, people taking certain medications, and people in a poor state of health are predisposed to environmental emergencies. The challenge for CCTPs is to recognize patients who are susceptible to environmental exposure in conditions that are not extremely hot or cold. CCTPs must also initiate or continue critical interventions during transport.

- The hypothalamus acts as the body's master thermostat, using negative feedback control. The three major components of the negative feedback system are temperature receptors, effector organ systems, and integrator or controller.
- To reduce excess body heat, blood vessels in the skin dilate, perspiration increases, and muscle activity is inhibited.
- To increase body heat, the posterior hypothalamus is stimulated to constrict blood vessels, and muscle activity, and the piloerector muscles are stimulated.
- The heat produced at rest by normal metabolic reactions is referred to as the basal metabolic rate (BMR). The BMR can be affected by age, sex, stress, hormones, and body surface area. As the ratio of body surface area to body volume increases, heat loss increases.
- Heat warms the body and maintains the core body temperature. The body transfers heat to the environment through radiation, conduction, convection, and evaporation. If the environment is hotter than the body, the body gains heat through absorption. Humidity can affect thermoregulation by impairing the evaporative process.
- In very cold temperatures, a fair amount of heat is lost through respiration. The body shifts to thermogenesis when the environment is cold. The BMR and physical exertion are increased.
- Heat illness occurs when an increase in core body temperature exceeds the body's ability to dissipate the excess heat. CCTPs in all geographic regions of the United States should be prepared to transport patients with heat-related illnesses.
- CCTPs should be familiar with medications and other factors that contribute to heat illness.
- Heat cramps are the result of a water-sodium imbalance and are often not accompanied by hyperthermia. Water intoxication may occur if the person tries to replenish lost fluids by drinking excessive amounts of free water in a very short time. Additional cooling measures may be needed if the person has heat exhaustion, heat stroke, or significant hyperthermia.
- The condition of patients with heat cramps usually improves after they are removed from the hot environment and drink a salt-containing liquid or an electrolyte drink. CCTPs should use caution when administering IV fluids to correct presumed hyponatremia if there is any possibility of hyponatremia.
- Treatment of heat syncope focuses on placing the patient in the recovery position and allowing fluid intake if mental status permits. If the patient does not recover quickly, heat exhaustion or heat stroke should be suspected.
- Two forms of heat exhaustion are water-depleted and sodium-depleted. Symptoms range from headache and fatigue to orthostatic hypotension and darker, brown urine. If left untreated, heat exhaustion may progress to heat stroke.
- Heat stroke is a severe disturbance in the body's thermoregulation, resulting in altered mental status and a core body temperature of more than 104°F (40°C). The critical thermal maximum is reached when the core body temperature exceeds 109°F (42.7°C).
- CCTPs should be aware of the differences between classic and exertional heat stroke and be suspicious of heat stroke during heat waves, when dealing with coma of unknown origin, and with cases of summer flu.
- Heat emergency can occur at any time of year, especially in elderly people. CCTPs should pay attention to signs of poor skin turgor and lack of sweating when transporting an elderly patient with a fever. The patient's history is also an important source of information in diagnosing heat stroke.
- Treatment of heat stroke focuses on regaining control of the core body temperature. Evaporative

cooling can be started and continued during transport.

- Most cold-related injuries are localized to exposed body parts. The most susceptible parts are the tip of the nose, the ear lobes, and the fingers and toes.
- Superficial frostbite (frostnip) comes on slowly, generally occurs without much pain, and is easily treated by placing a warm hand over the chilled area.
- Deeper frostbite involves the freezing of tissues. The most serious complication of frostbite occurs in gradual thawing or refreezing. Gangrene may set in within a few days, requiring amputation. Treatment depends on the distance to the receiving hospital and the degree of thaw before arrival at the hospital.
- Hypothermia is a decrease in core body temperature to less than 95°F (35°C). Mild hypothermia is defined by a core body temperature between 90°F and 95°F (32.2°C and 35°C). The body usually compensates for mild hypothermia with increased thermogenesis and interrupted thermolysis.
- Severe hypothermia occurs when the core body temperature drops below 90°F (32.2°C). The body reacts by slowing metabolism, which decreases thermogenesis, heart rate, blood pressure, and cardiac output and has many other effects. Treatment is based on warming the patient.
- Hypothermia can occur at any time of year, particularly in elderly people. CCTPs should sacrifice personal comfort to create an adequately warm environment for the resuscitation or transport of patients with hypothermia.
- Drowning includes any process of respiratory impairment from submersion or immersion in liquid. Only specially trained personnel should attempt to rescue a drowning victim from water.
- Divers may experience nitrogen narcosis, caused by nitrogen dissolving from gas inhaled into fatty tissues. Nitrogen gas bubbles expanding rapidly on ascent may cause the “bends,” the “chokes,” the “staggers,” and the “creeps” or “skin bends.”
- Barotrauma may occur during either ascent or descent. The patient’s lungs, ears, and gastrointestinal tract are prone to injury from barotrauma.
- Pulmonary overpressurization syndrome is caused by rapid ascent. Arterial gas embolism may occur, which can result in acute myocardial infarction or stroke.
- CCTPs can use the Divers Alert Network (DAN) hotline for guidance through decisions about treatment, transport, and patient disposition. CCTPs should closely monitor patients with decompression sickness, even if they show improvement or recovery. Relapses are possible.
- Hyperbaric oxygen therapy may be indicated for patients with decompression sickness. CCTPs should also be aware of other indications for hyperbaric therapy. Hyperbaric oxygen therapy facilities can be identified by contacting Duke University or the DAN.
- If air evacuation is used for an injured diver, cabin pressure must be kept near sea level and the aircraft should not fly above 800′ unless necessary for safety precautions. The latest evidence suggests that the supine position is best for transporting patients with diving injuries.
- Altitude sickness is also called acute mountain sickness. The Lake Louise criteria are useful for identifying acute mountain sickness.
- High-altitude pulmonary edema (HAPE) and high-altitude cerebral edema (HACE) are likely at higher elevations.
- HAPE may develop within 24 to 72 hours of reaching higher altitudes. Symptoms include cough, respiratory distress, chest tightness, fatigue, and fever. Rapid descent is the preferred treatment for HAPE, along with supplemental oxygen.

- HACE is life threatening; when it is recognized, immediate descent should be initiated. Mental status changes and ataxia are symptoms of HACE.
- CCTPs may be asked to rescue or evacuate a patient from a remote area at a high elevation. These locations are very hazardous, and safety issues such as training and experience of personnel, capabilities of the transport vehicle, weather and environmental concerns, and the severity of illness and capabilities of the patient must be considered.
- Capabilities and safety concerns related to the transport vehicle must be balanced with the patient's clinical needs. Although rapid descent is ideal for patients with severe altitude illness, it may not be possible owing to environmental factors. A thorough visual assessment or invasive interventions may have to be deferred because of environmental conditions. Critical supplies and equipment must be monitored closely.

Vital Vocabulary

absorption Acquisition of additional heat, radiation, or other energy from the environment; or, a substance's molecules are moved from the site of entry on the body into the systemic circulation.

barotrauma Injury to tissues, organs, or structures within the body, resulting from rapid or significant changes in environmental air pressure.

basal metabolic rate (BMR) The heat energy produced at rest by normal body metabolic reactions, determined mostly by the liver and skeletal muscles.

conduction Transfer of heat to a solid object or a liquid by direct contact.

convection The mechanism by which heat (body heat in the context of this chapter) is picked up and carried away by moving air currents.

deep frostbite A type of frostbite in which the affected part looks white, yellow-white, or mottled blue-white and is hard, cold, and without sensation.

evaporation The conversion of a liquid to a gas.

exertional hyponatremia A low sodium level as a result of prolonged exertion in hot environments coupled with excessive hypotonic fluid intake that leads to nausea, vomiting, and, in severe cases, mental status changes and seizures.

frostbite Localized damage to tissues resulting from prolonged exposure to extreme cold.

heat cramps Acute and involuntary muscle pains, usually in the lower extremities, the abdomen, or both, that occur because of profuse sweating and subsequent sodium loss in sweat.

heat exhaustion A clinical syndrome characterized by volume depletion and heat stress that is thought to be a milder form of heat illness and on a continuum leading to heat stroke.

heat stroke The least common and most deadly heat illness, caused by a severe disturbance in thermoregulation, usually characterized by a core body temperature of more than 104°F (40°C) and altered mental status.

heat syncope An orthostatic or near-syncopal episode that typically occurs in nonacclimated people who may be under heat stress.

high-altitude cerebral edema (HACE) An altitude illness in which there is a change in mental status and/or ataxia in a person with acute mountain sickness or the presence of mental status changes and ataxia in a person without acute mountain sickness.

high-altitude pulmonary edema (HAPE) An altitude illness characterized by dyspnea at rest, cough, severe weakness, and drowsiness that may eventually lead to central cyanosis, audible rales or wheezing, tachypnea, and tachycardia.

hypothalamic-pituitary axis An interrelationship between the hypothalamus and pituitary gland in which a releasing or an inhibiting factor is sent from the hypothalamus to the pituitary, resulting in an increase or a decrease in metabolism and other functions throughout the body.

hypothalamo-hypophyseal portal system The venules between the capillaries in the hypothalamus and pituitary gland by which the hypothalamus sends releasing or inhibiting factors to the pituitary gland, thereby increasing or decreasing metabolism.

hypothalamus The most inferior portion of the diencephalon; it is responsible for control of many body functions, including heart rate, digestion, sexual development, temperature regulation, emotion, hunger, thirst, and regulation of the sleep cycle.

hypothermia A condition in which the core body temperature decreases to less than 95°F (35°C).

malignant hyperthermia A condition that can result from common anesthesia medications (notably succinylcholine) and present with hyperthermia, muscular rigidity, altered mental status, and a hyperdynamic state.

mild hypothermia A condition in which the core body temperature is between 90°F and 95°F (32.2°C and 35°C); at this stage, the body usually compensates with increased thermogenesis and interrupted thermolysis.

neuroleptic malignant syndrome A condition caused by anti-psychotic and common antiemetic medications that presents with hyperthermia, muscular rigidity, altered mental status, and a hyperdynamic state.

nitrogen narcosis A state resembling alcohol intoxication produced by nitrogen gas dissolved in the blood at high ambient pressure.

pulmonary overpressurization syndrome (POPS) Also called “burst lung,” this diving emergency can occur during ascent and can cause pneumothorax, mediastinal and subcutaneous emphysema, alveolar hemorrhage, and the lethal arterial gas embolism.

radiation Emission of heat from an object into surrounding, colder air.

severe hypothermia A condition in which the core body temperature drops to less than 90°F (32.2°C).

superficial frostbite A type of frostbite characterized by altered sensation (numbness, tingling, or burning) and white, waxy skin that is firm to palpation, but the underlying tissues remain soft.

thermogenesis The production of heat in the body.

thermolysis The liberation of heat from the body.

thermoregulation The process by which the body maintains temperature through a combination of heat gain by metabolic processes and muscular movement and heat loss through respiration, evaporation, conduction, convection, and perspiration.

water intoxication A condition that occurs when the normal balance of electrolytes in the body is pushed outside safe limits by the overconsumption of water.

Infectious and Communicable Diseases

Authors

Marion J. Colburn, MD, MPH

Jill A. Loukides, PhD

Objectives

1. Describe the differences between eukaryotic and prokaryotic microorganisms (p 741).
2. Describe the types of immunity and the components of humoral and cell-mediated immunity (p 742–744).
3. Understand the types of anaphylaxis and state the signs, symptoms, and treatment of anaphylaxis (p 744–746).
4. Discuss the implications of transporting patients with immunodeficiencies (p 746).
5. Discuss the differences between normal, opportunistic, and pathogenic organisms (p 746–747).
6. State the virulence factors found in pathogenic organisms and how they can be spread from bacterial cell to bacterial cell (p 747–748).
7. Describe the portals of entry for infectious organisms and the process of infection once entry is gained (p 747).
8. Compare the effects of bacterial endotoxins and exotoxins (p 748).
9. Describe viral pathogenesis (p 749).
10. Give examples of reportable or notifiable infectious diseases (p 750).
11. Discuss epidemiology, including reservoirs of infection and transmission of infectious disease (p 749–751).
12. Discuss the etiologic agents, mode of transmission, signs and symptoms, and treatment of the following:
    - Meningitis (bacterial and viral) Respiratory syncytial virus
    - Necrotizing fasciitis
    - Epiglottitis
    - Tuberculosis
    - Pneumonia Fungal diseases Influenza
    - Various herpesviruses
    - Viral hepatitis
    - Human immunodeficiency virus Severe acute respiratory syndrome
    - *Escherichia coli* O157:H7
    - West Nile virus
    - *Helicobacter pylori*
    - Methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant *S aureus*
    - Vancomycin-resistant enterococci
    - Rickettsial diseases such as Rocky Mountain spotted fever (p 751–775)
13. Understand acquired immunodeficiency syndrome–defining conditions (p 763–766).

14. State the recommendations for use of standard precautions in all health care settings (p 768).
15. Understand how the overuse and misuse of antimicrobials leads to resistant infectious organisms (p 772–773).
16. Discuss the appropriate and correct use of personal protective devices (both donning and doffing) (p 769).
17. Understand the vaccinations needed for CCTPs and health care workers in general (p 776—777).
18. State universal precautions and discuss situations when these should be used (p 777).
19. State isolation, airborne, and droplet precautions and discuss situations when these should be used (p 777–778).
20. Discuss the importance of handwashing and use of hand sanitizers and/or hand antiseptics in preventing contamination and transmission of infectious diseases (p 778).
21. Understand decontamination chemicals and techniques appropriate for cleanup after transporting patients harboring various infectious diseases. Include decontamination of equipment and vehicle surfaces as well as uniforms (clothing and shoes) and personal protective equipment (p 778–782).
22. Discuss actions to take after blood exposure (p 782–783).

Introduction

CCTPs must be keenly aware of their risk of exposure to a multitude of infectious agents in the course of transporting patients. Patients, health care workers, and members of the community are at risk for contracting infectious diseases from their interactions with one another. Infectious agents are found in body fluids, on solid surfaces, and in the air. Transmission can occur directly from either a symptomatic or asymptomatic carrier, indirectly from contact with a **fomite** (eg, contaminated fluids or equipment), or from inoculation by a **vector** (eg, exchange of a pathogen via an animal or insect bite or sting). Patients are more susceptible to contracting infectious diseases because their defenses are diminished from sickness, immunocompromised states, broken skin, open wounds, and/or **iatrogenic** events. CCTPs are at increased risk for contracting an infectious agent because of the idiosyncratic nature of their job. They provide care for a large number of patients and, therefore, have a high frequency of exposure to serious diseases. Additionally, the work of a CCTP often involves the use of invasive instruments while being jostled about in a moving vehicle, providing for an increased risk of needlesticks and exposure to body fluids. The community is at risk if an infection is not contained, if members of the community are not immunized, or if the medical equipment used is not properly and adequately sanitized between patients. A solid understanding of the fundamental principles of infectious disease is an essential tool that will enable CCTPs to assess risk, minimize exposure, and prevent transmission of infection.

Fundamental Principles of Infectious Disease

Classification

Before the realm of the microscopic world was discovered, living organisms were classified as either animal or vegetable. After the discovery of microorganisms, scientists were not able to classify microbial life into the dichotomous groups of animal vs vegetable because some had characteristics of both, and others (such as viruses and prions) fit into neither category. A formal classification scheme for microorganisms was not developed until the late 1960s, when Carl Woese devised a system that classified microorganisms according to their physical properties and cellular components. A list of the

major classes of microorganisms and their properties is found in **Table 19-1.**

The same physical properties and components used to determine the classification of microorganisms also affect how they invade hosts, set up an infection, and cause disease. Microorganisms possess properties that are unlike their human hosts, and these differences are exploited when scientists are developing agents for inhibiting growth or eliminating infection. The practice of chemotherapy began as an attempt to find chemical agents effective in controlling microbial infection. The goal of such chemical therapy is to eradicate the offending organism without causing irreparable injury to the host. During World War I, Paul Ehrlich, a German physician, was the first to develop a synthetic agent—a "magic bullet"—that would target and destroy the invader while minimizing collateral damage to the host. This "magic bullet" archetype is still used in medicine today. All antibiotic, antiviral, and antifungal drugs are designed to target specific proteins, macromolecules, cellular organelles, and enzymatic pathways; or reproductive strategies unique to the infectious agent that are not shared by their human host.

Human Immune System

The diseases that affect humans do not arise in a vacuum, but result from complex interactions between the host, the agent, and the environment. For an organism to contract a disease, the host must be susceptible. Susceptibility is determined by factors such as nutritional status, immune status, genetic makeup, living conditions, and exposure. Disease can be transmitted directly through inhalation, ingestion, or direct contact with infectious agents; or indirectly via vectors, fomites, or some other complex cycle of interactions.

TABLE 19-1 Classification of Microorganisms

Organism	General Information	Cell Wall/ Cell Membrane Components	Drug Classes, Groups of Actions (Use)	Medication Examples
Bacteria	Prokaryote vs eukaryote: prokaryotes Cellularity: unicellular Reproduction: binary fission	Peptidoglycan cell wall No sterols in the membrane (except *Mycoplasma*) Mycolic acid in the cell wall of mycobacteria	Cell wall synthesis inhibitors • Beta-lactams • Glycopeptides Protein synthesis inhibitors • Tetracyclines • Aminoglycosides • Macrolides DNA/RNA synthesis inhibitors • Quinolones or fluoroquinolones Alter cell membrane permeability Antimetabolites • Sulfonamides	 Penicillins and cephalosporins Vancomycin (Lyphocin, Vancocin, Vancophed) Doxycycline (Vibramycin, Pentostat) Amikacin (Amikin) and gentamicin (Garamycin) Erythromycin (many brand names) Ciprofloxacin (Ciloxan, Cipro) Polymyxin B (Aerosporin) Sulfamethoxazole (Gantanol)
Viruses	Prokaryote vs eukaryote: neither Cellularity: acellular Reproduction: N/A	None (lack cells)	Viral attachment inhibitor Viral uncoating inhibitor (influenza) Neuraminidase inhibitors (influenza) DNA/RNA synthesis inhibitors (HIV, herpes, cytomegalovirus) Protease inhibitors (HIV) Interferon (hepatitis)	Enfuvirtide (Fuzeon) Amantadine (Symmetrel) and rimantadine (Flumadine) Zanamivir (Relenza) and oseltamivir (Tamiflu) Acyclovir (Zovirax), ganciclovir (Cytovene), and zidovudine (AZT, Retrovir) Indinavir (Crixivan) and saquinavir (Fortovase, Invirase) Interferon (Intergen)
Protozoa	Prokaryote vs eukaryote: eukaryotes Cellularity: unicellular Reproduction: asexual or sexual	No cell wall	Antimetabolites DNA synthesis inhibitors • Nitroimidazoles Unknown mode of action • Quinolines	Trimethoprim-sulfamethoxazole combination (Septra) Metronidazole (Flagyl, Metrogel) Chloroquine (Aralen) and quinacrine
Helminths	Prokaryote vs eukaryote: eukaryotes Cellularity: multicellular Reproduction: complex	No cell wall	Antimetabolites • Benzimidazole	 Mebendazole (Vermox) and Praziquantel (Biltricide)
Fungi	Prokaryote vs eukaryote: eukaryotes Cellularity: unicellular (yeasts) or multicellular (molds) Reproduction: asexual or sexual	Chitin cell wall Unique sterols (ergosterol) in the membrane	Ergosterol synthesis inhibitors • Azoles • Allylamines Alters cell membrane permeability • Polyene Mitotic inhibitor (prevents cell replication)	 Ketoconazole (Nizoral) and miconazole (Monistat, Micatin) Terbinafine (Lamisil) Amphotericin B (Fungizone) Griseofulvin (Fulvicin, Grisactin, Grisfulvin)
Prions	Prokaryote vs eukaryote: neither Cellularity: acellular Reproduction: N/A	None (lack cells)	N/A	N/A

Abbreviations: HIV, human immunodeficiency virus; N/A, not applicable.

Within the human body, there is a constant struggle between the host and would-be invaders, both competing for nutrients, energy, and control of cellular synthetic mechanisms. The perpetual struggle between host and microbe pits the human immune defenses against the microbial virulence factors. For the immune system to protect the body from invading microorganisms, it must be able to recognize "self" components or cells and distinguish those from nonself components or cells. The immune system must be both highly specific (keeping watch for specific antigens) and general (able to keep up with numerous assaults without sending the body into a perpetual state of inflammation). The protection it provides must consist of several layers so that once one level of immunity has been breached, additional methods of fighting infection are launched and continue the assault. This allows a gradation of response, appropriate for the current threat. The immune system must be capable of "remembering" previous interactions so that it is capable of mounting a response to the same or a closely related agent years after the initial exposure. All of these components must work in a coordinated effort, providing protection from infection and

malignancy, without self-destruction.

Types of Immunity

Immunity can be either innate or acquired. **Innate immunity** is the type of immunity an individual is born with. It provides protection from invading pathogens despite a lack of prior exposure. The skin and mucous membranes and their secretions provide mechanical and chemical barriers to invasion and are the primary components of innate immunity, providing protection against infection from birth. Innate immunity is nonspecific in nature, is activated immediately on invasion, and has no memory. It exists before exposure to the agent has occurred, and does not improve with repeated exposures. The components of the innate immune system work to eliminate invading organisms through various methods, including activation of the adaptive immune response, prevention of entry of the microorganisms into the body, and limitation of microbial growth within the body. Nonspecific factors of the immune system help limit growth of microorganisms within the body and include cells such as natural killer cells, neutrophils, and macrophages; proteins such as complement or transferrin; and the body's general responses to invasion with actions such as fever or inflammation. Macrophages are a type of white blood cell that ingest and destroy microbes. Natural killer cells, another type of white blood cell, have the job of recognizing and killing host cells that are infected with a virus. The complement system is a group of proteins that, when activated, begin a cascade of events that aid in the clearing of bacterial cells. Transferrin is a carrier protein that sequesters iron, keeping that vital element unavailable for the invading microbes.

Acquired immunity develops as a result of interactions between components of the immune system and the invading microbe, thus providing improved protection with repeated exposures to specific agents. The two main types of acquired immunity are humoral and cell-mediated immunity. Humoral immunity is provided by B cells through the production of antibodies and complement. Cell-mediated immunity is provided by T cells. Cytokines and macrophages are modulators of both cell-mediated and humoral immunity, providing signals to the players—revving up or toning down the immune response as appropriate. Acquired immunity results from the interaction of the agent with the host, is specific in nature, improves with repeated interactions, and allows for the development of immunologic memory. It is mediated by antibodies, B and T lymphocytes, and can be either active or passive.

Active immunity refers to an ongoing process of developing antibodies and activating T cells in response to invading agents. This occurs either when an individual is exposed to microbes through the natural process of infection or artificially stimulated through a vaccine.

Passive immunity is the process of giving an individual a preformed antibody (from a donor) in the event of an exposure to which the individual has not yet developed immunity. For example, if a provider were to be exposed to a patient known to have hepatitis B, the provider could be given hepatitis B immunoglobulin (HBIG) during the incubation period to prevent infection. Another example of passive immunity is the passing of antibodies from the mother to her fetus or infant by crossing the placenta into fetal circulation, or through breast milk.

Active immunity, once developed, provides long-lasting protection against invading microbes, but is initially slow to develop. Passive immunity is immediate, but does not confer a lasting effect, and because it does not originate with the individual, it must be continually re-dosed. There is also some level of risk of contracting blood-borne infectious diseases from the use of preformed or pooled human immunoglobulin.

Antigen

Antigens are typically proteins and/or sugars that are anchored into the cell membrane and displayed on the cell's surface. An antigen is recognized by the immune system as either self or nonself. All cells

display antigens, even our own cells. If an antigen is foreign or nonself, it will induce a response, either humoral or cell-mediated. An antigen can be presented to B or T cells by antigen-presenting cells, or it can react directly with an antibody. An antigen usually elicits an immune response and is, therefore, termed immunogenic, but there are some low-molecular-weight molecules called **haptens** that react with antibodies without turning on the immune system.

Organs and Cells of the Immune System

The immune system is complex and is composed of many organs and cell types. The organs of the immune system are categorized by anatomic location, either central or peripheral. The lymphatic system is the network of capillaries, vessels, ducts, nodes, and organs that produces lymph and conveys it through the body **Figure 19-1**. The central lymphoid organs are the thymus and the bone marrow. The thymus is located in the mediastinal cavity anterior and rostral to the heart. It weighs 15 to 35 g at birth and continues to increase in size until puberty, when it begins to regress and is replaced by fibrotic tissue. The thymus is where the T lymphocytes differentiate. In contrast, the bone marrow is the site of B-cell synthesis. The precursor B cells are first recognized in the fetal liver, but migrate to the bone marrow before birth, and lymphopoesis continues there throughout childhood into adult life. The central lymphoid organs are the site of synthesis and differentiation of immunocompetent cells.

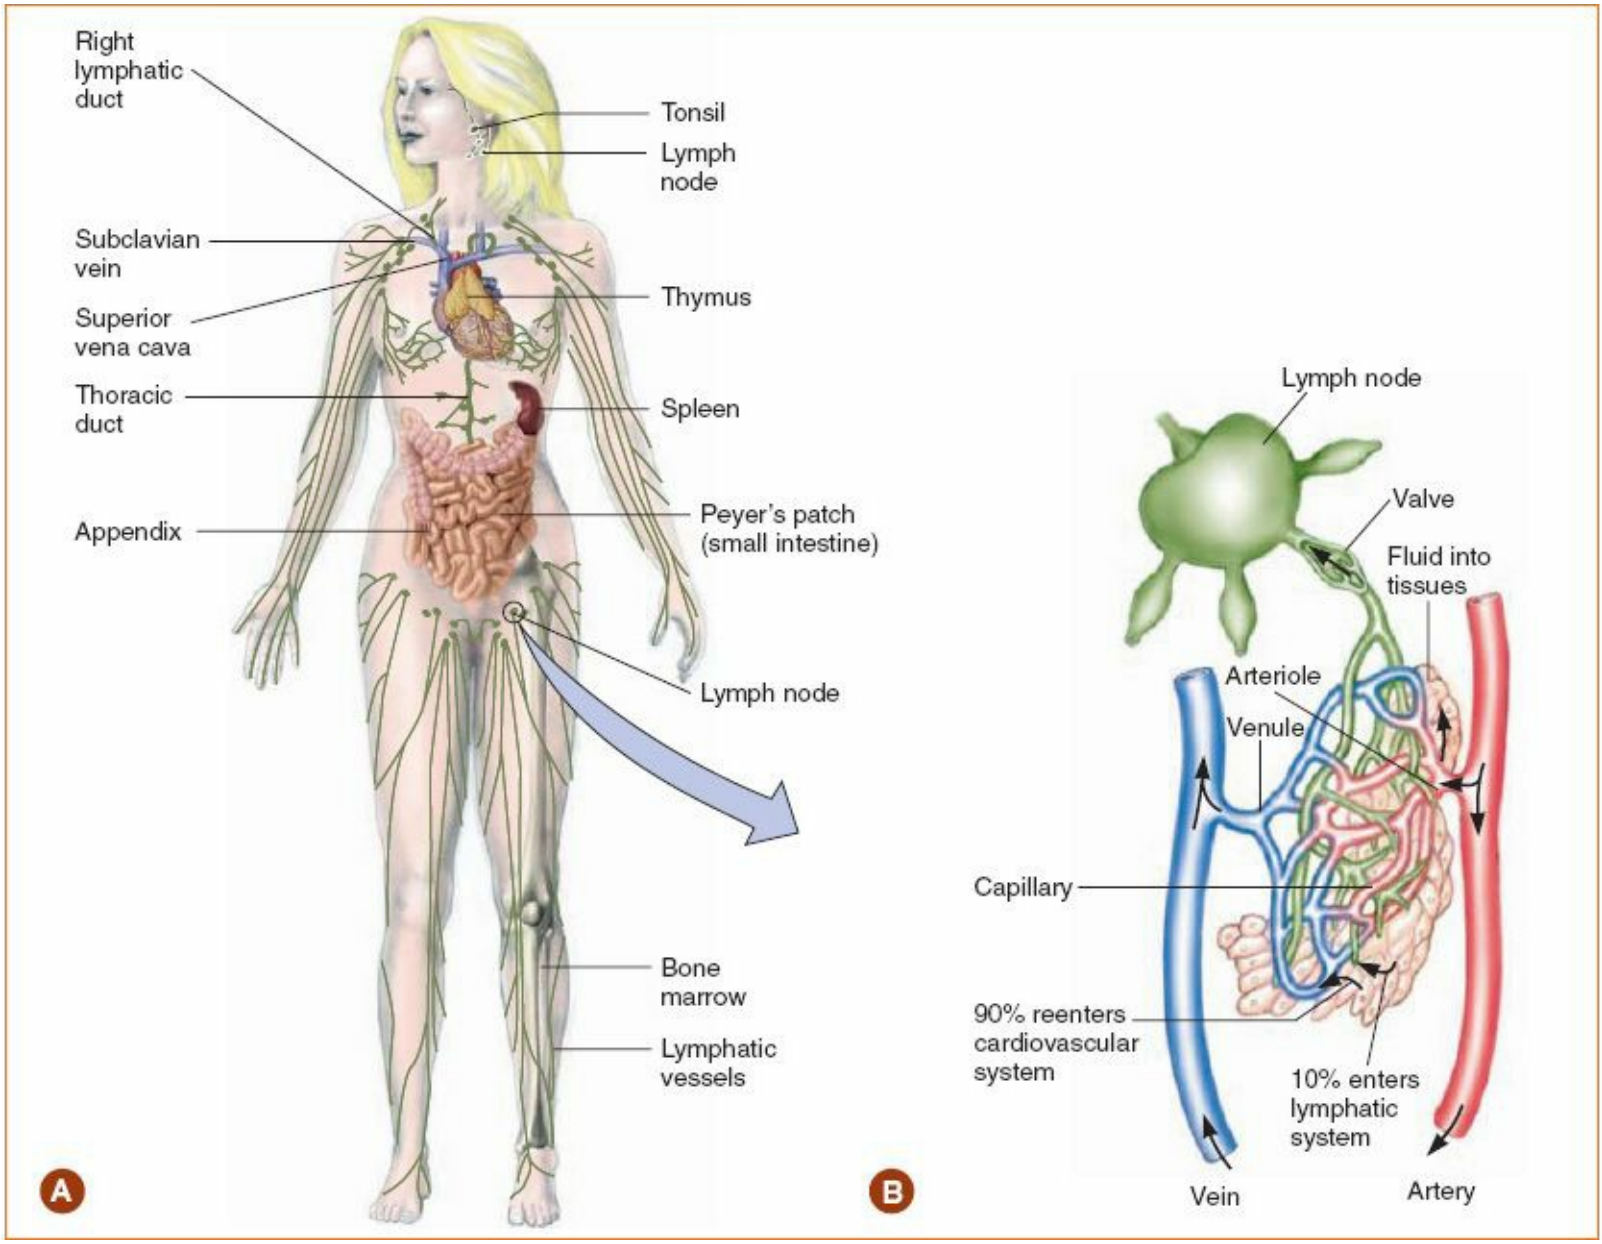

Figure 19-1 The lymphatic system. **A.** The lymphatic system consists of vessels that transport lymph and excess tissue fluid back to the circulatory system. **B.** Lymph is picked up by lymphatic capillaries that drain into larger vessels. Like the veins, the lymphatic vessels contains valves that prohibit backflow. Lymph nodes are interspersed along the vessels and filter the lymph.

The peripheral lymphoid organs are where immunocompetency is expressed; they include the spleen, lymph nodes, tonsils, intestinal Peyer's patches, and mucosa. The spleen is where encapsulated bacteria are encountered and destroyed. If the organ is removed, the patient may be more susceptible to infection, especially from *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Lymph nodes are made up of lymphoidal tissue located throughout the body as single units or in chains of units and are prominent in the neck, axilla, and groin. Lymphadenopathy is an increase in the size of a lymph node or lymph nodes and indicates a high level of immunologic activity. Lymphadenopathy is a clinical sign commonly seen in patients fighting infection or cancer.

T lymphocytes acquire their distinctive characteristics while maturing in the thymus. They mature to express phenotypic markers or clusters of differentiation called CD markers. CD4+ cells are the helper T cells, and CD8+ cells are the cytotoxic suppressor T cells. The CD4+ helper T cells are regulators of the immune system. They help B cells develop into antibody-producing plasma cells. They also help to activate CD8+ cells, and they participate in delayed hypersensitivity reactions, which is important in limiting *Mycobacterium tuberculosis* infections. CD8+ lymphocytes kill virus-infected and tumor cells. The B lymphocytes mature in the bone marrow, where they acquire their characteristic markers that include CD20, CD21, and CD37. B cells have two important roles in the immune system. They differentiate into plasma cells that produce specific antibodies on encountering an antigen, or they become memory cells.

Humoral Immunity

Humoral immunity is mediated by antibodies, which are produced by mature B cells, called the plasma cell. Antibodies are globulin proteins (immunoglobulins) that react to antigen. There are five classes of antibodies: IgA, IgM, IgG, IgE, and IgD. Immunoglobulins are glycoproteins made from differing combinations of protein chains, connected together in various combinations, leading to the different classes. IgA is the antibody found in secretions such as colostrum (early breast milk), saliva, and tears. This antibody is also present in the respiratory, intestinal, and genital tracts, where it prevents the attachment of bacteria and viruses to mucous membranes. IgM is the immunoglobulin produced in the primary immune response, whereas IgG is the immunoglobulin found in both the primary and secondary immune responses, but in much greater quantities in the secondary response. IgG is the only immunoglobulin that crosses the placental barrier. IgG and IgM are the only two immunoglobulins that activate complement. IgE is important in protecting against certain parasitic infections, such as helminths or worms, and mediates the immediate hypersensitivity reaction. In other words, IgE is responsible for the immunoglobulin involved in the anaphylaxis reaction. Antibodies protect against infection by neutralizing toxins and viruses, and they **opsonize** or make microorganisms more easily phagocytized.

The humoral or antibody-mediated response is effective against agents that produce toxins, against bacteria that have polysaccharide capsules, and against some viral infections. The primary response occurs when the immune cells encounter a specific antigen for the first time. Reactions between antigen and antibody are highly specific. In the primary immune response, antibodies do not appear until 7 to 10 days after the initial encounter. The first antibodies to appear are IgM. When there is a second encounter with the same antigen, or a closely related antigen, the response is more rapid, and is called the secondary response. In this case, the lag time until the antibody is detected in the serum is only 3 to 5 days, and the

antibody titers are much higher than those seen in the primary response. This is because of the actions of memory B cells that were produced as a result of the first encounter as well as their quick ability to produce a large quantity of their "memorized" antibody. During the second encounter, IgM is made in the same quantity as in the primary response, but IgG is produced in larger quantities. With repeated encounters, the response is elicited faster and becomes more specific.

Infection with a related virus may impart immunity against other viruses in the same family that are not so benign. Viruses within one family sometimes contain similar structural proteins. If there are enough similarities, the immune system recognizes both as nonself and destroys them before allowing infection to take hold.

Cell-Mediated Immunity

Cell-mediated immunity (CMI) plays an important role in defending against intracellular infections, such as tuberculosis or gonorrhea; and viral infections, fungal infections, parasites, and tumors. The strongest evidence of its importance is illustrated in human immunodeficiency virus/acquired immunodeficiency syndrome when the destruction of cell-mediated immunity results in overwhelming infections and unusual tumors. An antibody is not involved in the reactions of CMI except in the antibody-dependent cellular cytotoxic reactions. Cells involved in CMI include the following:

- **CD4-helper T cells**—participate in antigen recognition and modify the response by activating CD8 cytotoxic T cells, B cells, and macrophages
- **CD8 cytotoxic T cells**—kill other infected or endogenous cells by producing perforins (proteins that cause holes to form in cell membranes, causing cell death as a result of loss of the osmotic gradient) or by inducing apoptosis (programmed cell death)
- **Macrophages**—ingest or destroy foreign cells, viruses, or debris (phagocytosis); present antigens (by activating T cells that can recognize foreign antigens); and produce cytokine (namely, interleukin 1 and tumor necrosis factor). The process of phagocytosis is carried out by macrophages, neutrophils, and monocytes. They engulf and destroy bacteria, foreign antigen, and cellular debris. These cells process the bacteria, breaking them down by specialized cell processes. Fragments of the cell, known as **epitopes** or antigen, are displayed by the phagocytic cell in close association with specialized proteins on the exterior of the cell. These proteins are called major histocompatibility complex. There are two general classes of major histocompatibility complex—class I and class II. Class I proteins process antigen from virus-infected cells and present the processed antigen as epitopes in association with major histocompatibility complex to cytotoxic T cells, whereas class II proteins process bacterial antigen to the helper T lymphocytes.
- **Natural killer cells**—large granular lymphocytes that do not express T-cell antigen receptor. They destroy tumor cells or virus-infected cells by recognizing that those cells are not expressing "self" markers. Although they are regulated by other proteins in the immune response, they do not require specific activation to produce perforin and granzymes that, when released on target cells, cause apoptosis or necrosis of the nonself cell.
- **Cytokines**—proteins produced by immune cells that modify the immune response. Chemokines are a type of cytokines that attract macrophages or neutrophils to the site of an infection.

Hypersensitivity Reactions

The immune response also can be harmful to the host when it is inappropriate or exaggerated. These types of harmful reactions are called **hypersensitivity** or allergic reactions, and they occur when individuals are exposed to a specific antigen. The first encounter sensitizes the person to the antigen and induces an

antibody response. The subsequent encounters with the same or closely related antigen elicit the allergic response. There are four major types of hypersensitivity reactions. Types I, II, and III are antibody-mediated responses, whereas type IV is a cell-mediated response.

Type I is an immediate hypersensitivity reaction involving IgE and an antigen. The term immediate hypersensitivity reflects the fact that these reactions occur within minutes of exposure to the antigen. There are two categories of type I reactions: (1) atopy or a localized reaction and (2) anaphylaxis, which is a systemic reaction. IgE is produced in excessive amounts and binds to mast cells or basophils that then become activated and release their contents. The degranulation of mast cells releases histamine, leukotrienes, and tryptase and causes the production of various cytokines. In turn, the cytokines produce various reactions, including the rapid contraction of smooth muscle, increased vascular permeability, hypotension, and changes in the coagulation pathway. Localized histamine release causes urticaria, whereas systemic histamine release causes dose-dependent hemodynamic and cardiovascular changes, such as an increased heart rate, hypotension, and shock, which can be life threatening. Tryptase is an enzyme found in mast cells that, when released, activates complement and the coagulation pathway and has the potential to cause angioedema, clotting, and clot lysis, leading to disseminated intravascular coagulation in severe cases. Common triggers for anaphylaxis include foods, drugs, antibiotics, and *Hymenoptera* venom. The treatments for anaphylaxis are aimed at counteracting the mediators released from the mast cells. The goal of treatment is early recognition and the use of epinephrine to prevent progression to life-threatening symptoms.

Anaphylaxis is a serious allergic reaction that has a rapid onset of symptoms, a variable clinical presentation, and, if unrecognized, can lead to respiratory arrest, circulatory collapse, and death. Previously stated, the goal of treatment is early recognition, use of epinephrine, and reduced reliance on less-effective medications such as antihistamines and glucocorticoids. Most patients with anaphylaxis—up to 90%—will have cutaneous involvement, including flushing, itching, urticaria, or angioedema. Upper airway involvement occurs in up to 70% of patients, with signs and symptoms such as changes in phonation, the sensation of throat closure or choking, cough, wheezing, and shortness of breath. Cardiovascular symptoms are less common, but treatment should not be withheld if signs of tachycardia or hypotension are absent.

Anaphylaxis is usually characterized by a defined exposure, followed by rapid onset of symptoms, and evolution and resolution of symptoms within minutes to hours. Variations on the typical time course have been reported and may complicate treatment. Biphasic anaphylaxis has been reported in up to 20% of reactions. In a biphasic reaction, the initial resolution of symptoms is followed by a reappearance of symptoms, and, if not anticipated, can be the cause of a life-threatening recurrence. In some rare cases, the reaction can last for many hours to days in those with protracted anaphylaxis.

When anaphylaxis is not recognized by the health care provider, it is left untreated and this places the patient at the highest risk for complications, including death. There are unique circumstances that exist that place patients at risk for unrecognized anaphylaxis. For example, persons with a known history of asthma may be treated for an acute asthma exacerbation without taking into account any cutaneous symptoms, placing them at greater risk for unrecognized anaphylaxis. Their wheezing may be assumed to result from asthma when it actually is secondary to the respiratory symptoms associated with anaphylaxis. Having asthma puts patients at a high risk of death from anaphylaxis simply because it is not recognized until much later in the presentation, delaying appropriate treatment. Patients with underlying neurologic impairment and psychiatric illnesses that interfere with cognition or impair judgment may not be able to express symptoms of pruritus or throat closure. Additionally, a sedated patient is unable to recognize or communicate the presence of early symptoms and is, therefore, dependent on the health care provider to recognize any subtle changes in the skin or vital signs that may signal that an allergic reaction is taking place.

Prompt assessment and treatment are critical in cases of anaphylaxis. The first step in its management begins with the removal of the inciting antigen. Intramuscular epinephrine should be injected, and, if symptoms persist, an epinephrine drip should be established. As with all successful resuscitations, begin with airway management. If there is any evidence of stridor, significant airway edema, or impending respiratory arrest, perform intubation immediately. Maintain breathing and support circulation with supplemental oxygen and volume resuscitation. Place two large-bore IV lines for rapid fluid administration, and place the patient on continuous cardiac/respiratory monitoring until the episode has resolved. All patients with anaphylaxis require fluid resuscitation. Those with hypotension or signs of shock should receive large-volume resuscitation. Adjunctive agents such as H_1 blockers—antihistamines—can be used for the treatment of itching or hives that fail to resolve after the administration of epinephrine. Patients who are wheezing can be treated with an inhaled beta-2 agonist if wheezing does not resolve after treatment with epinephrine. The use of glucocorticoids does not appear to be helpful in acute anaphylaxis but may offer some protection against the biphasic or protracted reaction.

All patients who are discharged from the hospital after anaphylaxis should be educated about their allergy and should have an emergency action plan for any recurrence, including a prescription for and instruction in the proper use of an epinephrine autoinjector.

Anaphylactoid reactions are IgE-independent systemic reactions. In these reactions, the same types of cells are activated—namely, the mast cells and basophils via a direct mechanism independent of IgE activation. Although the mechanism that triggers activation differs between anaphylaxis and anaphylactoid reactions, the symptoms, treatment, and risks for complications are the same for both; therefore, the distinction is not one of clinical significance.

Type II or cytotoxic hypersensitivity reactions are antigen-antibody reactions in which antibody directed against antigen on the surface of the host cell membrane causes activation of complement and subsequent lytic and osmotic damage to the host cells. The cytotoxic antibody-dependent cell-mediated cytotoxic reaction is included in this category. This type of reaction is seen in transfusion reactions, hemolytic disease of the newborn (erythroblastosis fetalis), and some autoimmune diseases. The antibodies involved in this type of reaction are IgM or IgG.

Type III hypersensitivity reaction involves the interaction of antigen and antibody. In those types of reactions, circulating antigen-antibody complexes deposit in tissue or on the endothelium of blood vessels and cause damage by activating complement, releasing chemotactic and clotting factors, and attracting other immune cells to the area. Examples of this type of reaction include the arthus reaction, which is a rare severe inflammatory response to intravascular precipitates of antigen-antibody complexes, serum sickness, polyarteritis nodosa, glomerulonephritis, and systemic lupus erythematosus.

The fourth and final type is the delayed-type hypersensitivity reaction, in which tissue damage results from excessive activation of macrophages. Type IV reactions involve the interaction of macrophage and T cells, but the response is delayed from hours to days after the antigen is encountered. This hypersensitivity reaction is cell mediated and is not a humeral response as are the first three. This type of reaction is exemplified in contact hypersensitivity as seen in exposure to poison ivy or poison oak.

Signs and Symptoms

Anaphylaxis (Type I Hypersensitivity Reaction)

Cutaneous involvement:

- Flushing
- Itching

- Urticaria
- Angioedema

Upper airway involvement:

- Changes in phonation
- Sensation of throat closure or choking
- Cough
- Wheezing
- Shortness of breath

Cardiovascular involvement:

- Tachycardia
- Hypotension

Transport Management

Anaphylaxis (Type I Hypersensitivity Reaction)

- Remove the antigen.
- Inject intramuscular epinephrine.
- If symptoms persist, establish an epinephrine drip.
- If there is any evidence of stridor, significant airway edema, or impending respiratory arrest, intubate the patient immediately.
- Provide oxygen supplementation and volume resuscitation.
- Place two large-bore IV lines for rapid fluid administration.
- Place the patient on continuous cardiac/respiratory monitoring.
- In case of hypotension or signs of shock, provide large-volume resuscitation.
- Give H_1 blockers for ongoing itching or hives.
- Give an inhaled beta-2 agonist for ongoing wheezing.
- In case of a biphasic or protracted reaction, give glucocorticoids.

Immunodeficiency

Immunodeficiency occurs when one or more of the components of the immune system is damaged or is nonfunctioning as a result of illness or lack of functioning immune cells, or when intentionally suppressed by various immunosuppressant therapies. The specific component of the immune system that is not fully functional predisposes the patient to certain types of infection or disease. Various diseases or conditions that induce immunodeficiency demonstrate which arm of the immune system is responsible for protecting us against specific infections. For example, patients with B-cell deficiencies have recurrent infections with pyogenic bacteria such as *S pneumoniae* and *H influenzae*. A deficiency in T cells allows recurrent infections with viruses, fungi, or protozoa. Critically ill patients have little reserve to fight infections as the result of a decrease in host defenses and loss of innate immunity. The features of chronic illness that decrease innate immunity include stress, malnutrition, invasive procedures, loss of physical barriers of skin and mucosal surfaces, and pathogenic bacterial overgrowth or bacterial growth in normally sterile tissue. Patients who are maintained on immunosuppressive therapy for the management of autoimmune diseases or to prevent rejection of a transplanted organ are at increased risk for a variety of infections and

cancers.

Management of the transplant patient is another important aspect of critical care transports. Common management of illnesses and injuries may be complicated by the side effects of medications or by the patient's immunosuppressed condition. Immunosuppressive agents, such as cyclosporine, tacrolimus, azathioprine, and prednisone, are routinely prescribed to transplant patients in an effort to prevent rejection of the donor tissue. These medications can have serious side effects, including hypertension, hyperglycemia, hyperkalemia, nephrotoxicity, and neurotoxicity, so it is important to discuss the care plan with a transplant team representative prior to initiating transport.

In addition to surgical complications or manifestations of acute rejection, prevention and detection of infection are important when transporting these patients. For example, the presence of a life-threatening infectious illness may not be apparent until the diagnostic evaluations have been completed. In addition, mild symptoms that may be overlooked in routine transport patients could indicate serious problems in transplant patients.

Pathogenicity

Normal Bacteria

The relationship between host and microbe is not always adversarial, and not all microbes are pathogenic. Most bacteria are either beneficial or neutral. The presence of normal bacteria (normal flora) in and on the body plays an important role in disease prevention because their presence prevents colonization by pathogenic species. Normal flora refers to colonies of nonpathogenic species that assist the immune system by preventing the overgrowth of pathogenic strains by using up available nutrients, maintaining a certain pH, and creating bac-teriocins (antibacterial toxins). A good example of this beneficial relationship is demonstrated in the normal microbiota of the adult vagina. Lactobacilli normally present in the vagina produce acid and keep the pH of the adult vagina between 3.5 and 4.5. This creates a hostile environment for *Candida albicans*, the causative agent of vaginal yeast infection. If the normal flora of the vagina are reduced in numbers by extended use of antibiotics or excessive douching, the pH increases and *C albicans* can dominate, leading to fungal vaginitis.

Opportunistic Bacteria

Opportunistic infections are diseases caused by normally non-pathogenic agents in patients with an abnormally functioning immune system. The normally harmless organisms that cause these infections are termed opportunistic bacteria. In patients who are **immunocompromised**, the normal balance between host and microbe is upset by a weakness in the immune system that can be caused by a genetic defect, specific medications, and/or chronic diseases. When the host defense system is compromised, microbes that are otherwise harmless may replicate without check. In fact, AIDS is defined by the unusual infections that human immunodeficiency virus (HIV)-infected patients with compromised immune systems contract. These rare and unusual opportunistic illnesses are called **indicator conditions** or AIDS-defining diseases (listed later in Table 19-5) because they are rarely, if ever, seen in persons with intact immunity. Many of the patients requiring critical care transport will fall into the category of immunocompromised patients. Thus, CCTPs need to be keenly aware that these very sick patients can be inadvertently infected. CCTPs must adhere scrupulously to proper technique, keeping their equipment sanitized or sterile and using universal precautions such as masks and gloves when appropriate. CCTPs must be aware that even a mild dermatitis on the hands of a healthy person or a few bacteria left on respiratory equipment can translate to a lethal infection for the immunocompromised patient.

Pathogenic Bacteria

Pathogens are simply defined as those microorganisms capable of causing disease. Pathogenic organisms cause disease because they possess unique factors that help them gain entry into the body, colonize and overcome host defenses for at least a period of time, produce toxins that cause cytopathic effects, or do mechanical damage to the body. Entry of pathogens into the body and colonization of tissue may be enhanced by the production of certain excreted enzymes (invasins) and glycoproteins (adhesins) produced by some pathogenic bacteria. Pathogens may evade immune system destruction by producing capsules, slime layers, or specialized cell walls; mounting preemptive strikes by the destruction of phagosomes; or preventing phagocytosis by infecting only epithelial tissue or walling cells off on colonization.

Virulence Factors

The degree of pathogenicity is called the **virulence** of an organism. Properties of microbes that influence their virulence (called virulence factors) include:

- Host and tissue specificity (the ability of the organism to gain entry into a host)
- Adherence to specific host cells
- Invasion of host tissue
- Evasion of host defenses
- Toxicity

Pathogenic organisms may possess one or more virulence factors. Virulence can be experimentally quantified by two measures: the infective dose of an organism (ID_{50}) and the lethal dose of an organism (LD_{50}). The ID_{50} measures the number of organisms required to infect a susceptible test animal. The LD_{50} measures the number of organisms required to kill 50% of the test animals inoculated with the microbe. The lower the ID_{50} or LD_{50}, the more virulent the organism. The infective dose of Shigella is about 10 to 100 organisms, whereas the infective dose of Salmonella is about one million organisms. This means that it takes a larger quantity of Salmonella to produce an infection than it does Shigella or, simply, Shigella is more virulent.

Host and Tissue Specificity

A potential pathogen must gain access into the body before it can cause an infection. The typical portals of entry into the body are through broken skin, hair follicles, or sweat glands; through the mucous membranes of the respiratory, digestive, and genitourinary tracts; or through the conjunctiva of the eye **Figure 19-2**.

Pathogenic bacteria typically infect specific tissues or systems in the body; however, some bacteria are capable of infecting multiple tissues and can cause very different diseases. For example, various *Staphylococcus* species can cause localized skin infections such as an abscess. It can also cause toxic shock syndrome when present in large numbers in sites such as the vagina or sinuses and can release the exotoxin TSST (toxic shock syndrome toxin) into the bloodstream. Other organisms are extremely site specific for portal of entry and infectivity. For example, *Salmonella typhi* causes no infection when inhaled, but does cause infection if it enters the digestive tract. Conversely, *S pneumoniae* does not cause disease if ingested but does cause pneumonia if inhaled.

Adherence

Entry of a pathogen into a host does not mean that disease will necessarily follow. Once inside the body, the pathogenic organism must be able to adhere to specific cells to begin colonization. Most bacteria adhere to cell surfaces using specialized structures that project out of the cell wall, called pili or fimbriae **Figure 19-3**. Gram-negative bacteria possess common pili that allow them to adhere to surfaces in the

gastrointestinal tract. Other bacteria produce unique pili that bind tissues specifically.

Most organisms can begin to colonize as soon as they have adhered to the host tissue. As these microbes reproduce, they continue to bind to the surface of the host cells and spread along the tissue surface as they increase in numbers. Some microbes also can form biofilms, which are accumulations of bacteria and other organisms embedded in a matrix of polysaccharide along the surface of tissues. These microcolonies tend to be highly resistant to antibiotics and to the host immune system.

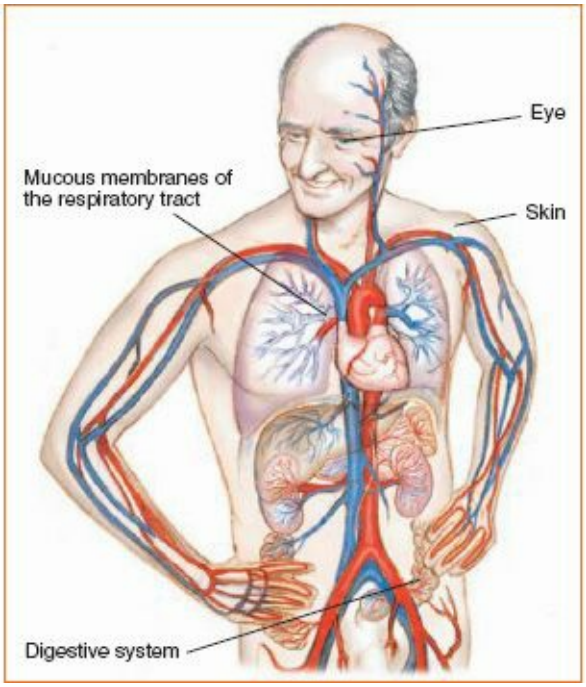

Figure 19-2 Portals of infection.

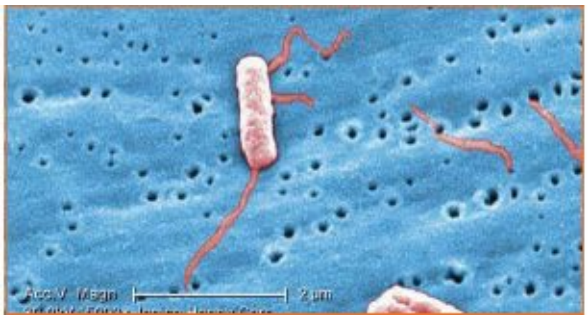

Figure 19-3 Pili (or fimbriae) on a bacteria.

Invasion

Once attached to tissue surfaces, some bacterial cells must then invade tissues in order to colonize. One mechanism for entry is the activation of receptor-mediated endocytosis. Because microbes are bound to tissue-specific receptor proteins, they trigger uptake or movement into the host cell by endocytosis. Once inside the host cell, the organisms multiply and easily invade neighboring cells through pores connecting the cells. This cell-to-cell infection also allows bacteria to evade destruction by the immune system. Other microbes invade tissues through the production of extracellular enzymes that break down the molecules that hold cells together.

Evasion

Colonization of tissues requires that microbes evade destruction by the host immune defense mechanisms. Different bacteria have developed various means to escape detection and destruction. Some organisms

produce polysaccharide layers and surround themselves with capsules or slime layers. These polysaccharide layers inactivate proteins essential for the immune system phagocytic mechanism, making ingestion by macrophages impossible. Other extracellular enzymes produced by bacteria also contribute to pathogenicity by protecting the organism from phagocytosis.

A number of bacteria are able to live and multiply within a phagocyte that protects them from antibody detection and destruction. Others avoid antibody recognition by mimicking host molecules and "trick" the immune system into ignoring them because they are disguised as "self" tissue.

Toxicity

Bacteria are capable of producing two types of toxins that are classified as exotoxins or endotoxins. Exotoxins are produced inside the cell and are released into surrounding tissues or fluids (blood or lymph). Endotoxins are part of the gram-negative cell wall and are not released until the bacteria are destroyed. The endotoxin component of the gram-negative cell wall is lipopolysaccharide (LPS). The bacterial cells release the LPS when they break apart. The free LPS causes fever, chills, and malaise; in extreme cases, it can lead to shock and death. All endotoxins elicit the same response from the host organism.

Exotoxins are generally specified by genetic information carried on plasmids (small pieces of DNA that are not part of the bacterial chromosome) or on bacteriophages (viruses capable of infecting bacterial cells). Exotoxins are highly specific and have differing modes of action. They are produced mostly by gram-positive bacteria but can be made by a few gramnegative organisms. Exotoxins are protein products that are soluble in the bloodstream and can be inactivated by heating. Exotoxins can be grouped according to the tissue type affected. There are neurotoxins that damage nervous tissue, enterotoxins that affect the tissues of the gastrointestinal tract, and cytotoxins that damage a variety of host tissues. Botulinum toxin is a potent neurotoxin that inhibits the release of acetylcholine and results in paralysis. Enterotoxins affect the digestive tract and disrupt the epithelial lining of the gut, leading to severe diarrhea such as that caused by *Vibrio cholerae*, the causative agent of cholera. Erythrogenic toxins specifically target capillaries and produce a red skin rash such as that seen in scarlet fever caused by *Streptococcus pyogenes*.

Transmission of Virulence Factors

The DNA of various bacteria encodes virulence factors and antibiotic resistance genes. Many virulence factors are carried on circular, extrachromosomal, self-replicating pieces of DNA called plasmids. Plasmid DNA is released into the environment upon lysis of the host bacterial cell. Other nearby bacterial cells can take up these plasmids and incorporate them into their own cells through the process of transformation. Transformation of bacteria can also take place by the uptake of fragments of the chromosomal DNA released upon lysis of a nearby cell. Once inside the recipient cell, the DNA may be either degraded by nucleases or integrated into the host chromosome, becoming part of that cell's genome. If the fragment of DNA integrated encodes a virulence factor, the newly transformed cell acquires that virulence factor and passes it on to ensuing generations as the cell divides. More frequently, plasmids carry antimicrobial resistance genes.

Bacterial cells are subject to infection by bacterial viruses called bacteriophages. Bacteriophages cause destruction of a host bacterial cell by growth and lysis of the host bacterium. Sometimes, however, the bacteriophage DNA integrates into the host chromosome (now called a prophage) and remains there as the bacteria undergo replication generation after generation. Any genetic information carried on the bacteriophage will be expressed as part of the bacterial protein complement, a process known as transduction. Sometimes bacteriophages carry genes for the production of virulence factors, such as capsules, exoenzymes, or toxins. At some point, usually when there is some environmental stress on the

host bacterial cell, the bacteriophage will excise from the bacterial chromosome and begin a lytic cycle, killing the host bacterium and releasing free bacteriophage into the environment. The free bacteriophage is then ready to infect another bacterial cell.

Viral Pathogenicity

Viruses, such as bacteria, must gain entry into the body to cause disease. Some viruses simply enter through broken skin, such as a puncture wound, an insect bite, or the entry port of a hypodermic needle. Others enter the body through the respiratory or digestive tract and bind to host cell surface receptors using viral proteins found on the surface of the virions. The binding of these protein "spikes" induces receptor-mediated endocytosis that brings the virus directly into the cell. Once inside, the virus particle can be "uncoated," releasing viral nucleic acid. The viral DNA or RNA begins to direct synthesis of viral-encoded protein and nucleic acid molecules, and the process of new virion assembly begins. The illness caused by the virus may be the result of the production of viral-specific molecules that deplete the host cell's resources and lead to eventual cell death. Other viruses cause illness because they induce programmed cell death or apoptosis, even when they do little harm to the cell during their active growth cycle. A third pathogenic mechanism is that some viruses induce large inflammatory responses, even with little or no actual damage to the host cell.

Epidemiology

Epidemiology is the study of how disease is distributed within populations and the factors that influence that distribution. The specific objectives of epidemiology are to identify the **etiology** (causes and risk factors that influence the occurrence of disease); to determine the extent of disease within a given community; to understand the natural history of disease; to evaluate the effectiveness of therapeutic methods; to identify sources of disease outbreaks; to identify modes of disease transmission; and to develop methods of disease prevention.

When discussing disease and the impact it has on the population, the incidence and prevalence of the disease must be quantified. The incidence of disease is the number of new cases of disease within a defined population over a defined period of time. The prevalence of a disease is defined as the number of cases of disease detected in a specified period of time, regardless of when the illness was contracted. Prevalence is expressed as the number of cases of disease found within a population at a specified time divided by the number of persons in that same population over the same specified time. Prevalence includes both old and new cases of disease. Incidence measures the risk of contracting the disease, whereas prevalence measures the burden of disease within a community. Both are used for understanding the patterns of disease occurrence and for utilization planning of health services, facilities, and the training of future providers.

The pattern of disease occurrence is another important element in understanding how populations are affected by disease. If a disease occurs only occasionally, the disease is called sporadic. If there are always a number of cases of a disease within a given population, and the numbers are expected and predictable, the disease is said to be endemic. If there is a clear rise in the number of cases (above a threshold level) of a disease for a given time or geographic area, the disease is said to be epidemic. Pandemic refers to a worldwide epidemic. The detection of emerging or reemerging infectious diseases is possible through the systematic collection of data and the constant surveillance of the incidence of disease. The Centers for Disease Control and Prevention (CDC) continually identifies certain "notifiable" diseases that require reporting to the health department in their effort to monitor and track the incidence of contagious diseases **Table 19-2**. New diseases can only be recognized as such when the normal background cases of infectious disease are well understood.

Disease is not randomly distributed, and the "where" of the disease outbreaks can be an important clue for identifying the cause or source of the disease. An example of the importance of the location of disease outbreaks was demonstrated in the severe acute respiratory syndrome (SARS) epidemic. Late in 2002, there was an outbreak of cases of life-threatening respiratory illnesses in the Guangdong Province of China with no identifiable cause. The first cases went unnoticed by international health organizations until February 2003, when a physician from Guangdong Province became ill while staying in a hotel in Hong Kong. During his visit to Hong Kong, 12 additional guests in the hotel contracted the illness, including seven who were staying on the same floor of the hotel as the physician. These hotel guests became the index patients, who then transported the disease to Singapore, Canada, Vietnam, Ireland, and the United States. Linking the cases together by location became an important component in the successful isolation and identification of the organism causing this mysterious disease, which was subsequently identified as a novel coronavirus.

TABLE 19-2 Infectious Disease Designated as Notifiable at the National Level

Acquired immunodeficiency syndrome	Hansen's disease (leprosy)	Novel influenza A virus (swine flu)	Streptococcal toxic shock syndrome
Anaplasma phagocytophilum	Hantavirus	Pertussis	*Streptococcus pneumoniae*, invasive and drug-resistant (children < 5 y)
Anthrax	Hemolytic uremic syndrome, postdiarrheal	Plague	Syphilis
Botulism	Hepatitis A, B, C	Poliomyelitis	Tetanus
Brucellosis	Human immunodeficiency virus, adult (≥ 13 y)	Psittacosis	Toxic shock syndrome (staphylococcal)
Chancroid	Human immunodeficiency virus, pediatric (< 13 y)	Q fever	Trichinellosis
Chlamydia	Influenza-associated mortality (children < 18 y)	Rabies	Tuberculosis
Cholera	Legionellosis	Rocky Mountain spotted fever	Tularemia
Coccidioidomycosis	Listeriosis	Rubella	Typhoid fever
Cryptosporidiosis	Lyme disease	Rubella, congenital syndrome	Vancomycin-intermediate and resistant *Staphylococcus aureus*
Cyclosporiasis	Malaria	Salmonellosis	Varicella (chickenpox)
Diphtheria	Measles	Severe acute respiratory syndrome	Vibriosis (noncholera)
Ehrlichia/ehrlichiosis	Meningococcal disease	Shiga toxin-producing *Escherichia coli*	Yellow fever
Encephalitis	Mumps	Shigellosis	
Giardiasis	Neurosyphilis	Smallpox	
Gonorrhea		*Streptococcus*, invasive group A	
Haemophilus influenzae, invasive disease			

Data Source: Nationally notifiable diseases and other conditions of public health importance event code list, Division of Integrated Surveillance Systems and Services, National Center for Public Health Informatics, Centers for Disease Control and Prevention. In infectious disease epidemiology, it is important to understand that there is a broad spectrum of disease severity. Often the prevalence or incidence of disease within a population only accounts for clinical illness or disease that produces symptoms. Disease without symptoms does not mean the same as no disease or no risk of spreading disease. Factors such as the incubation period of the disease or the presence of different carrier states may cause the disease to go undetected and unaccounted in an individual, but can place others at risk for contracting the disease because prevention and disease control efforts are not employed. This becomes a critical concept in the safe transport of patients. CCTPs are at risk for contracting disease from each patient transported; therefore, the use of disease control and prevention practices must be evaluated and employed as appropriate every time care is provided to patients regardless of whether the patient is or is not currently exhibiting symptoms.

Reservoirs of Infection

For a microorganism to infect and reinfect, it must have the ability to survive, duplicate or reproduce, and spread to new hosts. Reservoirs of infection provide a supply of nutrients and an environmental niche that enables long-term microbial survival. Bacteria have developed systems that enable them to withstand hostile environments. Spore-forming bacterial species are resistant to drying and environments with low nutrients. Encapsulated bacteria are resistant to changes in pH levels. Certain bacteria can make complex molecules from more basic components if certain nutrients are not available in their immediate environment. These adaptations allow organisms to survive in soil and water for significant lengths of time.

Both wild and domestic animals can also act as reservoirs of infection. Diseases that occur in animals and can also be transmitted to humans are called zoonoses. Influenza is the prototypic zoonosis. In this case, the virus transmission between the animal reservoir and the human host provides selective pressure to the virus that enables its long-term survival. The influenza virus will alter its surface proteins and can then reinfect and cause illness in individuals who had developed immunity to the old strain. The new strain is just different enough to escape activation of the immune system.

In the same way that animals can serve as reservoirs of infection, humans can act as reservoirs of infection. Persons who are colonized by pathogenic species but do not have symptoms of the infection are called asymptomatic or latent carriers. They have important roles in perpetuating diseases such as diphtheria, AIDS, hepatitis, gonorrhea, and amoebic dysentery.

Patients in whom pathogenic bacteria are colonized can serve as sources of infection during extended hospital admissions. These organisms coexist with normal skin or intestinal flora and are selected by the continual use of antimicrobial agents in the inpatient setting, meaning their numbers increase over the normal flora. Selection for increasing antibiotic-resistant bacteria happens when antibiotics are present at detectable levels in a particular environment over a period of time, as seen at inpatient settings. Bacteria that are sensitive to the antibiotics are killed easily in the presence of the antibiotic. Those bacteria that are resistant to antibiotics can survive and, therefore, “outcompete” over those that are sensitive, thus increasing antibiotic-resistant strains throughout patient treatment facilities. Health care providers unwittingly act as a major source of cross-infection when they interact with different patients without proper intervening antisepsis.

Finally, the health care environment itself may serve as a reservoir of infection. Some organisms are remarkably resistant to the effects of drying and, therefore, can survive on inanimate objects for an extended period of time. Durable medical equipment, even when treated with antimicrobial solutions, can harbor bacteria several days to several weeks after inoculation.

Modes of Transmission

Understanding the different modes of transmission of microorganisms is the first step in developing effective infection prevention measures. The unique properties and characteristics of the infectious agents determine how the disease is spread and how the infection is contracted. Infectious disease can be transmitted directly, indirectly, or mechanically.

Direct contact is person-to-person transmission (ie, no intermediate carrier is involved in the transfer). Direct transmission can occur vertically or horizontally. Horizontal transmission is the transmission of infection between members of the same generation (same generation refers to bacteria that are living at the same time, as opposed to vertical transmission, which is genetic information passed on to progeny). Types of direct horizontal transmission include sexual transmission, exchange of respiratory droplets or secretions, and transmission by contact. To guard against direct transmission, CCTPs should use protective barriers such as gloves, gowns, masks, and eye shields, which prevent direct contact with

infectious materials during invasive procedures or when providing care for an infectious patient.

Vertical transmission is the exchange of an infectious agent between mother and fetus *in utero*. Perinatal transmission is another form of direct transmission in which the exchange of the infectious agent from the mother to the baby occurs during the birthing process. It has been shown that the risk of vertical transmission of HIV can be greatly reduced by initiating therapy with zidovudine, a nucleoside reverse transcriptase inhibitor, between 14 and 34 weeks of gestation.

Indirect transmission occurs when there is an intervening step in the transmission from reservoir to susceptible host. The intermediate step involves an inanimate object or fomite such as towels, bedding, thermometers, and contaminated syringes. Prevention of infection can be as simple as properly disposing contaminated materials and cleaning equipment between patients.

Many infectious diseases are transmitted through the use of a medium, such as water, food, air, or contaminated body fluids. Water can be either the reservoir of disease or a vehicle for the transmission of that disease. Water that contains raw or poorly treated sewage is the perfect vehicle for the **fecal-oral route** of cholera transmission. Vehicle transmission can be prevented by good hygiene and proper food preparation and storage.

Vector transmission is the exchange of a pathogen from an infected organism to a susceptible host via an animal or insect. The method of vector transmission can be either mechanical or biological. Mechanical transmission is the passive transport of pathogens on the body of the animal to the susceptible host. Typhoid is an example of an infectious agent that is transmitted on the feet of houseflies. Biological transmission involves the vector, usually an arthropod, ingesting a blood meal from an infected organism and transmitting it after the pathogen has multiplied in the digestive tract of the vector, increasing the likelihood of transmission to a new host.

Selected Diseases

CCTPs are exposed to deadly agents on a daily basis. When providing care for sick patients, the risk of contracting their diseases is inherent, as well as the risk of passing the diseases onto other patients, fellow providers, or even family members. Knowledge of common infectious diseases and the appropriate responses can prevent the spread of disease.

Meningitis

Meningitis is the inflammation of the leptomeninges, the membranes that cover and enclose the spinal cord and brain. The meninges are composed of three distinct layers—the dura, arachnoid, and pia maters—that are the external, middle, and internal layers, respectively. Meningitis is a serious medical condition caused by bacterial, viral, or fungal infectious agents. Bacterial meningitis is a life-threatening illness that has an acute onset and is considered a medical emergency that requires prompt diagnosis and treatment to preserve life and neurologic function. Bacterial meningitis is fatal in up to 30% of patients and causes permanent neurologic impairment in 10% of patients who survive the illness.

Bacterial meningitis is caused by a bacterial infection that migrates to the meninges. Viral meningitis exhibits the same symptoms as bacterial meningitis and is also considered a serious medical condition; however, it typically resolves within 7 to 10 days. Because it is difficult to distinguish between bacterial and viral meningitis with the onset of symptoms, all cases should be treated as bacterial in origin until ruled out. The infectious agents may originate from structures close to the brain, such as the middle ear, sinuses, or respiratory tract, which can be colonized by pathogenic species. Bacterial meningitis can occur after trauma to the cranium in which the normal protective barriers to infection have been breached by penetrating objects or fractures, and it can occur by hematogenous spread of septicemia.

Although the classic triad of symptoms observed in patients with bacterial meningitis includes fever,

nuchal rigidity, and altered mental status, these symptoms are seen in less than 50% of patients. Other symptoms of meningitis include headache, significant photophobia, and cutaneous manifestations such as petechiae or palpable purpura. Most patients have fever (up to 95% of patients at presentation) of usually greater than 100.4°F (38°C), and virtually all patients with meningitis have at least one of the classic triad of symptoms. Additionally, neurologic complications may be present early in the disease course or can occur as a late complication. Seizures, papilledema (swelling of the optic nerve), and neurologic deficits have been described in up to 30% of patients. Hearing loss is a late neurologic complication. Treatment with dexamethasone, given at the same time as the first dose of antibiotics, may reduce this late neurologic complication, especially if the bacterial culprit is pneumococcal.

Patients may not specifically complain of a stiff neck, but nuchal rigidity can be demonstrated clinically by a few simple maneuvers. If the patient is unable to touch the chin to the chest by either active or passive flexion, one must suspect nuchal rigidity. This is classically demonstrated using the Brudzinski and Kernig signs, both of which demonstrated an extremely low sensitivity rating when tested in a large well-designed prospective study in 2002.

The Brudzinski sign is positive when there is spontaneous involuntary flexion of the hips during attempted passive flexion of the neck. The Kernig sign is elicited by straightening a patient's flexed legs. The inability to allow full extension of the knees when the hips are flexed is interpreted as a positive result.

When meningitis is suspected, the patient should undergo a lumbar puncture to obtain cerebrospinal fluid (CSF) unless contraindicated. If the collection of CSF is delayed, blood culture results are often positive and can be useful for diagnosis in the event that CSF cannot be obtained prior to the administration of antibiotics. Some physicians will delay the lumbar puncture until a computed tomographic (CT) scan has been obtained to exclude the possibility of increased intracranial pressure that may lead to cerebral herniation during the removal of CSF. It is not normally necessary to obtain a CT scan prior to a lumbar puncture except in the following circumstances:

- History of immunosuppression (a patient with HIV or a patient who has received a transplant)
- Seizure (new onset, within 7 days of presentation)
- History of central nervous system disease (tumor, stroke, or focal infection)
- Abnormal level of consciousness
- Focal neurologic deficit
- Papilledema

If for any reason the collection of CSF is delayed, the administration of antibiotics should not be withheld. Empirical antibiotic treatment is warranted when bacterial meningitis is suspected clinically.

Clinicians use epidemiologic knowledge to predict the infecting organism by understanding which bacterium (or virus) is the most likely pathogen, given the patient's age, medical history, immune status, and presenting symptoms. The organisms that cause community-acquired bacterial meningitis are quite different from those causing meningitis in the hospital or in immunosuppressed patients. The major causes of community-acquired bacterial meningitis in adults are *S pneumoniae* and *Neisseria meningitides*, and *Listeria monocytogenes* in patients older than 55 years.

Signs and Symptoms

Viral Meningitis

- Fever

- Severe headache
- Nuchal rigidity
- Nausea
- Vomiting
- Photophobia
- Malaise

The epidemiology of bacterial meningitis underwent a major change after the introduction of the *Haemophilus influenzae* type b conjugate vaccine in 1987. Before the 1990s, most cases of meningitis were seen in infants and children, and caused by *H influenzae*, a gram-negative bacterium. Currently, most of the cases of bacterial meningitis are observed in adults and can be caused by a variety of different bacterial species, including *N meningitidis, S pneumoniae*, and *H influenzae*.

H influenzae type b (Hib) is a small, pleomorphic, encapsulated, gram-negative coccobacillus that can colonize the respiratory tract of humans. Individuals colonized with *H influenzae* may be asymptomatic, and most isolates of *H influenzae* are nonencapsulated and are not pathogenic. *H influenza* type b is the most virulent, and it is encapsulated, which enables it to set up infection by evading destruction by phagocytic cells. It spreads from one individual to another via airborne droplets or direct contact with contaminated secretions. *H influenzae* is most commonly found in the nasopharynx of healthy asymptomatic children aged 2 to 5 years. When *H influenzae* meningitis is encountered in the adult population, it is suggestive of the presence of a predisposing medical condition such as paranasal sinusitis, otitis media, alcoholism, head trauma, asplenia, and other immunocompromised states. For this reason, the *H influenzae* vaccine is recommended for children and susceptible adults.

Signs and Symptoms

Bacterial Meningitis

Classic triad of symptoms:
- Fever
- Nuchal rigidity
- Altered mental status Possible other symptoms:
- Headache
- Photophobia
- Focal neural deficits
- Seizures

N meningitidis meningitis:
- Fever
- Headache
- Meningismus
- Petechial lesions (1- to 2-mm purple hemorrhagic spots that do not blanch with pressure), progressing to palpable purpura (larger areas of bleeding under the skin)

Differential Diagnosis

Bacterial Meningitis

- Viral meningitis
- Brain tumor
- Subarachnoid hemorrhage
- Herpes simplex encephalitis
- Febrile seizure
- Delirium tremens
- Hepatic encephalopathy
- Brain abscess

Transport Management

Bacterial Meningitis

- Administer IV fluids.
- Administer corticosteroids (such as dexamethasone) if indicated per protocols.
- Continue IV administration of antibiotics or other medications that have been started by the sending facility.

N meningitidis is a gram-negative diplococcus that causes 4,000 cases of meningitis each year in the United States. *N meningitidis* is pathogenic only in humans and is spread by prolonged close contact with infected individuals through direct contact with respiratory secretions. This is why outbreaks most often occur in prisons, military barracks, or college dormitories. The bacteria can be isolated from 10% to 30% of healthy adults, but the disease is not common. When a case of *N meningitidis* is reported, all close contacts of the infected individual are treated prophylactically.

N meningitidis enters the body through the epithelial surfaces of the nasopharynx. If the bacteria reach the bloodstream, they can cause gram-negative sepsis, extensive tissue damage, and death. The onset of symptoms is abrupt (ie, fever, headache, and meningismus). Patients with *N meningitidis* meningitis have a characteristic rash caused by meningococcal emboli that start as **petechial lesions** (small 1- to 2-mm purple hemorrhagic spots that do not blanch with pressure) and advance to **palpable purpura** (larger areas of bleeding under the skin) within a short period of time. This rash is classic and should not be missed because the mortality rate for untreated *N meningitidis* meningitis nears 100%.

S pneumoniae is the most common cause of community-acquired bacterial meningitis in adults. *S pneumoniae* are encapsulated, gram-positive cocci that are lancet shaped and are commonly arranged in pairs or short chains. They possess several pathogenic properties that make infection with *S pneumoniae* a serious medical event. Their polysaccharide capsule prevents them from being opsonized and phagocytized. They are able to adhere to the surface of epithelial cells that allows them to colonize, and they produce toxins that directly inhibit the body's cell-mediated phagocytic activity. They also possess specialized enzymes called neuraminidases and proteases, which allow them to grow in mucosal surfaces, facilitating colonization.

S pneumoniae is commonly isolated from the nasopharynx of healthy individuals. The rate of colonization is estimated to be as high as 70% in the winter and spring. Patients with chronic bronchitis are frequently colonized by *S pneumoniae*.

The development of *S pneumoniae* meningitis is often preceded by a mild upper respiratory tract

infection. Individuals at highest risk for contracting *S pneumoniae* include those with sickle cell anemia, chronic alcoholism, multiple myeloma, and general disability. The diagnosis is certain when the characteristic lancet-shaped gram-negative diplococci are isolated from the normally sterile cerebrospinal fluid. The mortality rate of *S pneumoniae* meningitis in the elderly and immunocompromised is quite high, even when treatment is initiated promptly. Therefore, vaccination against *S pneumoniae* is strongly encouraged for at-risk populations, and is now included in the routine childhood vaccination schedule.

Like bacterial meningitis, viral meningitis typically presents with fever, severe headache, and nuchal rigidity. Additional symptoms include nausea, vomiting, photophobia, and malaise. The severity of the symptoms and the disease is less serious than that of bacterial meningitis. Complete recovery can occur in 2 to 7 days without medical intervention.

There are 10,000 cases of viral meningitis reported each year in the United States. All age groups are affected, but viral meningitis is more commonly seen in young adults. Viral meningitis can be acute, subacute, or relapsing. The peak incidence occurs in summer.

There are a variety of species that can cause viral meningitis, including coxsackie A and B, echovirus, adenovirus, lymphocytic choriomeningitis virus, cytomegalovirus, poliovirus, and Epstein-Barr virus. Enterovirus is the most common cause of aseptic meningitis. All enterovirus species are transmitted through the fecal-oral route. Generally when providing care for a patient suspected to have viral meningitis, careful handwashing should be employed to prevent the spread of the disease.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) causes seasonal outbreaks of acute respiratory infections. RSV is caused by an RNA paramyxovirus. The virus is called a syncytial virus because the proteins on the virus surface are not hemagglutinins, but fusion proteins that cause cells to fuse and form multinucleated giant cells. The clinical manifestations of RSV are dependent on the age and health of the individual infected. RSV season in the United States occurs in the winter months, with the peak of the season in January and February. RSV accounts for more than 100,000 hospitalizations of children in the United States each year. For infants 1 year or younger, the virus usually causes a lower respiratory tract infection, either bronchiolitis or pneumonia. Apnea is a risk for 20% of all infants hospitalized with the infection and may put the child at risk for sudden death.

RSV can occur in individuals older than 1 year. In fact, most children test positive for RSV by the time they reach the age of 2 years. Persons at risk for severe infections or complications from infections are those with a history of prematurity or those who are immunocompromised. RSV can also be detected in adults, but it usually does not cause long-term pulmonary dysfunction. Currently, no vaccine exists to prevent respiratory tract infections by RSV. A monoclonal antibody called palivizumab is available, and it confers passive immunization to recipients. It can be used for **prophylaxis** in premature infants at risk for severe infections.

Transmission occurs via respiratory droplets and via direct contact with hands that have been contaminated with mucous from the nose or mouth of an infected individual. CCTPs should employ droplet and contact precautions when transporting patients with a suspected or a confirmed case of RSV. Diagnosis is made by testing the respiratory secretions of the infected individual by polymerase chain reaction.

Signs and Symptoms

Respiratory Syncytial Virus

- Runny nose
- Congestion
- Cough
- Sore throat
- Headache
- Malaise
- In infants and young children: listlessness, decreased appetite, fever, wheezing, tachypnea, and cyanosis

Differential Diagnosis

Respiratory Syncytial Virus

- Asthma
- Bronchiolitis
- Pneumonia
- Foreign body aspiration
- Pertussis

Transport Management

Respiratory Syncytial Virus

- Provide supportive care.
- Administer fluids.
- Administer oxygen.
- Administer a nebulized bronchodilator for wheezing, if indicated by protocols.
- Monitor mechanical ventilator, if applicable.

Necrotizing Fasciitis

Necrotizing fasciitis is a limb-threatening or life-threatening infection of the soft tissue that affects the subcutaneous tissues, fat, and fascia but usually spares the skin and the muscle. Prompt diagnosis and treatment with antibiotics and complete surgical débridement are important to reduce the high mortality rate associated with this disease.

There are two main types of necrotizing fasciitis. Type I is polymicrobial, meaning the infection is the result of a mixture of aerobic and anaerobic microorganisms. This type is commonly seen in postoperative patients with comorbid conditions such as diabetes and peripheral vascular disease. The microorganisms seen in type I necrotizing fasciitis may be a mixture of *Staphylococcus aureus, Streptococcus* species, *Enterococcus* species, *Escherichia coli, Peptostreptococcus* species, *Bacteroides* species, *Vibrio vulnificus*, and *Clostridium* species. Type II is a monomicrobial infection caused by the group A streptococci (GAS) *Streptococcus pyogenes*. This infection was previously known as "streptococcal gangrene." The skin barrier is breached during surgery and is thought to be the portal of entry for the GAS infection.

Patients may present with unexplained pain that increases over time. Initially, the skin may appear

normal or there may be mild erythema. Pain out of proportion to the exam may be the only initial clue that there is a serious problem. Within 24 to 48 hours, the erythema worsens and develops into a dark red to purple color. Blisters or bullae may develop on otherwise normal appearing skin. Fever or tachycardia may also be present. Hypotension may develop as the infection worsens. Gas, as evidenced by crepitus on exam, may develop under the skin. Often this gas can be detected on radiographic imaging as air along the fascial planes.

Aggressive fluid replacement should be initiated in the field. Treatment using antibiotics alone, without surgical intervention, is associated with a nearly 100% mortality rate. Time is of the essence when dealing with a patient with necrotizing fasciitis. Any delay in surgical diagnosis and treatment may increase mortality and cause extension of the disease. Sometimes hyperbaric oxygen therapy is used in the treatment of patients with necrotizing fasciitis. CCTPs may be called on to transport patients to facilities with the resources to provide care for these patients. In any case of suspected or known necrotizing fasciitis, contact precautions must be maintained at all times, and all equipment must be thoroughly disinfected after the transport of this type of patient.

Signs and Symptoms

Necrotizing Fasciitis

- Unexplained pain that increases over time and is out of proportion to the exam
- Mild erythema that develops into a dark red to purple color within 24 to 48 hours
- Blisters or bullae
- Fever or tachycardia
- Hypotension
- Gas, as evidenced by crepitus on exam

Differential Diagnosis

Necrotizing Fasciitis

- Cellulitis
- Gas gangrene
- Toxic shock syndrome

Transport Management

Necrotizing Fasciitis

- Provide supportive care.
- Provide aggressive fluid replacement.
- Continue IV administration of antibiotics that have been started by the sending facility.
- Perform cardiac monitoring.
- Monitor urine output to the indwelling catheter, if one has been placed at the sending facility.
- Provide immediate transport (to be followed by surgical intervention).

Epiglottitis

Epiglottitis is caused from an infected and inflammed epiglottis, aryepiglottic folds, and/or surrounding tissues. In the past, most cases were caused by infection with Hib. Since the introduction of the Hib vaccine in 1991 in the United States, the epidemiology of this disease and others caused by Hib has been changing. The incidence of epiglottitis has been drastically reduced, but because of its severity and rapid progression to airway obstruction, it is important to be familiar with its clinical presentation.

Epiglottitis can occur at any age; however, most cases occur in children aged 1 through 5 years. The agent and median age at presentation are likely to shift as the population continues to be immunized against Hib. Other causes of epiglottitis include *Haemophilus parainfluenzae*, *S pneumoniae*, *S aureus*, and beta-hemolytic *Streptococcus pyogenes*. *H influenzae* type b epiglottitis still may occur, but will likely occur in children who are incompletely immunized or those who are noncompliant with vaccinations. There is no predominate bacterial species found in adults with epiglottitis.

An abrupt onset of symptoms is the common theme for presentation. The symptoms include high fever, severe sore throat, dysphasia, and dysphonia. Often, a child will start drooling as a result of painful or difficult swallowing. The child's speech or voice may be altered so that it is muffled, and has been described classically as the "hot potato voice." As the symptoms progress, the child may assume a distinctive posture: while sitting, the arms extend backwards to support the forward leaning trunk and the chin will be thrust forward to maximize the diameter of the hypopharynx. Unlike croup, stridor is not a predominant sign and increased respiratory effort with use of accessory muscles may not be present, thus the severity of the disease may be underestimated. The symptoms can rapidly progress to airway obstruction, hypoxia, and cardiopulmonary arrest.

As in all resuscitations, diagnostic testing should be deferred for patients in extremis until stabilization is achieved. The diagnosis of epiglottitis can be made by visualization of a fiery-red and edematous epiglottis. The optimal method of visualization is under controlled conditions via direct laryngoscopy by an otolaryngologist. Radiographs are not usually necessary to make the diagnosis of epiglottitis; however, if direct visualization cannot be achieved and doubt remains as to the diagnosis, a lateral soft-tissue neck radiograph may aid in diagnosis. With imaging, a healthy child's epiglottis appears as a thin tall structure, but when epiglottitis is present, the image may reveal the classic "thumb print" sign (ie, the epiglottis appears thick and squatty like a thumb). If a radiograph is obtained, the patient should not go to the radiology department unaccompanied. There should always be an advanced airway cart available, and a person trained in advanced airway management should accompany the patient if the patient leaves the emergency department prior to the procurement of a secure airway. Epiglottitis is a potentially life-threatening infection; as such, patients with epiglottitis must be promptly treated with empirical antibiotics. The antibiotic regimen should be selected to provide coverage for streptococci, pneumococci, staphylococci, and Hib.

CCTPs must maintain a high level of suspicion for epiglottitis for any patient presenting with the abrupt onset of fever, sore throat, muffled voice, and drooling. Agitation of the patient should be minimized because this may lead to worsening of their condition and hasten the progression to complete airway obstruction. Interactions with the child should be conducted in a manner that minimizes his or her anxiety because agitation only makes the situation worse. If airway intervention is necessary in the prehospital environment, the task should be given to the most experienced team member. Orotracheal intubation can be difficult secondary to edema and anatomical distortion. Patients with epiglottitis often require advanced airway management, such as nasotracheal intubation or tra-cheostomy. Getting to the nearest, most appropriate level care facility as quickly as possible is a must.

Signs and Symptoms

Epiglottitis

- High fever
- Severe sore throat
- Dysphasia
- Dysphonia
- Drooling as a result of painful or difficult swallowing
- Alteration of speech or voice so that it is muffled–"hot potato voice"
- Sitting with the arms extended backward to support the forward-leaning trunk, with the chin thrust forward to maximize the diameter of the hypopharynx

Differential Diagnosis

Epiglottitis

- Anaphylaxis
- Croup
- Foreign body aspiration
- Laryngotracheobronchitis
- Mononucleos
- Pertussis
- Pharyngitis
- Pneumonia
- Caustic ingestion

Transport Management

Epiglottitis

- Support the airway.
- Continue IV administration of antibiotics if they have been started by the sending facility.
- Note: When epiglottitis is strongly suspected, transfer of a patient without an artificial airway (endotracheal tube or tracheostomy) is unsafe.

Tuberculosis

Tuberculosis (TB) is caused by the acid-fast bacterium called *Mycobacterium tuberculosis*. The only other genus of pathogenic bacteria that is classified as acid-fast is *Nocardia*. Acid fast refers to the staining process that differentiates these organisms from most other bacteria. Because of the high lipid content (specifically mycolic acid) in the mycobacterial cell membrane, they can be diagnosed by the acid-fast staining technique **Figure 19-4**.

The genus *Mycobacterium* includes other ominous organisms such as the organism that causes leprosy, *Mycobacterium leprae*, and *Mycobacterium avium-intracellulare* complex (called MAC), which causes a tuberculosis-like pneumonia that is usually seen only in immunocompromised patients such as those with advanced HIV/AIDS. MAC is particularly insidious because these organisms are very

resistant to antibiotics and are becoming even more resistant at an alarming rate.

Tuberculosis causes more deaths globally than any other single microbial agent, killing 3 million people per year. In the United States, the combination of deteriorating public health availability, inadequate control of infectious diseases, urban crowding, immigration, and increasing numbers of HIV patients has resulted in a resurgence of TB cases. The risk of this highly infectious disease is increased in persons who live in poor housing conditions, those who are usually malnourished, and those who are co-infected with HIV. With recognition and appropriate treatments, the United States saw approximately 16,377 documented cases in 2000, down from the peak of 67,000 cases reported in 1992. The United States continues to steadily decrease the case rate of TB through education and quick actions taken to control the spread of the disease.

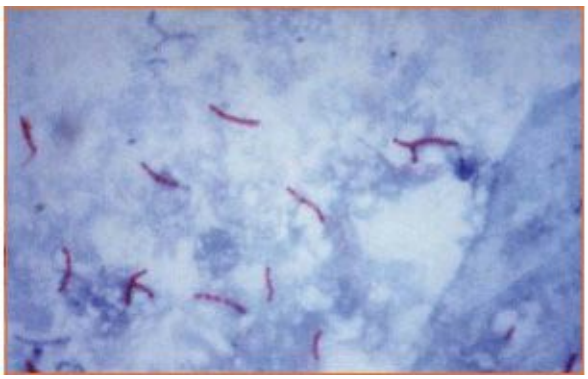

Figure 19-4 Acid-fast staining technique to diagnose tuberculosis.

M tuberculosis is transmitted via respiratory droplets, from the cough of an infected person to the respiratory epithelium of a susceptible person. The first site of infection is the lungs, and the bacterium, being an obligate aerobe, has a propensity to set up infection in the upper lobes of the lungs because that tissue is highly oxygenated. TB can also spread to the kidneys or spine. Most persons infected with *M tuberculosis* are asymptomatic. The immune status of the patient, in large part, determines the clinical symptoms of an infection with *M tuberculosis*. Persons with full-on pulmonary TB have five common symptoms: cough, fever, weight loss, night sweats, and fatigue.

M tuberculosis does not produce any toxins. *Mycobacteria* survive inside the phagosome of the reticuloendothelial cells (specifically, the macrophage). They avoid the normal phagocytic processes of the macrophage by producing a specialized protein that prevents the fusion of the phagosome with the lysosome. The two main types of lesions that *M tuberculosis* produces are exudative and granulomatous, depending on the immune response of the host. The Ghon complex is the pathognomonic lesion seen in the lung. It consists of an exudative lesion and an enlarged lymph node that drains the lesion. As discussed, the primary infection, which frequently goes undiagnosed, is often found in the lower lobes while the lesions of reactivation are found in the upper lobes. Reactivation of a previously contained infection occurs in the immunocompromised or debilitated patient.

After a person recovers from a primary infection, the immune system resists secondary infection and reactivation through cell-mediated immunity. Antibodies to tuberculin are formed and their existence is exploited in the purified protein derivative (PPD) test. The tuberculin antigen is injected into the skin; if positive, it indicates a previous infection, but does not necessarily indicate active disease. If the reaction is large (> 15 mm in diameter), then the person is considered to be actively infected and should receive treatment. As with some other infectious diseases, there is a delay between the primary infection and a positive PPD test result. In this case, it takes 4 to 6 weeks for the TB skin test to be reactive. The induration seen in the PPD is a type IV delayed hypersensitivity reaction, used for diagnostic advantage.

A vaccine is available for the prevention of TB. The BCG vaccine is made from a related bacterium,

Mycobacterium bovis, which usually infects bovines (cows). The BCG vaccine is not used in the United States because it is only effective 70% of the time and its use renders the PPD test useless. Inoculation with the BCG vaccine causes a person to have a positive PPD test result. If a vaccination campaign were to be initiated, the PPD test result of many persons would become positive and would result in loss of the ability to screen for exposure, without the assurance of induced immunity.

Infection with *M tuberculosis* can be difficult to diagnose because it is a slow-growing bacterium, taking weeks to culture. Because treatment must begin as soon as possible, diagnosis is based on clinical signs and confirmed via positive acid-fast staining of three sputum samples from patients suspected of being infected. The emergence of drug-resistant strains of TB has precipitated the use of a multidrug regimen for cure. The individual drugs used may vary slightly according to known sensitivities, but the mainstay of therapy is isoniazid. The drugs are typically given for 18 to 24 months.

Multidrug-resistant tuberculosis (MDR-TB) is TB that is resistant to at least two of the standard anti-TB medications, isoniazid and rifampin. Extensively drug-resistant TB (XDR-TB) is TB that is resistant to isoniazid, rifampin, any fluoroquinolone, and at least one second-line IV drug. Because XDR-TB is resistant to many first- and second-line drugs, treatment options are limited for patients with this form of the disease. Both MDR-TB and XDR-TB are contracted via the same mechanism as TB, through the inhalation of infected droplets from a person who is already infected when that person coughs, sneezes, or spits into the environment. These infected droplets can exist in the air for several hours and anyone who breathes in these particles is at risk for contracting the disease. The spread of MDR-TB is promoted by noncompliance with the full course of prescribed treatment for TB infection because the surviving bacteria develop resistance to the standard antibiotics.

When transporting a patient with a history of fever, weight loss, and night sweats, and anyone with a cough, take proper precaution by placing a mask on the patient (if tolerated); the CCTP should also wear a mask. CCTPs should comply with yearly PPD testing to determine a personal exposure history. If care was provided for a patient known to have TB and exposure was a possibility, providers should undergo PPD testing 6 weeks after exposure to assess his or her status. If the test result is negative, resume routine PPD tests. If a PPD test result is positive, a chest radiograph will be required to determine whether signs of active or previous TB infection exist.

Signs and Symptoms

Tuberculosis

- Cough
- Fever
- Weight loss
- Night sweats
- Fatigue

Differential Diagnosis

Tuberculosis

- Brucellosis
- Chronic cough
- Chronic obstructive pulmonary disease (COPD)

- Histoplasmosis
- Leishmaniasis
- Lung abscess
- Lung cancer
- Mesothelioma
- Myelofibrosis
- *Pneumocystic carinii* pneumonia
- Q fever
- Toxoplasmosis
- Typhoid fever

Transport Management

Tuberculosis

- Provide supportive care.
- Continue administration of IV antibiotics if they have been started by the sending facility.
- Ensure meticulous isolation precautions.

Pneumonia

Pneumonia is the number one cause of death as a result of infectious diseases and is the sixth leading cause of death in the United States for all causes including cancer and heart disease. In the United States, most patients who die of pneumonia are older than 65 years. Pneumonia is an infection of the lung parenchyma that is caused by bacterial, viral, or fungal agents. Physicians normally classify pneumonia as either community acquired or nosocomially acquired (contracted in a medical facility) because the differential acquisition of pneumonia has implications for the most likely infecting agent, treatment, and prognosis. The mortality rate for community-acquired pneumonia ranges from 5% to 14%, whereas the mortality rate for **nosocomial** pneumonia is as high as 40%. Pneumonia is generally diagnosed in a patient presenting with symptoms of sudden-onset fever, chest pain, or dyspnea, and leukocytosis. Patients may also have a cough, either dry or productive, depending on the causative agent. Plain chest radiographs, posterior-anterior and lateral, are the gold standard for diagnosing a consolidated or infiltrative lesion.

There are an estimated 2 to 3 million cases of community-acquired pneumonia in the United States each year. *S pneumoniae* is the most common pathogen for all age groups of patients with community-acquired pneumonia. *S pneumoniae* gains entry to the respiratory tract following aspiration into the lungs from previously colonized nasopharyngeal mucosa. Elderly patients and those with other comorbidities are at a higher risk for succumbing to pneumonia infections. A history of tobacco use, chronic obstructive pulmonary disease, immunosuppression, and obesity are independent risk factors for developing community-acquired pneumonia.

Symptoms of bacterial pneumonias are high fevers, productive cough, and pleuritic chest pain. Many different bacterial species cause pneumonia, the most common being *S pneumoniae*, *H influenzae*, *S aureus*, *Chlamydia pneumoniae*, and *Legionella pneumoniae*.

Mycoplasma pneumoniae and viruses cause atypical pneumonias. They are considered atypical because patients usually present with a slower onset of symptoms, low-grade fever, and a dry cough. *Mycoplasma* pneumonia is often misdiagnosed as viral because of a less severe presentation. The clinical

lung exam result may be normal, but the chest radiograph will demonstrate infiltrates. *Mycoplasma* pneumonias are often preceded by a flu-like prodrome of symptoms, including headache, malaise, and fever.

Viral pneumonia is more common in infants and young children. Respiratory syncytial virus and parainfluenza virus are the most common causes of viral pneumonia in children. The incidence of these viral infections peaks in the fall and winter. Viral pneumonia is often preceded by an upper respiratory tract infection. Like atypical pneumonias, the onset of viral pneumonia can be slower than the onset of bacterial pneumonia.

Hospitalized patients—particularly the elderly—are susceptible to nosocomial pneumonias. The definition of nosocomial or **hospital-acquired pneumonia (HAP)** is a pneumonia that occurs in a hospitalized patient within 48 hours or more after admission to the hospital. (This type of pneumonia was not apparent at the time of admission.) Hospital-acquired pneumonia is the leading cause of death among nosocomial infections and is associated with a mortality rate as high as 50%. **Ventilator-associated pneumonia (VAP)** is a type of HAP that occurs in ventilated patients that appears more than 48 hours after endotracheal intubation. **Health care–associated pneumonia (HCAP)** is a pneumonia that occurs in nonhospitalized patients who have contact with health care facilities or personnel, such as residents of long-term health care facilities, those undergoing hemodialysis, or those who have had a recent admission to an acute care facility.

HAP, VAP, and HCAP can be caused by a number of different pathogenic bacteria and can be polymicrobial. Common pathogens include *E coli, Klebsiella pneumoniae, Enterobacter, Pseudomonas, S aureus*, and *Streptococcus*. Nosocomial bacterial pneumonias secondary to viral or fungal infection are much less common except in patients with severe immunosuppression.

Pneumocystis jiroveci (previously *Pneumocystis carinii*) pneumonia (PCP) is a fungal infection that is seen in patients with immunosuppression, such as those taking immunosuppressive therapy for solid organ transplantation or those infected with HIV, and is included in the list of AIDS-defining illnesses (Table 19-5). In fact, when a patient's CD4 cell count is less than 200 cells/μL, he or she is placed on trimethoprim-sulfamethoxazole prophylactically to prevent the development of PCP. The classic radiographic findings for PCP are bilateral interstitial infiltrates.

As with all respiratory illnesses, CCTPs should use standard precautions when caring for patients suspected of having pneumonia or those diagnosed as having pneumonia. If a patient is actively coughing, place a mask on the patient (if tolerated) and on yourself, wear gloves, and use good handwashing technique between transports. Equipment, including the transport vehicle, must be thoroughly cleaned and decontaminated prior to further transports.

Signs and Symptoms

Pneumonia

- Sudden-onset fever
- Chest pain
- Dyspnea
- Leukocytosis
- Cough, either dry or productive

Differential Diagnosis

Pneumonia

- Asthma
- Bronchiectasis
- COPD
- Lung cancer
- Pulmonary edema
- Pulmonary emboli

Transport Management

Pneumonia

- Provide supportive care.
- Continue administration of IV antibiotics or other medications if they have been started by the sending facility.

Fungal Diseases

Over the last 20 years, serious fungal infections have been increasing in incidence. These infections are not particularly contagious to healthy individuals and their presence in patients is an indication of serious immunosuppression. It is especially important to decontaminate equipment, such as laryngoscopes and suction equipment, after transportation of patients with oral candidiasis (thrush) or patients infected with *P jiroveci*.

Influenza

Influenza virus causes an acute upper respiratory illness lasting between 7 and 14 days depending on the severity of symptoms. It is caused by an orthomyxovirus and has three variants (A, B, and C). Influenza has an incubation period of about 1 to 3 days and is spread by droplet or fomite transmission. Complications in the elderly and the very young include the development of primary or secondary pneumonia. Treatment for influenza is mostly supportive; however, when diagnosed within the first day of symptoms, treatment with an antiviral medication may reduce the severity and duration of symptoms. It is not uncommon for an influenza epidemic to cause illness in 10% to 20% of people; the virus can be responsible for as many as 36,000 deaths and more than 100,000 hospitalizations per year **Table 19-3.**

Influenza A (unlike influenza B and C) is subject to antigenic drift, which is caused by small genetic changes in the virus. This alters the virus just enough so that antibodies generated in previous infections no longer recognize the viral epitopes or surface proteins and therefore do not protect the body from the symptoms of a new infection. Influenza type A is divided into subgroups based on the presence of two surface proteins (also called envelope spikes): hemagglutinin and neuraminidase. In addition to antigenic drift, influenza A is subject to more drastic changes called antigenic shift. This happens when one or both of the spike proteins change the form of their protein structure. Antigenic shift typically occurs only once in several years, whereas antigenic drift occurs more frequently. The phenomenon of antigenic drift is what precipitates the need for yearly preparation of influenza vaccine, thus requiring annual immunization.

TABLE 19-3 Influenza Landmarks in Humans During This Century

Year	Colloquial Name (Subtype)	Source	Impact
Pandemics			
1918	Spanish flu (H1N1 viruses such as swine flu)	Possible emergence from swine or an avian host of a mutated H1N1 virus	Pandemic with > 20 million deaths globally
1957	Asian flu (H2N2)	Possible mixed infection of an animal with human H1N1 and avian H2N2 virus strains in Asia	Pandemic, H1N1 virus disappeared
1968	Hong Kong flu (H3N2)	High probability of mixed infection of an animal with human H2N2 and avian H3Nx virus strains in Asia	Pandemic, H2N2 virus disappeared
1977	Russian flu (H1N1)	Source unknown but virus is almost identical to human epidemic strains from 1950; reappearance detected at almost the same time in China and Siberia	Benign pandemic, primarily involving persons born after the 1950s; H1N1 virus has cocirculated with H3N2 virus in humans since 1977
Incidents With Limited Spread			
1976	Swine flu (H1N1)	United States/New Jersey; virus enzootic in US swine herds since at least 1930	Localized outbreak in military training camp, with one death
1986	(H1N1)	The Netherlands; swine virus derived from avian source	One adult with severe pneumonia
1988	Swine flu (H1N1)	United States/Wisconsin; swine virus	Pregnant woman died after exposure to sick pig
1993	(H3N2)	The Netherlands; swine reassortant between old human H3N2 (1973/1975-like) and avian H1N1	Two children with mild disease; fathers suspected of transmitting the virus to the children after being infected by pigs
1995	(H7N7)	United Kingdom; duck virus	One adult with conjunctivitis
1997	Avian flu (H5N1)	Hong Kong; poultry virus	Since 2003, 421 cases worldwide with 257 deaths
2009	Novel H1N1	Mexico	At publication, ~ 45,000 cases and > 600 deaths in the United States; > 360,000 cases and > 4,000 deaths worldwide

Source: Modified from Snacken R, Kendal AP, Haaheim LR, Wood JM. The next influenza pandemic: lessons from Hong Kong, 1997. *Emerg Infect Dis*. 1999;5(2):195–203.

Influenza is a virus that can also infect species of animals other than humans—in fact, waterfowl are the natural reservoir for the influenza A virus. The influenza A virus is an avian virus that has "jumped species" to infect humans and other mammals. Humans, pigs, ducks, chickens and other animals are susceptible to influenza A. This variability of hosts causes mutations to occur in the virus that facilitate antigenic drift. When animals are infected with swine, human, and avian influenza simultaneously, there can be a mixing of the genes that encode the neuraminidase and hemagglutinin proteins. A large number of variations of these proteins are possible because there are nine known variations of neuraminidase and 16 known variations of hemagglutinin. Variations in influenza A are closely monitored by the World Health Organization (WHO) and the CDC in the United States as well as other global health associations. The subtypes of influenza A are categorized and tracked each year. The predominant subtypes of influenza A circulating through the world in 2009 are called H3N2, meaning that the hemagglutinin is type 3 and the neuraminidase is type 2, and H1N1. The highly pathogenic forms of avian influenza are H5 and H7. When influenza undergoes a major antigenic drift or a novel combination of hemagglutinin and neuraminidase emerges (called an antigenic shift), people have little or no antigenic protection from prior infections. This is when pandemics of influenza break out and spread quickly, causing major illness around the world.

Historically, new strains of influenza A virus arise in the Far East and it is likely that socioeconomic and geographic factors enter into the reasons for this. It is common for farmers in southeast China to live in close proximity with pigs and ducks. This sets up a perfect environment for the avian and human strains to recombine in pigs and then jump species back into humans with an antigenic shift. Each year, the WHO

and the CDC collect samples from the Far East to use as sentinel viruses for preparation of the influenza vaccine offered in the United States and other countries.

Signs and Symptoms

Influenza

- High fever
- Runny nose or congestion
- Cough
- Sore throat
- Muscle aches
- Fatigue
- Headache
- Nausea, vomiting, or diarrhea

Differential Diagnosis

Influenza

- Bacterial infection
- Fungal infection
- Parasitic infection
- Viral infection
- Typhoid

Transport Management

Influenza

- Provide supportive care.

CCTPs should be aware of the signs and symptoms of influenza infection and should use standard and respiratory precautions to avoid infection and spread of infection.

Herpesviruses

The herpesvirus family is a group of double-stranded DNA viruses that are surrounded by a lipoprotein envelope. Herpesviruses are noted for their ability to cause latent infections when the acute viral syndrome is followed by a symptomfree period during which the virus is **quiescent** or inactive. Depending on the species, reactivation of the virus can occur when the patient is immunosuppressed or through inciting agents. There are six important pathogenic herpesvirus members that cause significant disease in humans:

- Herpes simplex types 1 and 2

- Varicella zoster virus
- Cytomegalovirus Epstein-Barr virus
- Human herpesvirus 8

Both Epstein-Barr virus and human herpesvirus 8 are associated with the development of cancer, Burkitt's lymphoma, and Kaposi's sarcoma.

Herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2) cause lesions, but the lesions differ in their location. HSV-1 is transmitted in saliva, whereas HSV-2 is transmitted via sexual contact. Therefore, it follows that HSV-1 causes lesions above the waist, whereas HSV-2 causes lesions below the waist. However, either virus can be isolated from either location through oral-genital contact. HSV-1 causes an acute gingivostomatitis in children and recurrent *herpes labialis* in adolescents or adults, commonly known as cold sores. HSV-1 can also cause keratoconjunctivitis and encephalitis in immunocompromised hosts. HSV-2 commonly causes genital herpes **Figure 19-5** and can cause life-threatening infection in the neonate if delivered vaginally during an outbreak.

Figure 19-5 Herpes simplex virus type 2.

Viral Hepatitis

Hepatitis is the inflammation of the liver. Hepatitis can be caused by exposure to infectious agents, usually viral, toxins such as alcohol, or drugs such as acetaminophen. The course and severity of the illness range from acute to chronic and mild to life threatening, respectively. The wide range of signs and symptoms of liver disease can range from subclinical symptoms and nonspecific malaise to jaundice, hepatomegaly, bleeding dyscrasias, altered mental status, and multiple organ failure. Damage to the liver can be caused by direct injury to the hepatocytes by the agent or may result indirectly from an inflammatory response or an autoimmune attack.

There are six known hepatotrophic viruses (hepatitis A, B, C, D, E, and G), each having its own characteristic causative agent, mode of transmission, incubation period, associated risk factors, and sequelae. Viral hepatitis is first classified by the duration of the illness into either acute or chronic. Acute viral hepatitis is defined as the presence of signs and/or symptoms of liver inflammation for less than 6 months duration, whereas chronic viral hepatitis is defined as the presence of persistent liver inflammation for 6 months or more. Liver inflammation can also be described by histologic and pathologic findings, which allows for the grading and staging of liver disease. The grade of liver disease describes the severity of the inflammatory process and cell necrosis, and the stage of liver disease describes the severity of the scarring of the liver tissue.

Elevation of liver enzyme levels in the serum is used as evidence of damage to the liver, and the pattern of their elevation provides insight into the nature and probable cause of the insult. An acute viral hepatitis will be accompanied by an acute onset and marked elevation in aspartate aminotransferase (AST) and alanine aminotransferase (ALT), whereas a chronic viral hepatitis produces a more moderate and persistent elevation in these same enzymes. The ratio of serum AST to ALT is commonly greater than

two in liver disease caused by alcohol abuse, whereas the ratio is characteristically less than one in liver disease caused by viral agents.

Alkaline phosphatase (AP) is an enzyme that is present in many different tissues within the body, such as bone, intestine, kidney, liver, and placenta, but when a rise in AP levels is accompanied by a rise in gamma-glutamyl transferase (GGT) levels, the hepatic origin of AP is assumed. Elevations in levels of AP and GGT are seen when there is damage to the bile canaliculi, the cells that line the intrahepatic bile ducts. Damage to the bile canaliculi can be caused acutely by bile ducts that have been blocked by an obstructive process, such as an impacted gallstone, or can develop more slowly from a chronic process. Chronic viral hepatitis may produce swelling within the liver that may result in compression of the pericanalicular cells, leading to a marked rise in the so-called cholestatic enzyme levels, with the rise in the levels of hepatocellular enzymes being more moderate. The resulting rise of GGT and AP levels that occurs as the result of a viral process will occur later in the course of the disease, and the elevation is more moderate.

Signs and Symptoms

Hepatitis

- Nonspecific malaise
- Jaundice
- Abdominal pain
- Loss of appetite
- Intermittent nausea and diarrhea
- Scleral icterus
- Hepatomegaly
- Bleeding dyscrasias
- Altered mental status
- Multiple organ failure

Differential Diagnosis

Hepatitis

- $Alpha_1$-antitrypsin deficiency
- Biliary obstruction
- Drug-induced liver disease
- Sclerosing cholangitis
- Wilson disease

Transport Management

Hepatitis

- Provide supportive care.

Hepatitis A

Hepatitis A virus (HAV), previously known as infectious hepatitis, is a positive single-stranded RNA virus of the Picornaviridae family and is usually transmitted via the fecal-oral route. Sexual and parenteral transmission is possible; however, because the period of **viremia** is brief, fecal-oral transmission is more common. Large-scale outbreaks can occur, usually the result of contaminated food or drinking water. The estimated incidence of HAV is 125,000 to 200,000 cases per year in the United States, but only 25,000 cases are reported because most infections are asymptomatic and go unreported. In fact, 40% of persons living in urban settings have serologic evidence of prior HAV infections, but only 5% report memory of the liver infection. HAV causes approximately 100 deaths per year as a result of fulminant hepatitis. The clinical features of HAV include jaundice, fatigue, abdominal pain, loss of appetite, and intermittent nausea and diarrhea. Those at highest risk of infection are household/sexual contacts of infected persons, international travelers, and persons living in American Indian reservations, Alaskan native villages, and other regions with endemic HAV. During localized outbreaks, those at greatest risk include children who attend day care centers or their employees, men who have sex with men, and IV drug abusers. The incubation period ranges from 2 to 6 weeks. The period of greatest infectivity is the last 2 weeks of incubation, just before the onset of clinical symptoms, but the infected individual continues to be infectious by shedding virus in the feces for 2 to 3 weeks after the onset of clinical symptoms. The diagnosis of HAV is made by detection of anti-HAV IgM antibody. Anti-HAV IgG antibody is detected in the blood after exposure and recovery or immunization, which signifies life-long immunity.

HAV infection can be prevented by active immunization with the HAV vaccine or by passive immunization with immune globulin administered before or after a known exposure. The vaccine is highly effective and is recommended for children starting at the age of 1 year and persons at high risk of HAV infection, such as those planning to travel abroad, persons living in HAV-endemic areas, and children and caregivers at day care centers. The prevention of infection can be accomplished by improving sanitation and by employing good personal hygiene and handwashing.

Hepatitis B

Hepatitis B virus (HBV) is a double-stranded DNA virus of the Hepadnaviridae family, and is transmitted through parenteral routes, or nonoral transmission, with an incubation period of 1 to 6 months. Each year in the United States, more than 200,000 people are infected with HBV, and nearly 5,000 people die from HBV infection. Transmission can occur by sharing needles, having sex with an infected person, or accidental medical exposures, such as needlesticks, blood spray, or touching bloody items with unprotected hands. Although blood is the most effective fluid of transmission, the virus lives in all human body fluids and is present in semen, saliva, urine, and breast milk. Therefore, because health care providers come into contact with patients who are infected with HBV, they are considered an at-risk group for viral infection and should receive the HBV vaccine series with immunity confirmed by titer.

The clinical features of HBV are similar to those of HAV, including jaundice, scleral icterus **Figure 19-6**, fatigue, abdominal pain, loss of appetite, and intermittent nausea or vomiting. However, unlike HAV, HBV can induce other disease states in addition to causing acute infections. HBV can cause acute hepatitis, fulminant hepatitis, and chronic hepatitis. Fulminant hepatitis is a severe inflammation of the liver, that is accompanied by rapid destruction of the liver, leading to liver failure. The liver damage is accompanied by encephalopathy within 8 weeks of the onset of the symptoms. Coagulopathy, electrolyte disturbances, and cerebral edema are common and death is likely if the patient does not receive an urgent liver transplant. Chronic HBV can take on several forms. A patient can be chronically infected yet remain symptomless. This state is termed a chronic asymptomatic carrier. The patient never develops immunity to the virus but harbors the virus and is infectious to others without actually suffering liver damage. There

are an estimated 200 million carriers of HBV worldwide. Chronic-persistent hepatitis is infection with HBV that "smolders," (ie, it is a persistent low-grade infection from which the patient eventually recovers). In addition, there is chronic-active hepatitis, which means the patient has an active hepatitis state and continues without recovery and without severe decline in liver function that continues for more than 6 months.

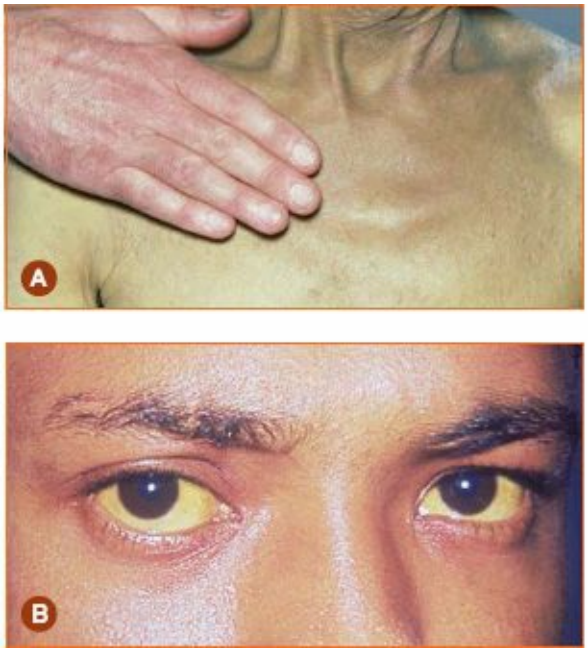

Figure 19-6 **A.** Jaundice. **B.** Scleral icterus.

The key to understanding HBV serology, infectivity, and immunity begins with understanding the viral structure. HBV is an enveloped DNA virus. Immunity to HBV is acquired after exposure to the surface antigen through exposure either to the natural virus or to viral surface components in the vaccine. In either case, immunity is acquired through the development of antibodies to the surface antigen or (anti-HBs). Antibodies to the core proteins, anti-HBc, do not confer immunity because, in order for an individual to ward off the virus, antibodies must attack the intact virion before the virus has a chance to replicate and before the individual is exposed to the core antigen. If the person only has anti-HBc, the immune response will not be mounted until the core protein is unmasked, which is too late to prevent infection. Therefore, antibodies to the core antigen, anti-HBc, are not protective and do not confer immunity, rather their presence in the serum is used as a marker of previous exposure. Only anti-HBs will develop in response to the hepatitis B vaccine. Knowing this helps a provider determine how immunity to HBV was acquired. For example, if the individual has both anti-HBs and anti-HBc, then the individual has been exposed to the wild-type virus (because of the presence of anti-HBc), and is now immune (because of the presence of anti-HBs). The subtype of immunoglobulin yields information about the duration of infection. If the anti-HBc is IgM-type immunoglobulin, then the infection is acute or is from a recent exposure. Anti-HBc IgG means that the exposure occurred more than 3 months prior and the infection is resolving or is chronic.

Those at highest risk for contracting HBV are individuals who participate in high-risk behaviors; live in or travel to disease-endemic areas such as parts of Greenland, northern Canada, southeast Asia, China, and all of Africa; or are exposed to infected body fluids through their lifestyle or occupation. They include IV drug users, sexually active heterosexuals, men who have sex with men, individuals of low socioeconomic status, children of immigrants from disease-endemic areas, infants born to infected mothers, health care workers, and patients receiving hemodialysis.

The treatment and prevention of HBV infection involves screening the blood supply and removing

HBV-contaminated units and donors from the blood pool. The HBV vaccine is recommended for all infants at birth and for children up to the age of 18 years. It is also recommended that adults with a high risk of exposure be vaccinated. All pregnant women should be screened for the disease, and infants born to infected mothers should receive treatment with hepatitis B immune globulin (H-BIG) at birth, in addition to completing the vaccination series during the first 6 months of life. The identification and treatment of individuals with chronic infections and asymptomatic carriers is important for preventing the spread of the disease. The vaccine is given in three separate doses at 0, 1, and 6 months. Passive immunity can be conferred by giving HBV immunoglobulin to persons with known exposures if given within 24 hours of the exposure.

Primary hepatocellular carcinoma is a known complication of chronic HBV infection. The risk of primary hepatocellular carcinoma is 200 times greater for those with chronic HBV infection over those who are not infected. In the United States, 20% of persons with hepatocellular carcinoma are hepatitis B surface antigen positive. Other complications of HBV infection include cirrhosis and fulminant liver failure in less than 1% of cases.

Hepatitis C

Hepatitis C virus (HCV) is an enveloped RNA virus of the Flaviviridae family, which was first known as non-A, non-B hepatitis. HCV causes both acute and nonacute or chronic hepatitis. The virus is transmitted parenterally through transfusion or IV drug use, through sexual contact with infected persons, and from mother to baby; however, the vertical transmission rate of HCV is quite a bit lower than that of HBV. The incubation period of HCV varies from 2 weeks to 6 months. There are 36,000 new cases of HCV infection each year in the United States, of which only 25% to 30% are symptomatic. In cases of acute hepatitis, the symptoms usually consist of nausea, vomiting, and jaundice. In most cases (more than 85% of infections), acute infection leads to chronic infection and spontaneous clearance of the virus is rare once chronic infection is established. Chronic infection typically begins with a long period in which there are no symptoms. The natural history of HCV has been difficult to determine because the disease is so often silent and goes undetected during the early stages, and the interval from infection to the development of cirrhosis can exceed 30 years. Most chronic infections lead to hepatitis and fibrotic liver disease. Cirrhosis develops in 15% to 20% of infected persons, which leads to 10,000 deaths per year. HCV cirrhosis is the leading cause of liver transplantation.

The risk factors most strongly associated with HCV infection include IV drug use and a history of blood transfusion before 1990. Others at risk for HCV infection include patients receiving hemodialysis, health care workers, sexual contacts of infected persons, hemophiliacs, and infants born to infected mothers.

Anti-HCV antibodies develop after exposure to the virus but do not confer immunity. However, their presence in the blood is exploited for serologic assays to screen for contaminated blood products and to identify the carrier of the infection. The antibody is detected through an enzyme-linked immunosorbent assay, a technique that has a sensitivity of 97%, but the positive predictive value in a low-risk population is only 25%. Other techniques, such as a recombinant immunoblot assay, have been developed and are more useful for testing low-risk persons.

There is no cure for HCV and there is no vaccine available to prevent infection. Patients with chronic active HCV infections are candidates for treatment. The goal of treatment is to prevent the development of cirrhosis and liver failure, but success is limited and the side effects of treatment with interferons and antivirals can be difficult to tolerate. Most clinicians agree that treatment should be offered to those patients who have detectable levels of HCV RNA with persistently elevated liver transaminases and who demonstrate evidence of liver damage on biopsy.

Hepatitis D

Hepatitis delta virus (HDV) is another RNA virus that is transmitted parenterally, but it can only replicate with the aid of HBV. HDV is endemic in the Mediterranean region, the Middle East, and parts of South America. Outside of these areas, most HDV infections are a result of transfusion with tainted blood products or IV drug use. The two ways in which a person can be infected with HDV are by coinfection with HBV or superinfection. In coinfection, the two viruses are transmitted together parenterally and cause an acute hepatitis similar to HBV alone. In superinfection, persons with chronic HBV infection are later exposed to HDV and have a superimposition of an acute-on-chronic hepatitis picture. This type of HDV infection is often severe and is associated with a higher incidence of fulminant hepatitis with a greater mortality rate. Therefore, all patients with severe HBV infection should be tested for HDV coinfection or superinfection. There is no treatment for HDV; therefore, the best way to combat the disease is to control or prevent HBV infection.

Hepatitis E

Hepatitis E virus (HEV) is rare in the United States and is limited to travelers to endemic areas of India, Southeast Asia, Africa, and Mexico. The virus is transmitted via the fecal-oral route through the ingestion of contaminated food or water sources. Its transmission and course are most like those of HAV, but HEV is associated with a high fatality rate in pregnant women.

Hepatitis G

Hepatitis G virus (HGV) is another RNA virus of the Flaviviridae family and is transmitted through parenteral routes. It has frequently been detected in patients with chronic liver disease, but a causative link has not yet been established.

Human Immunodeficiency Virus

Human immunodeficiency virus is the virus that causes AIDS and AIDS-related complex (ARC—a syndrome or a group of symptoms associated with AIDS). The first reported case of AIDS occurred in 1981 in Los Angeles. Although the disease was first encountered in homosexual men, it was also seen in IV drug users, transfusion recipients from Haiti, female sexual contacts of infected men, prisoners, and Africans. In the beginning, there were many theories regarding the causative agent of the disease, but the observation that the epidemiology of AIDS was similar to that of hepatitis B infection persuaded researchers to search for a viral component. The cause of AIDS, a novel retrovirus that belongs to the human T-lymphotropic virus group, was isolated in 1983, and was positively linked as the primary cause of AIDS in 1984. At the end of 2004, an estimated 1,147,697 HIV or AIDS cases had been diagnosed and reported to the CDC. The estimated prevalence of HIV in the United States—the total number of people living with HIV infection—is just over 1 million, and as many as 27% of these persons are unaware of their infections. AIDS is the sixth leading cause of death in the United States for those between the ages of 25 and 44 years. AIDS is now pandemic. According to recent estimates, there are 33 million people infected with HIV, with 7,500 new infections occurring daily worldwide.

HIV is a retrovirus that infects T lymphocytes and other cells that display the CD4 surface protein. HIV belongs to a subgroup of retroviruses called the lentiviruses, which cause “slow” infections with long incubation periods. HIV has a bar-shaped core that contains the RNA virus and three essential retroviral enzymes **Figure 19-7**. The core is surrounded by an envelope that contains the virus-specific glycoproteins gp120 and gp41. The viral genome consists of two identical positive single-stranded RNA molecules. HIV has been categorized into subtypes (clades) A through I based on the differences in base-pair sequences that encode the glycoprotein gp120.

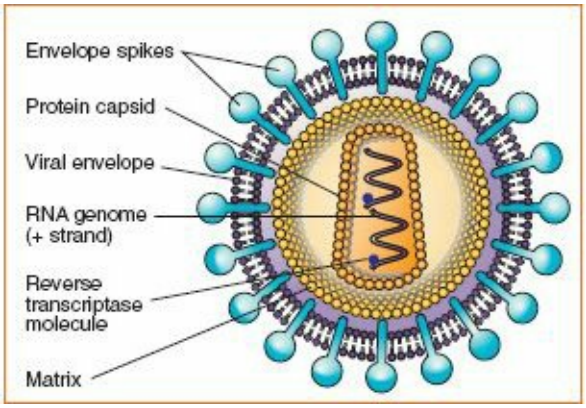

Figure 19-7 The human immunodeficiency virus.

The three essential enzymes enclosed in the retroviral capsid are reverse transcriptase, integrase, and protease. Reverse transcriptase is an RNA-dependent DNA polymerase that gives the retroviruses their name. This enzyme is responsible for converting the RNA viral genome into a DNA provirus. Integrase is the enzyme that catalyzes the integration of the newly transcribed proviral DNA into the host cell genome. Protease is the enzyme that is responsible for producing functional viral proteins. Understanding these specific retroviral enzymes becomes important for understanding how antiretroviral therapy was designed for the treatment of HIV/AIDS.

Transmission of HIV infection occurs by the transfer of infected cells or free virus from one individual to another. The transmission occurs horizontally via sexual contact or by exposure to infected blood, and vertically from mother to neonate across the placenta, during delivery. The infant can also contract HIV from an infected mother through breast milk. The transmission rate of HIV during pregnancy and birth is 25% to 45% and 15% to 25%, with and without breastfeeding, respectively. The transmission rate can be reduced to less than 2% if the mother is treated adequately with zidovudine (AZT) during the pregnancy, the baby is delivered by cesarean section, and the mother does not breastfeed. The HIV transmission rate increases in persons who also have other sexually transmitted infections, especially those that cause disruption of the mucous membrane barrier. The risk of contracting HIV from a blood transfusion has been reduced through aggressive screening of donated blood, and the risk is extremely low but cannot be completely eliminated because there is a small window of time when the virus is not detected in persons with new infections. The CDC, in partnership with 14 countries in Africa and the Caribbean and under the President's Emergency Plan for AIDS Relief (PEPFAR), has worked to reduce the risk of transmitting HIV through blood transfusions. The goal is to deliver an adequate supply of safe blood to these participating countries by collecting blood from low-risk, voluntary, nonremunerated donors and strengthening laboratory and screening capacity.

As a CCTP, exposure to patients with HIV infection is a potential risk for disease contraction. Prevention of exposure (ie, needlesticks) is the most important method of protection for the health care worker. The incidence of needlesticks has been reduced by advances in needleless devices, safety education, and emphasis on proper sharps disposal. Regardless of the stated considerations, needlestick injuries still occur. Fortunately, the risk of becoming infected with HIV after a significant exposure to body fluids from a patient infected with HIV is low. The estimated risk of transmission is 0.33% for hollow-bore needlesticks and 0.09% for mucosal contact; there are no known cases of HIV transmission for intact skin exposures.

HIV infects CD4+ helper T cells and kills them, resulting in the suppression of cell-mediated immunity. There are three stages in HIV infection: acute, latent, and late (or the period of immunodeficiency). The stage of the illness is largely determined by the CD4 cell count and/or symptoms of the disease **Table 19-4.** The initial exposure to the virus starts a sequence of events that goes virtually

unnoticed by the individual, but allows the virus to be permanently established in the individual's immune system. The initial infection begins in the immune cells of the genital tract, and the virus quickly spreads to localized CD4+ helper T cells. However, the virus is not detected in the blood until 4 to 11 days after the initial infection. The acute phase of the disease occurs 2 to 6 weeks after the initial exposure. The patient may present with mononucleosis-like symptoms of fever, lethargy, generalized lymphadenopathy, pharyngitis, and arthralgias. A maculopapular rash on the trunk, arms, and legs, sparing the palms and soles, may also be seen during this time. The acute phase of the disease usually resolves within 2 weeks.

TABLE 19-4 HIV/AIDS Classification of Disease Stage

Stage	Classification	CD4 Cell Count (cells/μL)
1	Asymptomatic	> 500
2	AIDS-related complex	200–499
3	AIDS	< 200

Abbreviations: AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

The disease classification is based on the lowest T-cell count, not the current count. Once a patient has a T-cell count of less than 200 cells/μL, the patient is diagnosed with AIDS regardless of whether the T cell rebounds with therapy. Antibodies to HIV are not detected in the blood until 3 to 4 weeks after the initial infection. Once antibodies are detected in the serum, the patient is said to have seroconverted. The inability to detect antibodies in the blood prior to **seroconversion** results in false-negative serologic test results. This has important implications for the transmission of the virus and for the screening of the blood supply. The person is infected with HIV and is capable of spreading the disease through sexual or blood contacts during this window of time, even though the HIV antibody test result is negative.

After the initial viremia, a viral set point is reached. The viral set point represents the amount of virus present in the blood, is called the viral load, and tends to remain fairly constant for many years. The lower the viral set point at the end of the initial infection, the more likely the patient will remain in the latent stage of the disease. The latent stage of the disease usually lasts for years (the median duration is 10 years), and the patient is generally asymptomatic during this period. While the patient is asymptomatic and the symptoms are latent, the virus is not "latent," but is actively replicating within the lymph nodes of the patient. Toward the end of clinical latency, the patient may begin to experience a syndrome of symptoms called AIDS-related complex. The symptoms of AIDS-related complex include fevers, unexplained weight loss, fatigue, diarrhea, and generalized lymphadenopathy. Often, these symptoms are what persuade the patient to seek help in the health care system. AIDS-related complex may mark the beginning of the final progression toward AIDS.

AIDS is the term that refers to the late stage of HIV infection. The criteria for the diagnosis of AIDS include HIV infection with a CD4+ helper T cell count of less than 200 cells/μL and/or the presence of an AIDS-defining condition. The presence of an AIDS-defining condition supercedes any CD4 cell count **Table 19-5.**

TABLE 19-5 AIDS-Defining Conditions

Candidiasis of the bronchi, trachea, lungs, or esophagus
Cervical cancer, invasive*

~~Coccidioidomycosis, disseminated or extrapulmonary~~ Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (> 1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes simplex: chronic ulcer(s) (>1 month's duration) or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (> 1 month's duration)
Kaposi's sarcoma
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis, any site (pulmonary* or extrapulmonary)
Pneumocystis jiroveci pneumonia
Toxoplasmosis of the brain
Abbreviation: HIV, human immunodeficiency virus syndrome. *Added in the 1993 expansion of the acquired immunodeficiency syndome surveillance case definition. *Source*: Data from Castro KG, Ward JW, Slutsker L, et al. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. Centers for Disease Control and Prevention. *MMWR*. December 18, 1992/41 (RR-17). Available at: http://www.cdc.gov/mmwr/preview/mmwrhtml/00018871.htm. Accessed June 29, 2009.

Patients with HIV often present many years after the initial infection or the acute stage of the disease because in the initial stages, the disease is often mild and the symptoms are nonspecific. For many patients with HIV, the illness is noticed when the patient begins to experience symptoms such as generalized lymphadenopathy, weight loss, fatigue, fevers, or night sweats. As the disease progresses, the patient may experience frequent severe herpes infections of the mouth or anus and/or recurrent or persistent yeast infections. The loss of cell-mediated immunity predisposes the host to many opportunistic infections. Symptoms of opportunistic infections commonly seen in patients with AIDS include cough, dyspnea, headache, altered mental status, memory loss, seizures, ataxia, dysphagia, nausea, vomiting, severe persistent diarrhea, and marked weight loss.

The viral load is estimated by determining how much viral RNA is present in the blood. The viral load indicates the magnitude of HIV replication and its associated rate of CD4 cell destruction. It is the most accurate indicator of the risk for disease progression and is used for planning and monitoring anti-retroviral therapy. The CD4 cell count is used to evaluate the extent of HIV-induced immune damage that has occurred, to provide an estimate of the immunologic status of the patient, and to predict the likelihood of the patient developing opportunistic infections. The initiation of antiretroviral therapy is based on the

viral load, the CD4+ T-cell count, and the patient's clinical conditions.

Three general classes of antiretroviral drugs are currently available for the treatment of HIV infection: nucleoside analog reverse transcriptase inhibitors (NRTIs), protease inhibitors (PIs), and non-nucleoside reverse transcriptase inhibitors (NNRTIs). There is a fourth class of drugs in development called fusion inhibitors for which two drugs are currently available.

NRTIs target the enzyme reverse transcriptase. They act to block the transcription of the viral RNA to the proviral DNA by competing with physiologic nucleosides for the enzyme-binding site. Once they are added to the growing DNA sequence, they block the addition of the next nucleoside and, thus, interrupt the synthesis process causing chain termination. The prototype of the NRTIs is AZT.

NNRTIs are similar to the NRTIs in that they target the same viral enzyme, reverse transcriptases. In contrast to the NRTIs, they are not competitive inhibitors of the enzyme, rather they are noncompetitive inhibitors of the enzyme. They bind to the enzyme near the binding site for the nucleoside substrate and alter the configuration of the enzyme, preventing it from carrying out its catalytic function. Nevirapine is an example of an NNRTI.

PIs target the viral enzyme protease that cuts the viral polyprotein into functional individual proteins. Inhibiting the protease prevents the processing of viral proteins, which then prevents the building of mature virion. Indinavir is an example of a typical PI. Because the step that the PIs inhibit is late in the viral replication process, PIs are most often used in combination with other agents.

There are three crucial steps for the entry of HIV into the CD4+ T cell: the binding of HIV to the CD4 receptor, also called attachment; the binding of HIV to the co-receptor; and the fusion of the virus and the cell membranes. All three steps are the targets of a new class of drugs collectively known as entry inhibitors. Enfuvirtide is the prototype of the fusion inhibitors. It binds to gp41, which is thought to be important in the fusion process. It was approved for use in the United States in 2003. Its role in HIV treatment is limited to those in whom the standard therapies fail. It is prohibitively expensive and is only available for parenteral administration.

The goal of current therapies for HIV infection is to prolong life, while maintaining the best possible quality of life. Achieving this requires that the prevention of opportunistic infections and malignancies, and slowing the rate of virus production, be weighed against the side effects of therapy, and therapy must be delivered to the patient in a manner that promotes compliance. The most difficult question in the treatment of HIV is when to start therapy. The current treatment of choice for advanced disease uses a combination of the described agents, usually consisting of two NRTIs and one PI, known as HAART, or highly active antiretroviral therapy. This treatment is very effective in prolonging life and reducing the viral load, but ensuring patient compliance can be challenging because the regimens are often complicated and the side effects can be debilitating. Viral resistance to the antiretroviral drugs is increased when patients use the drugs intermittently or incorrectly. Indications for treatment are based on clinical assessment of the patient's condition, the CD4 cell count, and viral load. The risk of AIDS must be weighed against the risks of long-term toxicity and resistance. The risks of occupational exposures and postexposure prevention protocols are discussed later in this chapter.

Signs and Symptoms

HIV Infection/AIDS

Early symptoms:

- Generalized lymphadenopathy
- Weight loss

- Fatigue
- Fevers
- Night sweats

Symptoms associated with disease progression:

- Frequent, severe herpes infections of the mouth or anus
- Recurrent or persistent yeast infections

Symptoms associated with opportunistic infections:

- Cough
- Dyspnea
- Headache
- Altered mental status
- Memory loss
- Seizures
- Ataxia
- Dysphagia
- Nausea
- Vomiting
- Severe persistent diarrhea
- Marked weight loss

Differential Diagnosis

HIV Infection/AIDS

- B-cell deficiency
- Brucellosis
- Chronic fatigue syndrome
- Dementia
- Epstein-Barr virus
- Fibromyalgia
- Hodgkin disease
- Hypogammaglobulinemia
- Immunodeficiency syndromes
- Influenza
- Lyme disease
- Multiple sclerosis
- Myositis
- Non-Hodgkin lymphoma
- Pelvic inflammatory disease
- Pyoderma gangrenosum
- Severe combined immunodeficiency (SCID)
- T-cell deficiency
- Thrombocytopenic purpura, autoimmune

Transport Management

HIV Infection/AIDS

- Provide supportive care.

Emerging Infectious Diseases

The eradication of infectious diseases has been one of modern medicine's most important achievements. The influenza pandemic of 1918 and 1919, which caused more than 20 million deaths, was thought to be a phenomenon of historic interest. With the advent of effective vaccinations and antibiotics, the death rate from infectious disease declined dramatically during the 20th century, and this success led to complacency. The death rate from infectious disease increased by 58% between 1980 and 1992. Infectious diseases are still the leading cause of death worldwide. Hantavirus, West Nile virus, SARS, and avian influenza have emerged as new threats on the medical landscape. The emergence and re-emergence of drug-resistant infectious agents, such as methicillin-resistant *S aureus*, vancomycin-resistant enterococci, and MDR-TB, have increased dramatically in the last 2 decades.

The term "emerging infectious disease" refers to diseases caused by infectious agents that have increased in incidence within the past 20 years or those that threaten to increase in the near future. The CDC has identified several major factors that contribute to the development or re-emergence of infectious disease. The CDC points to the changes in human behaviors, the changes in economic and technologic advances, and the adaptive changes of the infectious agents. The mobility of modern society has facilitated the movement of people, animals, and foodstuffs across countries and continents. The triangle of transmission between microbe, vector, and host enlarges when access to naïve populations who lack immunity is provided. Selective pressures from overuse of antibiotics (as described earlier when selection was discussed) have precipitated the development of resistant microbes, and abuse of antimicrobials has enhanced the re-emergence of more deadly infections.

Additionally, infectious agents are now thought to be important in the etiology of many diseases previously thought of as noninfectious. *Helicobacter pylori* has long been found in association with peptic ulcer disease, but it is now known to have a causative association. Human papillomavirus is the major cause of cervical cancer (a vaccine that is now available). Hepatitis C virus is a leading cause of chronic liver disease and cirrhosis in the United States and is a major risk factor for the development of hepatocellular carcinoma.

Emerging infectious diseases are particularly damaging to immunocompromised individuals, such as those with HIV disease, those receiving immunosuppressive therapy such as recipients of organ transplants, or those who are immunosuppressed as a result of their treatment for cancer. Public water supplies that are contaminated by emerging infectious agents put entire communities at risk. In 1993, *Cryptosporidium* contaminated a municipal water supply in Wisconsin and caused 4,400 people to be hospitalized from the infection. Large segments of populations may also be exposed to emerging infections through contaminated food sources. *Escherichia coli* O157:H7 was found to have contaminated beef cooked in fast food restaurants, causing a multistate outbreak of hemorrhagic colitis and serious kidney disease and resulting in the deaths of at least four children.

To effectively detect and prevent the threat of emerging infections, the public health sector, health care providers, and emergency medical services must cooperate in an effort to control any potential outbreaks and prevent the spread of potentially deadly diseases.

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is an emerging lower respiratory tract illness caused by a corona virus. SARS appeared as a highly contagious, deadly virus early in 2003 in the Guangdong Province of China. The virus quickly disseminated via person-to-person droplet transmission to persons in Hong Kong and Vietnam and subsequently to Singapore and Canada. Those at highest risk in the early spread of the disease were health care workers. Ultimately, the epidemic spread to 29 countries, resulting in more than 8,000 infected persons and 780 deaths. The cooperative efforts of scientists and physicians in the WHO and CDC as well as China, Canada, Hong Kong, and other countries proved effective for quick identification of the etiologic agent and isolation and prevention of the spread of the disease. Because of the high morbidity and mortality associated with SARS, the CDC has included it on its list of notifiable diseases to ensure careful monitoring of the US population for further outbreaks.

The virus has an incubation time of 4 to 6 days, and most patients show symptoms within 2 to 10 days after exposure. Early symptoms of fever, headache, and muscle aches are nonspecific and may be mistaken for other viral illnesses. The presenting symptoms are followed within 2 to 7 days by a dry cough and pneumonia. The overall mortality rate (10%) is dramatically higher in the elderly, causing death in 50% of those older than 60 years.

Constant surveillance and early detection of SARS are necessary to prevent future epidemics. One lesson learned in the 2003 outbreak was that international air travel was a key factor in the rapid and global spread of this disease. The WHO quickly recommended screening of international passengers from affected areas and disinfection of aircraft suspected of carrying infected persons. Additionally, the lack of respiratory isolation and respiratory precautions for patients hospitalized early in the disease outbreak permitted nosocomial transmission of the virus, in particular to health care workers. Thus, when transporting persons with a cough, fever, headache, and myalgias of unknown etiology, it is important to place a mask on the patient, keep the patient in respiratory isolation, and sterilize all equipment following transport **Table 19-6. Table 19-7** lists recommended personal protective equipment (PPE), organized by infectious disease.

Signs and Symptoms

Severe Acute Respiratory Syndrome

- Fever
- Headache
- Muscle aches
- Later symptoms: dry cough and pneumonia

Differential Diagnosis

Severe Acute Respiratory Syndrome

- Bacterial septicemia
- *C pneumoniae* infection
- Influenza
- Legionellosis
- Leptospirosis
- *M pneumoniae* infection

- Hantavirus infections (Old World)
- Q fever
- Typhoid and enteric fever

Transport Management

Severe Acute Respiratory Syndrome

- Place a mask on the patient.
- Manage the airway.
- Keep the patient in respiratory isolation.
- Monitor the mechanical ventilator, if applicable.
- Continue IV administration of antivirals or corticosteroids if they have been started by the sending facility.
- Perform high-level disinfection of all equipment after transport.

Escherichia coli O157:H7

Escherichia coli are microorganisms found in the intestinal tract of humans and other mammals. There are hundreds of different strains of *E coli*, most of which are harmless, and a few strains that are pathogenic. The pathogenic strains may have specialized fimbriae (ie, finger-like border), allowing them to adhere to certain intestinal epithelial cells and produce toxins that cause gastrointestinal problems. There are several specific pathogenic groups of *E coli*, including enterotoxigenic, enteroinvasive, enteroaggregative, enteropathogenic, and enterohemorrhagic. *Escherichia coli* O157:H7, which causes hemorrhagic colitis, is emerging as a particularly virulent strain.

Escherichia coli O157:H7 is found in the intestinal tracts of ruminant animals, especially cattle. Individuals have become infected after eating undercooked, contaminated ground beef; drinking unpasteurized milk and fruit drinks; eating unwashed lettuce or sprouts; eating salami; and swimming in or drinking sewage-contaminated water. Transmission can also occur via person-to-person contact, usually from infected persons who have poor hygiene or handwashing technique. It takes fewer than 10 *E coli* bacteria to cause the onset of symptoms.

The Shiga-like toxins produced by these microorganisms are responsible for causing hemorrhagic colitis, an inflammation of the colon with bleeding and abdominal cramps. Most episodes are self-limiting and last only 5 to 10 days. A small number of infected people, usually those younger than 5 years or older than 65 years, experience hemolytic uremic syndrome. This syndrome is manifested when the toxin affects the kidneys, leading to kidney failure and end-stage renal disease that necessitates dialysis or transplant to sustain life.

TABLE 19-6 Recommendations for the Application of Standard Precautions for the Care of All Patients in All Health Care Settings

Component	Recommendations
Hand hygiene	After touching blood, body fluids, secretions, excretions, and contaminated items; immediately after removing gloves; and between patient contacts

Personal protective equipment	Gloves, mask, and gown
Gloves	For touching blood, body fluids, secretions, excretions, and contaminated items; for touching mucous membranes and nonintact skin
Mask, eye protection, and face shield	During procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, and secretions; N95 mask to prevent respiratory transmission
Gown	During procedures and patient care activities when contact of clothing/exposed skin with blood/body fluids, secretions, and excretions is anticipated
Soiled patient care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; and perform hand hygiene
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient care areas
Textiles (linen and laundry)	Handle in a manner that prevents transfer of microorganisms to others and to the environment
Needles and other sharps	Do not recap, bend, break, or hand-manipulate used needles; use safety features when available; and place used sharps in a puncture-resistant container
Patient resuscitation	Use mouthpiece, resuscitation bag, and other ventilation devices to prevent mouth contact
Patient placement	Prioritize for the single patient room if the patient is at increased risk of transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk of acquiring infection or developing an adverse outcome following infection
Respiratory hygiene/cough etiquette (source containment of infectious respiratory secretions in symptomatic patients, beginning at the initial point of the encounter)	Instruct symptomatic persons to cover their mouth/nose when sneezing/coughing; use tissues and dispose in a no-touch receptacle; observe hand hygiene after soiling of hands with respiratory secretions; and place a surgical mask on the patient if tolerated, wear an N95 mask, or maintain spatial separation, greater than 3′ if possible

Severe acute respiratory syndrome: Public health guidance for community-level preparedness and response to severe acute respiratory syndrome (SARS)–version 2, January 8, 2004. Available at: http://www.cdc.gov/ncidod/sars/guidance/I/index.htm. Accessed April 29, 2004.

The diagnosis of *E coli* infection consists of performing stool cultures using a specialized growing medium such as sorbitol-MacConkey agar plates. Treatment is difficult because of emerging antibiotic

resistance. Thoroughly cooking beef, avoiding unpasteurized drinks, and washing hands after handling raw meat can prevent infection with *E coli* O157:H7.

West Nile Virus

West Nile virus (WNV) is an arthropod-borne virus that was first isolated in Uganda's West Nile district in 1937. It was never isolated in the United States until 1999, when the first cases of West Nile virus–associated encephalitis were reported in New York City. Evidence suggests that international travel and commerce have played a significant role in its introduction into the Western hemisphere. In Africa and Asia, disease outbreaks caused by WNV were infrequent and were not associated with serious morbidity or mortality. Since its introduction in the United States, the frequency and apparent severity of WNV cases have increased. The WNV epidemic of 2002, the largest meningoencephalitis epidemic recorded to date, resulted in more than 4,000 cases and 200 deaths. In 2008, there were more than 1,300 documented cases and 44 deaths in the United States.

WNV is a single-stranded RNA *Flavivirus* of the Flavi-viridae family. Virion binding to host cells is mediated by an E-glycoprotein. The E-glycoprotein is a viral hemagglutinin that is highly immunogenic and elicits production of virus-neutralizing antibodies in the immunocompetent host. WNV is a member of the Japanese encephalitis virus serocomplex that contains other medically important viruses, such as the St. Louis encephalitis virus. The close antigenic profiles of the flaviviruses, especially those of the Japanese encephalitis group, cause serologic cross-reactions in the diagnostic laboratory.

WNV is a mosquito-borne pathogen. Adult mosquitoes emerge in the spring. Viral amplification occurs in mosquito-bird-mosquito cycling until early fall when female mosquitoes begin diapause and infrequently bite humans to gain protein for egg development from a blood meal **Figure 19-8**. The virus is found in the salivary glands of the mosquito and is transferred during the bite. Mosquitoes are the bridge vectors that maintain the cycle of infection by feeding off both humans and birds.

TABLE 19-7 Personal Protective Equipment Recommended (by Infectious Disease)

	Standard Precautions				
	Airborne		Droplet	Contact	Eye Protection
Disease	Negative Pressure Transport	N95 Mask	Surgical Mask	Gloves and Gown	Goggles or Face Mask/Shield
Respiratory infections					
Respiratory syncytial virus			Required	Required	Recommended
Influenza			Required	Required	Recommended
Novel respiratory infection (such as SARS or avian flu)	Required	Required	Required if N95 is not available	Required	Required
Pulmonary TB	Recommended	Recommended	Required if N95 is not available	Required	
Meningitis					
			Surgical mask	Required	
Hepatitis					
				Required	Recommended
MDR diseases					
MRSA or VRSA			Recommended	Required	Recommended
VRE			Recommended	Required	Recommended
MDR TB	Recommended	Recommended	Required if N95 is not available	Required	Recommended
Clostridium difficile					
				Required	
Human immunodeficiency virus					
		Required	Required if N95 is not available	Required	Required
Necrotizing fasciitis					
			Required	Required	
Hemorrhagic fevers of unknown etiology					
	Recommended	Recommended	Required if N95 is not available	Required	Required
Any contact with blood, body fluids, or feces, especially if aerosolized					
			Required	Required	Required

Abbreviations: MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus;* SARS, severe acute respiratory syndrome; TB, tuberculosis; VRE, vancomycin-resistant enterococci; and VRSA, vancomycin-resistant S *aureus*.

In temperate climates, human disease outbreaks peak in late summer and continue into fall; however, year-round transmission is possible in the more southern states. WNV is endemic in all of the continental United States and in the District of Columbia (as well as Canada and Mexico). The mosquito responsible for transmission to humans is primarily the *Culex* species; however, other types of mosquito can carry the disease.

The incubation period of WNV ranges from 3 to 14 days. Most infections are subclinical and patients remain asymptomatic. A febrile viral syndrome develops in approximately 20% of infected persons; only 50% of those infected will seek medical attention. The signs and symptoms of WNV infection are variable, but they frequently include sudden onset of fever with malaise, anorexia, nausea, vomiting, eye

pain, headache, and myalgia, which last 3 to 6 days. Symptoms may also include rash, lymphadenopathy, fatigue, and arthralgias. Approximately 1 in 100 infections result in meningitis or encephalitis. Advanced age is the most significant risk factor associated with severe neurologic sequelae following infection. There is no cure for WNV encephalitis. Infections are treated symptomatically, and supportive therapy is important in the more severe illnesses.

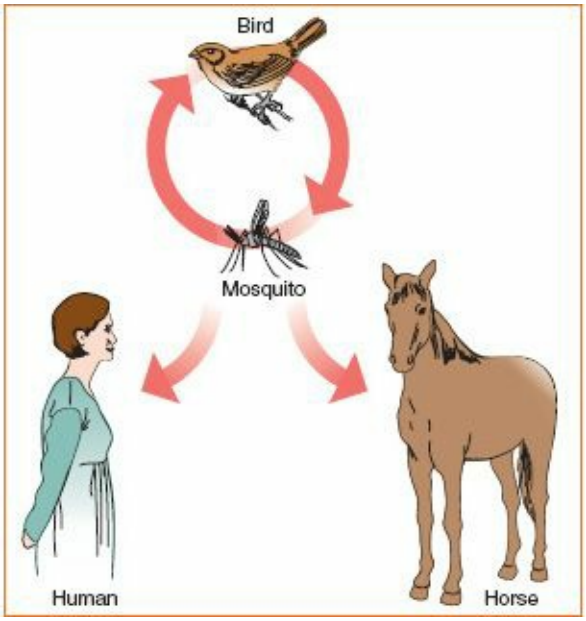

Figure 19-8 Transmission cycle of the West Nile virus.

A high index of clinical suspicion is required for prompt diagnosis. Arboviral disease should be included in the differential diagnosis in any older adults who present with the sudden onset of unexplained encephalitis or meningismus in the late summer or early fall. The presence of local WNV enzootic activity or other human cases should amplify the level of suspicion. Because WNV infections have occurred in all ages and because year-round transmission is possible in southern states, any person presenting with unexplained encephalitis or meningismus should trigger suspicion of WNV infection.

WNV is most efficiently diagnosed by detection of IgM antibody to WNV in the CSF via antibody-capture enzyme-linked immunosorbent assay. WNV-positive IgM antibody present in the CSF strongly suggests WNV infection of the central nervous system because IgM antibody does not cross the blood-brain barrier. The CSF may reveal normal to elevated leukocyte levels, with lymphocytes predominating, an elevated protein level, and normal glucose levels. Serum samples also have a high rate of positive results for WNV IgM antibody.

WNV encephalitis has been added to the nationally notifiable arboviral encephalitides. The timely identification of acute WNV has substantial public health implications, and case reports will likely prompt augmentation of the public health response to reduce the risk of additional human infections.

Integrated vector management programs are the best method for control and prevention of human infection. Mosquito control measures should emphasize the elimination of standing water because mosquito development consists of three aquatic stages: egg, larva, and pupa. Therefore, elimination of their environmental niche is an effective way to reduce the mosquito population without the use of insecticides.

CCTPs working in the outdoors should be instructed to apply an insect repellent while engaging in prolonged extraction or search-and-rescue activities. The CDC recommends repellents that contain the active ingredient *N*,*N*-diethyl-m-toluamide (DEET). Increasing the concentration of DEET in the repellent does not increase the strength, but it does increase the duration of effect. DEET concentrations of 50% or more do not increase the duration of protection significantly and, therefore, little benefit is gained by

using them. DEET does not kill mosquitoes; rather it prevents them from detecting human skin odors and, thus, finding a blood meal. Peak mosquito biting times are dawn, dusk, and early evening. Long pants and long-sleeve clothing provide an added measure of protection.

Signs and Symptoms

West Nile Virus Infection

- Sudden-onset fever
- Malaise
- Anorexia
- Nausea
- Vomiting
- Eye pain
- Headache
- Myalgia
- Rash
- Lymphadenopathy
- Fatigue
- Arthralgias

Differential Diagnosis

West Nile Virus Infection

- *Borrelia burgdorferi* infection
- Brain abscess
- Brain tumor
- Dengue fever
- Guillain-Barré syndrome
- Leptospirosis
- Meningitis
- Paraspinal epidural abscess
- Stroke
- Tick paralysis
- Eastern equine encephalitis
- Other infectious encephalitis

Transport Management

West Nile Virus Infection

- Provide supportive care.

Helicobacter Pylori

Helicobacter pylori bacteria, also discussed in Chapter 16, are spiral-shaped bacteria that infect the stomach and duodenum and are the causative agents of 80% to 90% of peptic ulcers. *Helicobacter pylori* are capable of evading the immune response (largely the result of a protective mucous covering), resulting in the bacteria being able to continue colonization and transmission. Once ingested, the bacteria embed within the mucosa of the stomach to protect themselves from the acidic environment of the gastrointestinal tract. Additionally, these bacteria secrete the enzyme urease (which converts urea and acid into the strong bases ammonia and bicarbonate), thus creating a localized environment favorable for survival and growth. Furthermore, the spiral shape and corkscrew movements of the bacteria enable them to penetrate the stomach's protective lining, resulting in irritation of the lining by stomach acid. The end result is an ulcer that forms at the site of continued irritation. In adults, this is usually a chronic condition that will not heal without specific therapy.

Helicobacter pylori bacteria are acquired via oral ingestion and are transmitted mainly within families during early childhood. Transmission is predominantly direct from person to person via vomitus, saliva, or feces. However, other modes of transmission, such as food, water, nonhuman primates, and other animals, may be responsible for transmission in developing countries. Improved sanitation conditions play an important role in reducing transmission of the bacteria.

Patients infected with *H pylori* may be asymptomatic or may exhibit signs and symptoms of a mild to severe gastritis. The predominant symptom is abdominal discomfort and is described as a dull, gnawing ache. This pain may come and go for several days to several weeks. The pain commonly occurs 2 to 3 hours after eating or in the middle of the night when the stomach is empty and is usually relieved by eating. Other signs and symptoms include weight loss, poor appetite, bloating, burping, nausea, and vomiting.

The diagnosis of *H pylori* infection may include serologic blood tests, a urea breath test, stool antigen assays, and tissue samples obtained through endoscopic biopsy. Testing is important to differentiate whether the ulcer was caused by *H pylori* or by the use of nonsteroidal anti-inflammatory drugs, because the treatments vary based on cause.

The goal of *H pylori* treatment is the complete elimination of the organism from the body. Once this is accomplished, reinfection rates are low. Treatment of *H pylori* requires triple therapy and consists of one antisecretory agent and two antimicrobial agents.

Signs and Symptoms

***H pylori* Infection**

- Abdominal discomfort described as a dull, gnawing ache
- Abdominal pain that occurs 2 to 3 hours after eating or in the middle of the night when the stomach is empty; it is usually relieved by eating
- Weight loss
- Poor appetite
- Bloating
- Burping
- Nausea and vomiting

Differential Diagnosis

H pylori Infection

- Cholecystitis
- Chronic active gastritis
- Drug-induced dyspepsia
- Esophagitis
- Gastroesophageal reflux disease (GERD)
- Ischemic heart disease
- Pancreatitis
- Peptic ulcer disease

Transport Management

H pylori Infection

- Provide supportive care.
- Continue IV administration of any medications started by the sending facility.

Strategies for the Treatment of Infectious Disease

As discussed earlier in this chapter, microorganisms possess unique properties that allow them to invade their human hosts, evade immune detection, and set up infection. These properties are exploited when developing an agent to inhibit their growth or eliminate them from the body. The goal of any such therapy is to eradicate the pathogen without causing undue harm to the host. The following section explores how antibiotics, antivirals, and antifungal agents are designed to target the unique organelles of each class of organism.

Antibiotics

Antibiotics are compounds that are produced by bacteria or fungi that inhibit the growth of or kill other bacterial organisms. Compounds that inhibit bacterial growth are called **bacteriostatic**, and compounds that kill bacteria are termed **bacteriocidal**. Synthetic antimicrobials are designed using the "magic bullet" concept, exploiting the differences between human and microbial cells. The beta-lactam antibiotics include penicillin, ampicillin, amoxicillin, and carbenicillin, among others. These bacteriocidal drugs act on gram-positive bacteria by competitively inhibiting the enzyme, transpeptidase, which catalyzes peptidoglycan cell wall synthesis.

Different families of bacterial cells have unique components that are targeted by different classes of antibacterial drugs. All antibacterial agents follow the same basic principle of targeting bacterial proteins, processes, or cellular components that are not found in human cells. Even though human cellular components are not the targets of antimicrobial therapies, there are adverse effects that must be considered when choosing the appropriate therapy.

The most accurate method for determining sensitivity and resistance of a specific bacterial strain is to perform an antimicrobial susceptibility test. A bacterial isolate is applied to the surface of an agar plate. Then, small disks impregnated with various antibiotics are placed on top of the agar and the plate is incubated for 24 hours. If there is a zone of clearing around the disk, the bacteria is said to be sensitive to the agent. If the growth of the bacteria is unaffected by the disk, the bacteria is said to be resistant to that agent.

Antivirals

Currently, viruses cause 60% of all infectious illnesses, with approximately 90% of the US population experiencing a viral infection during any given year. In light of these numbers, relatively few treatment modalities have been developed to care for patients with a viral illness. The difficulty lies in isolating the steps of the virus replication because they are intimately involved with the normal synthetic processes of the human host cell. The medications that are effective rely on the ability to interrupt the viral replication cycle at a specific step. Virus replication takes place during an incubation period, when the patient is asymptomatic and, thus, not likely to be taking any antiviral medication. The virus can also become latent within the body, rendering it almost impossible to eradicate.

There are three classes of antiviral medications: nucleoside analog, enzyme inhibitors, and interferon. Nucleoside analogs such as acyclovir and AZT are used to treat herpesviruses and HIV infection, respectively. Enzyme inhibitors are used to treat influenza and consist of drugs such as indinavir and zanamivir. Alpha-interferon is used to treat viral hepatitis. Because of the limited number of medications available to treat active viral infections, prevention of viral infections in health care workers is best achieved through available vaccination. Meanwhile, biochemists are working continuously to create novel medications to treat both viral and bacterial infections.

Antifungals

Human and fungal cells are similar in that both are eukaryotic. Because they are similar in makeup, finding agents that affect the fungal cell without harming the human cell is challenging and antifungal agents can produce toxic results when used systemically. A primary difference between human and fungal cells is their membrane components. The fungal cell membrane contains ergosterols, whereas the human cell membrane contains cholesterol. This structure is different enough for it to be a target of antifungal therapy. Polyene compounds bind with the sterol in the fungal cell membrane, making the membrane less fluid and more susceptible to rupture. As a result of the change in fluidity, the cell membrane leaks, loses its integrity, and leads to cell death. There are other antifungal therapies available, but all are a variation on this theme. They target pathways or enzymes that are specific to fungal cells.

The Post-Antibiotic Era

Before the advent of antibiotic agents, bacterial infections were the cause of significant morbidity and mortality. In 1900, the three leading causes of death in the United States were by infectious diseases. In 2006, the leading causes of death were the result of noninfectious diseases: heart disease, cancer, and stroke. Today, the only infectious diseases ranked in the top 10 leading causes of death are lower respiratory tract infections and sepsis. However, many scientists worry that we are entering the "Post-Antibiotic Age" because of the emergence of antibiotic-resistant bacteria. Virtually all important pathogenic bacteria have demonstrated resistance to current Food and Drug Administration–approved antibiotics. Antibiotic resistance is predicted to be one of the world's most pressing public health problems in the 21st century.

Three important factors contribute to the emergence of resistant bacteria within a given population or community:

- Misuse of antibiotics
- Poor infection control
- Importation or intrusion of already resistant strains

The continual use of antibiotics paradoxically leads to declining effectiveness through selective pressures and the development of resistance because increasing resistance causes a concomitant decrease in the therapeutic options for eliminating infections. In the critical care environment, there are many opportunities for contamination and subsequent cross-transmission of resistant bacteria. Infection control measures, such as handwashing, patient isolation, and proper disposal of contaminates, are important in breaking the cycle of transmission. As a CCTP, it is important to always be aware of how your actions can either hinder or hasten the spread of disease.

Antibiotic resistance occurs when the bacteria acquire new properties through mutation, protein alteration, or conjugative transfer of plasmid-encoded resistance factors. Resistant organisms coexist with healthy skin or gastrointestinal flora. When antibiotics are used to treat infection or used inappropriately for viral infections, the normal, protective flora is eliminated and the resistant strains dominate. This relative decrease in the sensitive strains and increase in the resistant strains leads to selective pressure on the weaker protective bacteria. The bacteria that are not eliminated are stronger (ie, more resistant to antibiotics), making it more difficult to cure the patient, and these resistant strains move on to cause infection in the next host. When this theme is applied on a grander scale to the critical care setting where the use of antibiotics is routine and infectious sources are plentiful, the magnitude of the problem becomes apparent.

Infection control is critically important in thwarting the development of new resistant strains and preventing the spread of currently resistant strains. Health care workers are a major source of cross-

infection between critically ill patients. Handwashing is the single most important act that a health care provider can perform to reduce the spread of infection. However, even under the best circumstances, compliance with handwashing is low. It is even more difficult to accomplish in the critical care transport environment, but it is the choice of the CCTP to either practice proper hand sanitation methods when providing care or allow the hands to be vectors for transmission of infectious disease. Another important method for reducing the spread of resistant bacteria is the isolation of infected patients. Methods of isolation include geographic isolation, negative-pressure isolation, contact precautions, and barrier isolation, discussed later in this chapter.

Antibiotics should be prescribed only when they are likely to be beneficial. The choice of antibiotic should be appropriate—using a drug that will eliminate the pathogen most likely to be causing the infection or, better yet, using definitive culture and sensitivity testing to identify the infecting bacterial strain and then combating it with the correct drug. The prescription should be for the appropriate dose and duration of treatment. Using a drug for longer than is required to eliminate the offending bacteria does not offer any additional benefit to the patient.

Each year in the United States, 160 million prescriptions are dispensed for antibiotics, half of which are likely prescribed unnecessarily for viral upper respiratory tract infections. The public must be made aware of the role they play in promoting the emergence of resistant strains and, thus, must be educated to reduce demands for inappropriate prescriptions. Although completely ineffective against viral infections, tens of millions of antibiotics are prescribed for viral illnesses. Time pressure on physicians and patients alike, diagnostic uncertainty, and demand from uninformed patients contribute to the continued inappropriate use of antibiotics. To ensure that patients return to their practice, physicians are under pressure to prescribe, but prescribing for the sole purpose of convenience and patient demand is never appropriate. Patients must be instructed to take antibiotics as directed and for the full duration of the intended treatment. Once symptoms of the illness are relieved, patients are likely to stop taking the drug, but the infection may not be cured. Infections that are treated incompletely kill the weaker strains, leaving the stronger or antibiotic-resistant strains unaffected, which then contributes to the emergence of resistance by selection. Patients should be warned against the dangers of using "leftover" antibiotics prescribed from prior infections to treat their current ailments. First, the symptoms may not be caused by a bacterial infection, and if there is an actual bacterial infection, the drug may be completely ineffective against this causative bacterial strain and may cause the patient to become sicker. Also, partially treating bacterial infections with antibiotics may make it more difficult to isolate, identify, and perform sensitivity testing on the culprit microbe, making treatment decisions all the more difficult for the health care provider.

Antibiotic resistance can cause significant morbidity and mortality in persons infected with previously easily treatable infections. Staphylococci are one of the most common causes of community- and hospital-acquired infections. *Staphylococcus* commonly colonizes on the skin and the nares of healthy people. If *Staphylococcus* causes a simple infection, most people can be successfully treated with beta-lactam antibiotics. However, *Staphylococcus* also causes serious infections, such as postoperative infections or pneumonia; during the past 50 years, treatment of these infections has become increasingly difficult because of the emergence of resistance.

Methicillin-Resistant *S aureus*

Methicillin-resistant *S aureus* (MRSA) is a gram-positive, coagulase-positive, nonmotile coccus that produces an altered penicillin-binding protein that confers resistance to beta-lactam antibiotics, including methicillin. Most strains of MRSA are also resistant to multiple classes of antibiotics, making the infection difficult to control. MRSA can colonize a variety of tissues causing infections such as cellulitis,

cutaneous abscesses, wound infections, osteomyelitis, septic arthritis, endocarditis, pneumonia, and septicemia.

MRSA was first detected in Europe and Australia in the 1960s, and it was detected in the United States 10 years later. MRSA has gradually become a major player in resistant nosocomial infections. Humans are the major reservoir of MRSA. Most carriers are colonized in the nares, pharynx, and skin. High rates of MRSA are found among residents of long-term care facilities, but serious infections with MRSA are more prevalent in the acute care setting. Risk factors for colonization include dialysis, diabetes, use of injectable drugs, chronic skin conditions such as decubitus ulcers, and a history of prior antibiotic use. MRSA is also emerging as a community-acquired pathogen, which is MRSA acquired by persons who have not been hospitalized recently nor undergone a recent medical procedure.

Transient contamination of the hands of health care providers results in the transmission of resistant organisms to other patients. MRSA is spread by direct contact with patients who are either colonized or infected with MRSA or by contact with contaminated objects. Patients with known MRSA infections should be placed on contact precautions until they have been successfully treated and the results of their nasal and rectal swabs are negative. As always, CCTPs should avoid direct contact with wounds by wearing gloves for all dressing changes and avoiding direct contact with a patient with a known MRSA infection

Vancomycin is the drug of choice for treating MRSA infection. An alternative to vancomycin for the treatment of MRSA skin infections and nosocomial pneumonia is linezolid. The advantage to using linezolid is that it is available in an oral form, whereas vancomycin is not absorbed in the gastrointestinal tract. Until recently, all strains of MRSA have been sensitive to vancomycin; however, vancomycin-resistant *S aureus* has also emerged and resulted in deaths in the United States.

The emergence of vancomycin-resistant MRSA poses a serious threat to patients and health care workers; if encountered, the patient should be isolated and the infection should be reported to public health authorities. Implement contact precautions, minimize the number of persons with access to the colonized/infected patient, and dedicate one-on-one care for the colonized patient. Avoid transferring infected patients between or within facilities. If a transfer is necessary, fully inform the receiving institution of the patient's status.

Vancomycin-Resistant Enterococci

Enterococcus is a gram-positive bacterium normally found in the intestinal tract (normal flora); however, antibiotic-resistant species of *Enterococcus* have become a major cause of nosocomial infection in the United States. These bacteria rarely cause illness in healthy people but can cause serious infections in immunocompromised, postoperative, and other seriously ill persons. Because enterococcal bacteria colonize the intestinal tract, transmission is largely the result of direct person-to-person contact or indirect contact (eg, door knobs and toilet seats) from inadequate handwashing after evacuation of feces.

Two types of antibiotic resistance are found in enterococci—intrinsic and acquired. Intrinsic resistance is a natural resistance found in the bacteria and is caused by the vanC gene. Acquired resistance is genetically transferred from another resistant organism. The two responsible genes are transmissible to other bacteria by plasmids and transposons, and they confer resistance to much higher levels of vancomycin. Another critical consideration is that the vancomycin-resistant genes present in VRE have the potential to be transmitted to other gram-positive organisms, such as *S aureus*. For these reasons, health care facilities should test all persons at high risk for VRE and, if found positive, patients should be isolated and standard precautions should be used. Patients can carry VRE organisms for long periods of time, particularly in their stool. Therefore, the CDC and the Hospital Infectious Control Practices Advisory Committee recommend that isolation should continue until the patient has three sets of negative cultures from all appropriate sites taken at least 1 week apart.

In the critical care environment, there are many opportunities for contamination and subsequent cross-transmission of resistant bacteria. When transporting VRE-positive patients, infection control measures such as handwashing, patient isolation, use of protective barriers such as gloves and gowns, and the proper disposal of contaminates are important in breaking the cycle of transmission.

Rickettsial Diseases

Rickettsial diseases are transmitted via tick bite and, therefore, patients with these diseases are not considered infectious by human-to-human contact (however, known cases of transmission have occurred via blood transfusion from an infected but asymptomatic donor). There are three major diseases classified as tick-borne rickettsial diseases—Rocky Mountain spotted fever, ehrlichiosis, and anaplasmosis. Of these diseases, the highest mortality rate is seen with Rocky Mountain spotted fever. Early signs and symptoms of these tick-borne diseases are generally mild and nonspecific, making diagnosis problematic; however, Rocky Mountain spotted fever should be considered a possible diagnosis in all patients presenting with fever and having suspected or known tick exposure (outdoor activities during April through September in North America). In particular, children and young adults are at risk because of their increased outdoor activity. Despite its name, Rocky Mountain spotted fever is seen mostly in the southeastern United States (especially North Carolina) followed by two midwestern states (Missouri and Tennesee). **Table 19-8** compares initial signs and symptoms of anaplasmosis, ehrlichiosis, and Rocky Mountain spotted fever.

Rocky Mountain spotted fever begins acutely with fever accompanied by one or more of the following: headache (usually severe), rash, muscle aches, nausea and vomiting, and malaise. Patients may also exhibit neurologic symptoms resembling meningitis. Children may present with abdominal pain, altered mental status, and conjunctival injection (bloodshot eyes). Within a few days after the initial fever, a petechial rash develops on the hands and feet, and may spread to the rest of the body in about half of the adults and most of the children. The skin on the hands and feet of some patients will slough off about a month after a severe petechial rash occurs. Of patients with tick-borne rickettsial diseases, 50% or more require hospitalization, and some patients will experience long-term complications such as renal failure, myocarditis, meningoencephalitis, hypotension, ARDS, thrombocytopenia, and multiple organ failure.

Diagnosis is determined using a serum antibody test or polymerase chain reaction test or by obtaining a biopsy specimen of the rash. If rickettsial disease is suspected, treatment with doxycycline (or a similar antibiotic) should be initiated immediately and not delayed by waiting for results from diagnostic tests.

TABLE 19-8 Initial Signs and Symptoms of Tick-Borne Rickettsial Diseases

Anaplasmosis	Ehrlichiosis		Rocky Mountain Spotted Fever
Anaplasma phagocytophilum (anaplasmosis)	*Ehrlichia chaffeensis* (ehrlichiosis)	*Ehrlichia ewingii* (infection)	*Rickettsia rickettsii*
Fever	Fever	Fever	Fever
Headache	Headache	Headache	Headache
Malaise	Malaise	Malaise	Malaise
Muscle aches	Muscle aches	Muscle aches	Muscle aches
Vomiting		Vomiting	Vomiting
		Nausea	Nausea
			Loss of appetite
Rare rash	Rash in < 30% of adults and approximately 60% of children	Rare rash	Maculopapular rash approximately 2-4 d after onset of fever in 50%-60% of adults (and > 90% of children); might involve the palms and soles

Source: Centers for Disease Control and Prevention. Available at:

http://www.cdc.gov/ticks/symptoms.html. Accessed July 13, 2009.

Prevention of tick-borne diseases includes use of insect repellents containing DEET and wearing light-colored clothing (to make ticks more apparent). If possible, long sleeves and long pants should be worn and pants should be tucked into socks when outside—particularly when walking through grassy areas. The body should be inspected for ticks after being outdoors.

Removal of embedded ticks should be done with tweezers or gloved hands (avoid removal with bare hands). Grasp the tick as close to the skin as possible and lift the tick with enough force to "tent" the skin surface. Hold the tick in this position for a minute or until the tick lets go and either save the tick for analysis (in a plastic bag placed in the freezer) or dispose of the tick by flushing it down a drain. To avoid contamination from body fluids, do not crush or squeeze the tick. After removal, thoroughly wash the area of the tick bite with soap and warm water and apply rubbing alcohol. Wash hands with soap and water.

Bioterrorism

Bioterrorism (biological weapons) is an emerging threat to the health and safety of the community. There are many countries that currently have or are developing offensive biological weapons programs. With the events of September 11, 2001, and the continued threat of terrorism in the United States, there is increasing concern over the possibility of terrorists using biological agents against civilian populations. Therefore, local, state, and federal officials have implemented education and training of first responders in preparation for potential intentional biological disasters **Figure 19-9**.

The goals of a bioterrorism emergency response should be to contain the agent, protect critical personnel, and manage the health consequences of the event. Containment of a contagious disease resulting from deliberate release of an infectious agent requires that it has to be recognized as a non-natural event based on a presentation that differs from the usual background of the endemic infectious diseases that affect a population. The first cases are likely to go unrecognized because most agents likely used present with initial nonspecific symptoms such as fever, malaise, and headache; these types of findings make the biological attack difficult to recognize in the initial stages of infection.

Figure 19-9 Homeland security or other government agency training responders work to prepare for bioterrorism.

The covert release of any agent could take place over a period of days to weeks and it may be even longer before the initial cases of infection are identified, depending on the mode of transmission and incubation period of the agent. As the duration of time between exposure and symptoms increases, so does the likelihood that the agent will be distributed over a wide geographic area and result in an epidemic. It

is also possible that the deliberate release of a biologic agent will be announced as such and, therefore, poses a different set of problems for the emergency response system. In this case, there would likely be large-scale panic with many individuals calling on emergency services without actual need, overwhelming health care systems and preventing the efficient use of medical resources. The challenge would then be to differentiate those actually exposed to the agent from those whose fear of the agent has caused them to seek care. To date, a number of announced events have occurred in the United States since 1998, but these events were later determined to be hoaxes. In any event, the CCTP must be prepared to deal with either scenario. Knowledge of epidemiologic principles is crucial in differentiating between the presentation of a naturally occurring disease and an unusual, non-natural event that should raise concern that a bioterrorist event has been initiated and that local emergency response systems should be activated.

The CCTP must maintain an index of suspicion regarding a potential threat because early symptoms may be nonspecific, but early treatment will be required to prevent severe injury or death. Before approaching a patient, CCTPs must always take steps to protect themselves first, using standard precautions and additional precautions outlined in **Table 19-7.** In addition, immunologic protection is the responsibility of the CCTP. Stay current on required and recommended vaccines, keeping in mind what is appropriate for a particular patient population, and consider the appropriateness of being vaccinated against agents that may be exploited in bioterrorism attacks. For the most updated information, visit the Web site of the Centers for Disease Control and Prevention at http://www.cdc.gov and search for the Infection Control Guidelines.

Exposure and Protection

CCTPs have unique occupational exposures to a variety of biologic, chemical, and physical hazards. CCTPs are in contact with critically injured and very sick patients, often in uncontrolled settings under emergent conditions. Resuscitating the critically ill is associated with being in contact with potentially infected body fluids 31% of the time. CCTPs also provide care to trauma patients with open wounds that may be actively bleeding. Managing trauma patients is associated with exposure to body fluids 80% of the time. In the chaos of providing care for life-threatening diseases in unpredictable or dangerous conditions, well-established exposure prevention procedures are essential for protecting the health of the CCTP.

Figure 19-10 All sharps must be placed into containers that are puncture-resistant, closable, and leakproof, and that contain the biohazard symbol.

The health risks associated with being a CCTP are not simply limited to blood or body fluid exposures; infectious agents pose a significant risk. The greatest risk comes from patients who are actively infectious but are undiagnosed. Activities and tasks during which exposure may take place include the following:

- Patient assessment
- Airway management
- Establishing IV access
- Clean-up of the vehicle and equipment
- Assisting in childbirth
- Contact with blood or body fluids

Prophylactic measures must be taken to prevent infection prior to exposure. There are several effective ways to reduce the risk of contracting an infectious agent or transmitting infections to patients, but disease prevention is best achieved when the CCTP is fully prepared and properly equipped.

The use of protective clothing and PPE reduces exposure risks. Employers are required to provide their employees with the proper protective equipment at no cost to the employee. The proper handling of contaminated medical devices, such as sharps, soiled bandages, linens, and reusable medical equipment, is essential in reducing the risk of indirect transmission of infectious diseases **Figure 19-10**. In addition, the consistent implementation of isolation precautions is required to control the spread of infections to others.

Immunizations

The CDC recommends that all emergency medical care providers be vaccinated against preventable infectious diseases. The immunization recommendations are based on the risk of exposure. All new employees should not begin taking an active role in caring for patients until their immunization status is reviewed and up to date.

The current recommendations for emergency medical care providers include the following:

- Measles
- Mumps
- Rubella
- Varicella (immunization or proof of prior infection)
- Hepatitis B
- Annual influenza
- Pertussis
- Tetanus
- Polio
- Diphtheria
- Pneumococcal vaccine
- Meningococcal vaccine

All employers of health care providers exposed to blood or other infectious materials during the course of performing work-related duties are required to provide the hepatitis B vaccine to their employees at no cost. Ideally, the vaccination should start during the training period, before patient contact is initiated. The vaccine is administered at 0, 1, and 6 months, with 95% of healthy adults developing protective titers on completion of the three scheduled immunizations. If an employee has already received the full series of vaccinations, an antibody titer should be drawn to verify immunity. The duration of protection is unknown, but it lasts at least 7 years in healthy young adults. If there is a medical contraindication to the vaccine, this should be documented and readdressed if the medical condition

changes. Any employee who declines the hepatitis B vaccine must sign a waiver releasing the employer from responsibility for the work-related exposure.

The influenza vaccine is recommended for CCTPs because the influenza virus easily spreads through close contact with infected individuals via small aerosolized particles. Although most healthy adults are able to recover from influenza without significant morbidity, sick and elderly patients do not have the same immunologic reserve. On that basis, the influenza vaccine is recommended for CCTPs to prevent spread of the virus to their patients and thereby prevent significant morbidity and mortality.

Measles, mumps, and rubella—although rare—can cause significant disease in susceptible individuals. The risk of contracting such infections is increased 13 times for the CCTP over that of the general public. Most adults in the United States have been immunized, but immunity should be confirmed via a serologic titer. This is especially important for women of childbearing age to prevent the advent of rubella syndrome in pregnancy.

The varicella vaccine is important for CCTPs for two main reasons. First, varicella is highly contagious, and varicella infection can cause serious complications in normally healthy adults. Second, vaccination of CCTPs is important to prevent the transmission of the disease to their patients. Individuals with a positive history of chickenpox as children are considered immune, but if one's medical history of varicella is in doubt, he or she should undergo immunologic confirmation of serologic status. If the person is seronegative and has no contraindications to the vaccine, the vaccine should be administered.

All CCTPs are encouraged to discuss immunizations with employer health personnel or their own private physicians before vaccinations are given to ensure that there are no contraindications to receiving specific vaccines.

Needlestick Injuries

Needlestick injuries do occur. By law, all needlesticks and other injuries with sharps contaminated by blood must be reported to the employer. Reporting sharps injuries is necessary when the injury occurs in the course of performing work-related duties and when the object causing the injury is contaminated with blood or other potentially infectious materials. It is not necessary to report sharps injuries that occur with clean objects. When reporting the injury, it is important to characterize it by type of injury (ie, splash, spill, stick, or cut) and by the type and amount of contaminating fluid (eg, saliva, semen, ascites, or blood). It is also important to determine the infectious status of the source patient. The Ryan White Act enacted in 1990 mandated that all EMS personnel could request testing of the source patient to determine if they had been exposed to a life-threatening disease and allowed the results to be given to the affected employee. When the act was renewed in 2006, the clauses protecting emergency personnel were removed by Congress, making it much more difficult for the CCTP to gain access to this critical information.

The risk of a CCTP acquiring an infectious disease from a contaminated sharps exposure is proportional to infectivity of the source and type or severity of the exposure. The larger the number of viral particles exposed to, the greater the risk. The estimated risk of HIV transmission is 0.33% for hollow-bore needlesticks and 0.09% for mucosal contact; there are no known cases of HIV transmission for intact skin exposures. The following factors increase the risk of acquiring HIV after a needlestick injury:

- Deep injury
- Needle placed directly in a vessel (artery or vein)
- Visible contamination with source patient's blood
- Terminal illness in the source patient

Universal Precautions

Universal precautions are recommended to prevent transmission of bloodborne pathogens such as HIV and hepatitis B and C. In these cases, all blood and body fluids are considered to be a source of infectious material. These precautions stipulate the use of gloves, gowns, or aprons (or uniforms) and masks or other eye protection to reduce exposure of the skin (especially abraded or broken skin) and mucous membranes. CCTPs should be especially cautious with needles and sharps used on infected patients to prevent parenteral exposure.

The first response to a percutaneous exposure should be to wash the wound thoroughly with soap and water. If water is not available, an alcohol-based hand cleanser is a reasonable alternative. After a significant exposure, the source patient and CCTP both should be tested for baseline testing and the exposed CCTP should receive follow-up testing at 6 and 12 weeks and at 6 months. During the period following exposure, those potentially exposed to an infectious agent such as HIV should refrain from donating blood products, refrain from sexual intercourse, or use condoms to prevent sexual transmission and avoid pregnancy. If breastfeeding, this should be discontinued. All CCTPs who have been exposed to potentially infectious body fluids should seek prompt medical attention. The decision to start postexposure prophylaxis should be discussed with your health care provider, and the risks and benefits of such treatment should be considered. The risk of contracting HIV from exposure to contaminated body fluids is very low, about 3 per 1,000 for needlesticks. The risk of seroconversion is reduced by approximately 80% by starting postexposure prophylaxis in a timely fashion. The side effects, complications, drug interactions, and proper dosing instructions should be discussed prior to initiating treatment.

Isolation Precautions

There are two levels of isolation precautions. The first level of precaution is designed for the care of all patients, regardless of their diagnosis, presumed infections, or immune status. The main goal of the first level is the successful control of nosocomial infection by facilitating the safe and proper handling of blood and other potentially infectious materials. These are the standard precautions, the major features of which are designed to reduce the risk of transmission of bloodborne pathogens from both known and unknown sources of infection. They should be universally applied to all patients. They protect against contact with blood, body fluids, and secretions, regardless of the presence of visible blood, and contact with nonintact skin and mucous membranes.

The second level of isolation precautions is the transmission-based precautions that consist of isolation precautions designed to be employed during the transport of all patients with documented infections or those suspected to be infected with highly transmissible or epidemiological significant infectious agents for which additional precautions above the first tier of standard precautions are warranted. The three means of providing transmission-based precautions are airborne, droplet, and contact precautions. These are to be used over and above the universal precautions and can be used singly or in conjunction, as the circumstances require.

Airborne precautions include use of an N95 mask by CCTPs, a negative pressure room (airborne infection isolation room) or transport vehicle, or the use of the exhaust fan during transport. Airborne precautions are designed to reduce the risk of transmitting infectious agents that are contained in airborne droplet nuclei or dust particles. Examples of agents carried in droplets, equal to or less than 5 μm, are tuberculosis (either pulmonary or laryngeal), measles, chickenpox, viruses that cause hemorrhagic fevers, and smallpox. Microbes found in droplet nuclei can remain viable suspended in the air for long durations, and can be dispersed over a wide area where they may be inhaled by susceptible hosts. Specialized air handling equipment is required to provide airborne precautions.

Droplet precautions include isolation of the patient and use of surgical masks by CCTPs (or keeping at a distance of 3′). Droplet precautions are designed to reduce the risk of transmitting infectious agents that are found in large-particle droplets (> 5 μm). Transmission via large-particle droplets requires close contact between the source of the infection and the susceptible recipient. Droplets are generated from infectious persons during coughing or sneezing, and during invasive procedures such as suctioning of the airway, intubation, or bronchoscopy. Unlike airborne droplet nuclei, large-particle droplets only travel short distances and are airborne only for a short time after being generated. Examples of infectious agents found in large-particle droplets include *S pneumoniae*, *Corynebacterium diphtheriae*, *Bordetella pertussis*, *N meningitidis*, *H influenzae*, the influenza virus, and *Yersinia pestis* (pneumonic plague). Droplet precautions should be implemented when caring for persons suspected or known to be infected with epidemiologically important pathogens known to be transmitted by infectious droplets. Eye protection (goggles, face shields, and safety glasses) is recommended for use while transporting patients known to carry infectious agents that can be spread via mucous membranes of the eye (conjunctiva), including *S aureus*, rhinovirus, adenovirus, herpes simplex virus, and any bloodborne agents such as hepatitis B and C viruses and HIV. These can be spread via respiratory droplets or by touching the patient and then touching the eyes with contaminated hands/fingers. Eye protection prevents introduction of infectious agents into the conjunctiva. (Note: Full-face respirators also provide eye protection.)

Contact precautions for CCTPs include isolation of the patient, use of a gown (or uniform) and gloves, and, if warranted, face protection. Contact precautions are designed to decrease the risk of transmission of infectious agents that can be transmitted by direct or indirect contact. Direct contact transmission is defined as skin-to-skin contact and subsequent transfer of an infectious agent from an infected person to a susceptible host. Contact transmission can occur during any patient care activity that requires physical contact between the CCTP and the infectious patient. Direct contact transmission can also occur between two patients, and between a patient and a family member. Indirect transmission is the transfer of infectious agents from an infected patient through an intermediate, most often inanimate, object touched by or used during the caring of the infected patient. Objects that transmit infectious agents to susceptible hosts are called fomites. Examples of epidemiologically important infectious agents that can be transmitted via contact include MRSA, VRE, *Clostridium difficile*, scabies, smallpox, and viruses that cause hemorrhagic fevers, and *Bacillus anthracis*. Contact precautions must be employed during the transfer of patients known or suspected to be infected with microorganisms that can be transmitted through direct or indirect contact. Equipment used on these patients during the course of a transport must be discarded or disinfected to interrupt the cycle of indirect transmission.

There should be a regimen in place for donning and removing PPE as established by the infection control staff **Figure 19-11**. In general, never touch your eyes, nose, or mouth with contaminated gloves or hands. After handling contaminated equipment, always wash your hands. If handwashing is not possible, use a waterless hand sanitizer and then wash hands as soon as it is practical.

It is likely that during the transport of critically ill patients from the scene to the tertiary facility, the etiology of any infectious disease will not be known. The risk of transmission is greatest before definitive diagnoses are made. Standard precautions should be implemented without fail on all transported patients. The use of transmission-based precautions should be implemented if there are any known risk factors or if suspicious symptoms or syndromes are observed. It is much better to err on the side of prevention, until the definitive diagnosis can be determined, than to try to contain an infectious disease outbreak after the fact. Certain clinical syndromes and conditions are red flags for which the empiric use of the second layer of precautions is warranted. In the case of interfacility transfers, the infectious agent may have already been identified. If so, it is imperative that this information be known and contact precautions implemented accordingly.

Handwashing

Handwashing is the single most important measure employed to reduce the person-to-person transmission of infectious agents **Figure 19-12**. However, washing your hands between patient transports is logistically difficult because sinks are not available on transport units. Therefore, the conscientious CCTP must make a concerted effort to wash between patients and after touching any body fluid. Waterless antiseptic agents can be used as a substitute for washing under certain conditions. The use of alcohol-based waterless handwashing antiseptic has been shown to improve rates of handwashing among health care workers. Therefore, transport units should be equipped with easily accessible dispensers of hand antiseptic to facilitate compliance in handwashing. Alcohol-based hand antiseptics are not effective against all infectious agents. *C difficile*, for example, is not killed by hand sanitizers. Therefore, handwashing with soap and water between transports is of paramount importance.

Personal Protective Equipment

Personal protective equipment is specialized clothing or equipment worn by an individual that provides protection from a potentially hazardous agent. PPE is required to be provided by the employer at no cost to the employee. It should be readily available and used consistently by the CCTP.

Clean, nonsterile, disposable gloves are standard equipment on critical care transport units. They must be donned by all personnel prior to initiating patient care. Gloves are worn by CCTPs for three important reasons. First, gloves provide a protective barrier to prevent gross contamination of the hands when exposed to blood and body fluids, and while working on patients with open injuries or nonintact skin. Second, gloves protect patients from the microbial agents that exist on the hands of CCTPs while performing invasive procedures. Third, gloves decrease the likelihood of transmission of microorganisms between patients or from fomites to patient, but only if the gloves are changed each time a new patient is encountered. Gloves should be removed if torn, punctured, or contaminated with gross blood. They should be promptly discarded after each use and before touching noncontaminated objects or surfaces. Once the gloves are removed, hands should be washed or sanitized with an alcohol-based waterless handwashing antiseptic.

SEQUENCE FOR DONNING PERSONAL PROTECTIVE EQUIPMENT (PPE)

1. GOWN

- Fully cover torso from neck to knees, arms to end of wrists, and wrap around the back
- Fasten in back of neck and waist

2. MASK OR RESPIRATOR

- Secure ties or elastic bands at middle of head and neck
- Fit flexible band to nose bridge
- Fit snug to face and below chin
- Fit-check respirator

3. GOGGLES OR FACE SHIELD

- Place over face and eyes and adjust to fit

4. GLOVES

- Extend to cover wrist of isolation gown

SEQUENCE FOR REMOVING PERSONAL PROTECTIVE EQUIPMENT (PPE)

1. GLOVES

- *Outside of gloves is contaminated!*
- Grasp outside of glove with opposite gloved hand; peel off
- Hold removed glove in gloved hand
- Slide fingers of ungloved hand under remaining glove at wrist
- Peel glove off over first glove
- Discard gloves in waste container

2. GOGGLES OR FACE SHIELD

- *Outside of goggles or face shield is contaminated!*
- To remove, handle by head band or ear pieces
- Place in designated receptacle for reprocessing or in waste container

3. GOWN

- *Gown front and sleeves are contaminated!*
- Unfasten ties
- Pull away from neck and shoulders, touching inside of gown only
- Turn gown inside out
- Fold or roll into a bundle and discard

4. MASK OR RESPIRATOR

- *Front of mask/respirator is contaminated—do not touch!*
- Grasp bottom, then top ties or elastics and remove
- Discard in waste container

Figure 19-11 An example of a regimen for donning and removing personal protective equipment. Courtesy of CDC.

Figure 19-12 Handwashing is critical to preventing the spread of infection.

Figure 19-13 The N95 mask.

Masks, face shields, and eye protection are worn to protect mucous membranes of the eyes, nose, and mouth during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, or excretions. Not all masks offer sufficient protection from airborne infectious agents. The N95 mask must be worn when patients are known (or suspected) to be infected with agents that are transmitted by droplet nuclei. The N95 mask requires proper fitting, so the CCTP should be fit tested before the need arises **Figure 19-13**.

Gowns are used to protect the skin and prevent the soiling of clothing during procedures that are likely to generate splashes of blood or body fluids. However, they may not be appropriate garb for the CCTP because they may increase the risk of injury to the provider if trying to don the gown while in a moving vehicle. Also, if working in a small space, the gown may catch on equipment. If clothing or the gown becomes soiled, it should be removed as quickly as possible and disposed of properly, and the provider's hands should be washed promptly after removal to avoid the transfer of contaminants to the patient or the environment.

The two types of allergic reactions to latex are type I and type IV hypersensitivity reactions. Type IV is the more common and less debilitating of the two reactions. It is a cellmediated delayed reaction causing redness, chafing, and blisters to develop in areas of contact. Type I hypersensitivity is the more dangerous allergic reaction. It is antibody-mediated, specifically IgE, and causes the immediate and rapid development of symptoms of rhinitis, pruritus, and urticaria. If this reaction is not immediately recognized and treated, anaphylaxis may develop.

The prevalence of type I latex allergy in the general population is estimated as 4% to 8%. The prevalence of type IV latex allergy is not known. The risk factors for latex allergy are a history of atopy, spina bifida, and frequent exposure. Latex allergy can be devastating to CCTPs because it interferes with their ability to work safely among patients, thus these persons should wear nonlatex gloves such as nitrile or vinyl.

Other Exposure Prevention Practices

It is important to notify the accepting institution of the nature of the patient's illness or potential infectious diseases so that the receiving facility can arrange for proper isolation. This should be communicated by the transferring facility, but it is always a good policy to notify the receiving facility. Patients with epidemiologically important infections should be sufficiently isolated from other patients.

Patients themselves should be enlisted in the effort to prevent transmission by educating them on methods to prevent spreading infectious organisms to other vulnerable individuals. They can wear masks while being transported between or within medical facilities. They can cover their mouths while coughing, frequently wash their hands, and refrain from sharing drinking cups or utensils with family and friends.

Work Practice Controls

Control of the work environment and practices, when used consistently, reduces the risk of contamination and subsequent transmission of infectious agents. The prohibition of eating, drinking, smoking, applying cosmetics or lip balm, and handling of contact lenses in the patient work areas helps to reduce the risks of uncontrolled exposures. Actions that cause splattering of fluids should be avoided. All single-use items should be disposed of immediately after they are used. Contaminated gloves must be removed before driving the ambulance and touching the steering wheel.

The proper handling of sharps is another method for controlling exposure risk in the work environment. Do not bend, remove, or recap needles. If there is no choice but to recap a needle (ie, no sharps receptacle is available, which in practice, should never occur), the one-handed "scoop" technique should be used. Shearing or breaking of needles is prohibited. Dispose of sharps in an appropriate container as soon as possible after use. Sharp containers should be easily accessible, puncture-resistant, labeled or color-coded, and leakproof. They should not be filled beyond capacity and should be disposed of as medical waste.

Contaminated work surfaces must be decontaminated with an Environmental Protection Agency–registered disinfectant on completion of the transport. All equipment used during the course of the transport must also be decontaminated. All bins, cans, and reusable receptacles must be decontaminated on a regular schedule and emptied after each use. Contaminated laundry should be placed into leakproof bags, labeled, and stored until proper disposal is possible. Regulated waste must be placed in closeable, leakproof containers designed for disposal. Regulated wastes include semiliquid blood or other potentially infectious materials, contaminated items that would release blood if compressed, and items that are caked with dry blood, contaminated sharps, and biological wastes. If droplet precautions are required, the transport vehicle should be equipped with negative-pressure exhaust in the patient compartment. If this is not possible, the transport vehicle windows should remain open with the ventilation system set on "high" to move the air from within the vehicle to the outside.

Table 19-9 lists resistance of infectious organisms to disinfectants. Low resistance to disinfectant does not mean the organism is not dangerous. It simply means some organisms can be killed easier than other organisms. Assume that *all* patients transported carry infectious pathogens and take the necessary steps to decontaminate the equipment and vehicle prior to the next transport. There are three levels of disinfection:

- **High-level disinfection**, used on inanimate objects to kill all microorganisms. This does *not* kill bacterial spores.
- **Intermediate-level disinfection**, used on inanimate objects to kill *M tuberculosis*, vegetative bacteria, most viruses, and most fungi. This does *not* kill bacterial spores.

- **Low-level disinfection**, used on inanimate objects to kill most bacteria, some viruses, and some fungi. This does *not* kill *M tuberculosis* and does *not* kill bacterial spores.

According to the CDC, handwashing is the *single most important means* of preventing the spread of infection. CCTPs should strictly and properly decontaminate vehicles and equipment, change uniforms (including shoes/boots) or don new protective gowns over their uniforms and shoe covers, and perform handwashing between patient transports. Do not allow time constraints between transports to deter proper disinfection. Improper, cursory, or no **decontamination** of equipment and vehicles allows transfer of organisms to susceptible hosts and spreads disease. Transport equipment, PPE, and personnel can become reservoirs for disease organisms.

TABLE 19-9 Resistance of Infectious Organisms to Disinfectants

Resistance to Disinfection	Class of Organism	Organism Example	Class of Disinfectant	Example of Disinfectant
Most resistance	Spore formers	*Clostridium difficile*	EPA-registered sporicidal	Glutaraldehyde; household chlorine bleach (1:10 dilution)
High resistance	Mycobacteria	TB	EPA-registered tuberculocidal	Combinations of high-percentage hydrogen peroxide (*not* household hydrogen peroxide) and peracetic acid; chlorine dioxide; various phenolics
Medium resistance	Nonenveloped viruses	Norovirus, poliovirus, adenovirus, papilloma viruses	EPA-registered effective agent against norovirus	Household chlorine bleach; Quats; high-percentage hydrogen peroxide (*not* household hydrogen peroxide)
	Cationic detergent (Quats)-resistant bacteria	*Pseudomonas aeruginosa* and *Acinetobacter baumannii*		Household chlorine bleach; high-percentage hydrogen peroxide (*not* household hydrogen peroxide); note: do not use Quats (Pseudomonads are resistant to Quats)
Low resistance*	Fungi	*Trichophyton* and *Aspergillus*	EPA-registered fungicidal	Quats
	Vegetative bacteria	*Staphylococcus aureus* (including MRSA, VRSA, and VRE)	Germicidal, EPA-registered anti-MRSA and anti-VRE	Quats; high-percentage hydrogen peroxide (*not* household hydrogen peroxide); various phenolics
Least resistance*	Enveloped viruses	Influenza, hepatitis B, and HIV	EPA-registered anti-hepatitis B and anti-HIV	Most environmental cleaning agents, including bleach; Quats; phenolics

Abbreviations: EPA, Environmental Protection Agency; HIV, human immunodeficiency virus; MRSA, methicillin-resistant *Staphylococcus aureus;* Quats, quaternary ammonium compounds; TB, tuberculosis; VRE, vancomycin-resistant enterococci; VRSA, vancomycin-resistant *Staphylococcus aureus*.
*Note that low resistance to disinfectant does not mean the organism is not dangerous. It simply means some organisms can be killed easier than other organisms. Assume all patients transported carry infectious pathogens and take necessary steps to decontaminate the equipment and vehicle prior to the next transport.
Data source: Selected EPA-registered disinfectants. US Environmental Protection Agency. January 9, 2009. Available at: http://www.epa.gov/oppad001/chemregindex.htm. Accessed June 29, 2009.

Use barrier protection (eg, plastic wrap) for surfaces of equipment touched frequently with gloved hands or those difficult to clean with disinfectants (such as computer keyboards) or more likely to be contaminated with blood or body fluids. Do not attempt to clean and reuse disposable materials. Place contaminated disposable materials (dressings, gloves, syringes, tubing, gowns, surgical masks, and disposable N95 respirators) into appropriately marked biohazard containers. Always place reusable contaminated PPE (eye protection, uniforms, and shoes/boots) into appropriately marked storage

containers until it can be decontaminated. Do not reuse contaminated PPE until it has been disinfected. All biohazardous waste and uniforms should be handled with gloved hands. Uniforms should first be autoclaved and then laundered after transporting patients with highly virulent and communicable diseases, such as anthrax or avian influenza (H5N1). CCTPs should decontaminate the transport vehicle, shower and scrub with antibacterial soaps, and don street clothes prior to leaving for home after the transport of patients with highly virulent and communicable diseases. It is important to consider treatment of footwear worn during transport or to cover shoes during transport. Shoes should be considered part of the uniform and treated with disinfectant. Uniforms and shoes or boots should not be worn home routinely after patient transport—particularly after transporting patients ill with *C difficile* who had active diarrhea during the transport or patients who were ill with an antibiotic-resistant infection, necrotizing fasciitis, or pulmonary TB.

Postexposure Risks and Protocols

After a blood exposure, the appropriate actions differ depending on the type of exposure. Generally, the appropriate actions taken should be immediately employed: wash the area with soap and water, flush mucous membranes with copious amounts of water, and irrigate eyes with sterile solutions of saline or water. Exposure should be reported immediately to supervisory personnel and those managing blood exposure. Prompt reporting is paramount to ensure that any applicable postexposure treatment begins as soon as possible.

CCTPs who have received the hepatitis B vaccine are protected against contracting HBV from a blood exposure. CCTPs who have not been vaccinated or have not yet achieved full immunity have a 6% to 30% risk of contracting HBV from exposure to HBV-infected blood. The wide range of risk varies depending on the severity of exposure and the hepatitis B antigen status of the source. Blood that is positive for the antigen is more likely to transmit infection. The risk of infection after direct nonintact skin exposure to blood infected with HCV is approximately 1.8%. The average risk of contracting HIV after a needlestick or cut exposure to HIV-infected blood is 0.33% or approximately 1 in 300. The risk decreases for exposures to the eye, nose, or mouth. A small amount of blood splashed on intact skin poses no risk, except if the skin is damaged.

Postexposure prophylaxis is available for the prevention of seroconversion after a known exposure to HBV or HIV. If the exposed worker has not been immunized against hepatitis B, he or she should receive HBIG within 24 hours, followed by the hepatitis B vaccine within 7 days of the exposure. If the CCTP has been vaccinated against hepatitis B, but the anti-HB titer is unknown, an assay for anti-HB antibodies should be drawn to determine the person's immune status, followed by the administration of HBIG and a booster dose of hepatitis B vaccine, if necessary.

If exposed to HCV, there is no prophylactic treatment available to the exposed CCTP. The current recommendations are for the individual to receive interferon, if and when signs of an acute infection develop. Acute infection is diagnosed by increasing liver enzyme levels and detecting viral RNA in the serum.

If the source patient is HIV negative, nothing needs to be done. If the patient's status is unknown, the risks and benefits of postexposure prophylaxis should be discussed with employer health personnel, and the exposed person should be informed of his or her options. The basic regimen is administration of two drugs for 1 month for small exposure risks. Prophylaxis treatment for exposure to a hollow-bore needle contaminated with the blood of a patient known to be HIV positive should consist of three different antiretroviral drugs for 1 month. The exposed individual should be tested immediately following the injury and again at 6, 12, and 24 weeks after exposure. The employee should be aware of and report any febrile illnesses that occur during the 12 weeks following the exposure. The employee should also refrain from blood donation and unprotected sexual encounters during that same postexposure 12-week period,

until the employee's negative HIV status can be confirmed.

Postexposure prophylaxis is the treatment of persons with a known exposure to an infectious agent and is undertaken to prevent contracting the disease. HBIG is effective against HBV infection after an exposure has occurred. However, use of HBIG is not without risk; therefore, the risks and benefits of treatment should be considered. Treatment is appropriate for unvaccinated CCTPs who have been exposed to a source individual known to be positive for the hepatitis B antigen. In order for it to be effective, treatment should begin within 24 hours of exposure. HBV immunity should be confirmed by drawing an HB antibody titer (IgG). Any person whose antibody titer is negative, with a blood exposure regardless of the source person's HBV status, should receive the hepatitis B vaccine. Follow-up after postexposure prophylaxis for HBV is not recommended because the treatment is highly effective. However, any symptoms associated with hepatitis should be reported to the CCTP's health care provider.

There is no effective postexposure prophylaxis for HCV. Immune globulin is not recommended for exposures to HCV-tainted blood. As soon as possible after exposure, baseline laboratory studies should be performed for liver function test results and an HCV antibody titer should be drawn. These tests should be repeated at 4 to 6 months after exposure.

HIV postexposure prophylaxis is recommended for only a few types of occupational exposures to HIV-tainted blood because most exposures do not lead to contracting HIV, and the drugs used to prevent seroconversion are not benign. Common adverse effects include nausea, vomiting, diarrhea, lethargy, and headache. More serious adverse effects include kidney stones, hepatitis, and suppression of bone marrow. The risks and benefits of postexposure prophylaxis for HIV exposures must be weighed before starting treatment. The dangers associated with the antiviral drugs for a low-risk exposure may outweigh the reduction in risk in an already low-risk situation.

Treatment should begin as soon as possible after the exposure, as soon as within the first few hours. Animal studies have demonstrated the treatment is not effective after 24 to 36 hours have passed since the exposure event. The recommended postexposure protocol for HIV exposures is a 4-week course of two nucleosides. For those exposures associated with a higher rate of seroconversion, a protease inhibitor is added to the regimen. HIV antibody titers should be drawn immediately following exposure and periodically for at least 6 months after exposure. Any flu-like symptoms that occur with an abrupt onset during the follow-up period should be reported. If in doubt about the appropriate prophylactic treatment, consult the CDC Web site for the most current treatment regimen.

Transmission of HIV to health care providers following an occupational exposure has been documented in 57 patients. Of the 57 individuals, 26 have gone on to develop AIDS. An additional 139 cases of HIV have occurred in health care workers who have no reported risk factors for HIV other than occupational exposure, but for whom seroconversion after an occupational exposure was not documented. None of the 57 documented cases are EMS personnel; however, 12 of the 139 undocumented seroconversions were EMS providers.

The risk of seroconversion from an occupational exposure is related to percutaneous injury as it occurs when the patient is HIV positive. The risk of seroconversion is 0.33% from a deep puncture wound from a hollow-bore needle, visibly contaminated with blood from an HIV-positive patient with a high viral load. The risk of contracting HIV from such an injury is lower than the risk of contracting HBV or HCV from the same type of injury, if the health care provider is unvaccinated (the risk of contracting HBV from this type of injury is reported to be between 6% and 30%).

Flight Considerations

There are no special patient care considerations specific to air medical transport of patients with infectious diseases. Follow the same precautions and management strategies discussed in this chapter.

One important air medical service consideration when receiving a transport request is the length of out-of-service time required to properly disinfect or decontaminate the aircraft afterwards.

Summary

CCTPs must be aware of the risk to exposures from a variety of infectious agents. Their job makes them inherently at risk to both contagious agents and those transferred by needlesticks or body fluids. A solid knowledge of microorganisms and the diseases they cause is necessary to ensure their protection. An understanding of the fundamental principles of the immune system and infectious disease is an essential tool for medical care professionals. This knowledge, when applied to the critical care arena, will enable one to assess risk, minimize exposure, and prevent transmission of infection.

Case Study

YOU ARE DISPATCHED TO A RURAL HOSPITAL INTENSIVE CARE UNIT (ICU) for an emergency transfer to a tertiary hospital facility. En route to the hospital, dispatch relays the following limited patient information. Your patient is a 58-year-old man who weighs 72 kg. He was admitted to the ICU from the emergency department with respiratory failure. The patient has been diagnosed with postinfluenza methicillin-resistant *Staphylococcus aureus* (MRSA) pneumonia and he requires further consultation and treatment in a tertiary facility. The transport time for this patient typically would be only 30 minutes via air, but weather issues necessitate that the patient be transported via a ground unit. The ground transport time is approximately 2 hours with the inclement weather conditions.

On arrival to the hospital ICU, you are informed that the staff nurse and referring physician are at the patient's bedside. Both are dressed in full personal protective equipment (PPE) and are attempting to suction the patient's endotracheal tube with assistance from the respiratory therapist. You and your partner note the droplet precaution signage posted on the patient's door and the isolation cart placed outside the patient's room. After you and your partner don the appropriate PPE (gloves, gown, and surgical mask with a faceshild), the referring physician reports to you that the patient arrived at the hospital emergency department approximately 6 hours ago in acute respiratory distress and was electively intubated successfully with rapid sequence intubation medications. Prior to arrival at the emergency department, EMS performed multiple intubation attempts without success. They were able to assist the patient's ventilations with a bag-mask device but achieved an oxygen saturation level of only 86%. EMS reported that the patient was discharged from this same hospital just 2 days ago, after being treated for an upper respiratory infection. He has a medical history of hypertension, type II diabetes mellitus, chronic obstructive pulmonary disease, seizures, and gastroesophageal reflux disease. He has no known drug allergies to report, which is consistent with his recent admission record obtained by the emergency department physician. The patient is homeless and is a "frequent flyer" known to the EMS and emergency department staff. He admits to smoking a pack-a-day of cigarettes and drinks about 3 to 4 beers a day. He is not compliant with his daily prescription regimen to control his blood pressure, high glucose levels, and seizure disorder.

Your initial assessment of this patient reveals a Glasgow Coma Scale (GCS) score of 8. The patient appears anxious with restlessness noted in his lower extremities. The patient's upper extremities are secured with padded restraints because it was reported that he tried to pull out his endotracheal tube prior to your arrival. No sedation has been administered because his blood pressure was so labile. His airway is secured with an 8.0 endotracheal tube at the 24-cm mark (lip). The patient is being ventilated with synchronized intermittent mandatory ventilation (SIMV) with the following settings: tidal volume, 600 mL; rate, 26 breaths/min; FIO_2, 60% with 10 cm H_2O of positive end-expiratory pressure (PEEP). After

the previous suctioning of the endotracheal tube, it was noted that his secretions were thick, rusty colored (blood tinged), and had a foul odor. The patient has two peripheral IV lines in his left arm with normal saline running at 30 mL/h and a dopamine drip infusing at 10 μg/kg/min. The other IV line has a vancomycin drip (15 mg/kg) infusing over 1 hour. Prior to placing the transport monitoring equipment on this patient, the following vital signs are noted on the patient's ICU monitor: ECG, sinus tachycardia with occasional unifocal PVCs; heart rate, 138 to 145 beats/min; blood pressure, 88/40 mm Hg (confirmed with manual blood pressure to right arm); respiratory rate, 26 (SIMV); Spo_2, 88%; $ETCO_2$, 58 mm Hg; and a reported temperature of 101°F (rectal). After receiving the transfer chart, the following laboratory values are noted: WBC count, 26,000/mm^3; BUN, 58 mg/dL; creatinine, 2.3 mg/dL; Na+, 148 mEq/L; K+, 4.5 mEq/L; Cl^-, 109 mEq/L; glucose, 212 mg/dL; pH, 7.30; PCO_2, 54 mm Hg; PaO_2, 68 mm Hg; and HCO^-, 16 mEq/L. A chest radiograph reveals bilateral lobular infiltrates consistent with pneumonia. A gram stain shows gram-positive cocci in a cluster and the patient has a prior history of MRSA infection. The staff nurse reports his daily input/output as 600 mL/50mL/h with amber-colored urine.

On completion of your assessment of this patient, you note the following findings. The skin is "hot" to the touch, dry, and pale. The pupils are equal and reactive to light at 5 mm (bilateral/brisk), and your patient remains at a GCS score of 8 with eyes opening to tactile stimulus. The endotracheal tube remains secured with tape at the 24-cm mark at the lip line. The trachea is midline with noted "mild" jugular venous distention to the right neck with the head of the bed at 30°. The remainder of the head/eyes/ears/nose/throat examination is within normal limits for this patient. The chest wall has an equal symmetrical rise and fall with mechanical ventilations, but shallow effort is noted with patient-initiated ventilations. The lungs sounds reveal bilateral coarse rhonchi, and the abdomen is soft with no distention noted. The pelvis is within normal limits with an indwelling urinary catheter to gravity drainage. The lower extremities are pale and cool to the touch without edema. Pedal pulses have been only obtained via Doppler, and a weak, thready radial pulse is noted with delayed capillary refill of greater than 3 seconds. There is no swelling or redness noted to the two peripherally inserted IV lines being used with no signs of infiltrates.

Before you move the patient to the transport stretcher, your partner transfers the dopamine and vancomycin drip to your transport pumps with the normal saline at a keep vein open rate of 30 mL/h. The patient is placed on your unit transport monitor with ECG, Spo_2, $ETCO_2$, and noninvasive blood pressure with alarms on and functioning. The patient remains on the hospital ventilator while your partner duplicates the above ventilator settings from the referring hospital. The patient is moved to your stretcher without incident as the transport ventilator is attached (alarms are on and functioning). You depart the ICU with the transfer documentation and radiology studies to your awaiting ground unit. All PPE is properly disposed. The patient is loaded and secured to the ground unit with all power and oxygen requirements transferred to the ground unit source. You depart the referral hospital en route to the receiving facility with routine traffic due to the weather conditions.

While en route to the receiving hospital, the patient's condition remains the same without any change or improvement in the hemodynamic status (manual BP, 90/38; heart rate, 140 beats/min with occasional unifocal PVCs). The neurologic status remains the same with a GCS score of 8 with periods of noted agitation and restlessness to his lower extremities. The Spo_2 remains at 88% to 92% with the above ventilator settings, and an $ETCO_2$ of 45 to 54 mm Hg. Your partner contacts your dispatch center to relay an updated report and an estimated time of arrival to the receiving hospital. No orders are requested or received from the receiving facility, but your partner advises that you will be following your standing protocols for this patient's care.

1. Is there anything that you would want to change (ie, ventilator settings) or initiate on this patient?

2. What other interventions or medications would be beneficial for this patient?
3. Is this a suitable mode of transfer based on the patient's condition?

Analysis

This is a complex patient scenario that should have been corrected in a more stable environment, such as the referring hospital ICU with a multidisciplinary team approach. The incidence of postinfluenza MRSA pneumonia is rare, and demands critical thinking skills and rapid interventions by the CCTP. This patient was recently discharged after being treated for an upper airway infection, and he is also noncompliant with his daily medication regimen. He is homeless with admitted alcohol and tobacco abuse that exacerbates his history of other medical issues (COPD, diabetes, hypertension). Treatment at the ICU bedside or en route to the receiving hospital should include, but not be limited to, the following interventions:

- Administration of a chemical paralytic such as vecuronium (Norcuron) at 0.1 mg/kg.
- Administration of a sedative medication such as etomidate (Amidate) at 0.3 mg/kg or half dose at 0.15 mg/kg for this patient's declining hemodynamic status.
- Changes to the ventilator settings could include the following:
  - Increase the FIO_2 from 60% to 100%.
  - Decrease the rate from 26 to 14 to 16 breaths/min, which decreases the potential for increased air trapping.
  - Lengthen the inspiratory time, which would allow for exhalation of retained CO_2 (already has a history of COPD and hypercapnia).
- Decrease the PEEP setting from 10 to 5 cm H_2O, which has inadvertently increased the intrathoracic pressure and decreased the venous return to the right atrium, causing hypotension. The unstable hemodynamic status (hypotension) is also the result of the patient's septicemic shock state.
- Administration of an additional fluid bolus (3 to 4 liters) because the patient remains hypotensive. The CCTP must reassess breaths sounds frequently and be cautious of pulmonary edema. After fluid resuscitation has taken place, the dopamine dosage can be increased.
- Administration of an additional infusion of another vasopressor agent such as vasopressin or norepinephrine.

After the following interventions have taken place en route to the receiving hospital, the patient responds well to the treatment and his hemodynamic status is within normal limits with noted clear yellow urine in the indwelling urinary catheter. Though it would have been a more expedient transport via air, the weather conditions hindered this mode of transport. The patient tolerated the ground transport and was subsequently transferred to the ICU nursing and medical staff's care.

Prep Kit

Ready for Review

- Patients, health care workers, and members of the community are at risk for contracting infectious diseases from their interactions with one another, and through contact with infectious agents that are found in body fluids, on solid surfaces, and in the air.

- A solid understanding of the fundamental principles of infectious disease is an essential tool that will enable CCTPs to assess risk, minimize exposure, and prevent transmission of infection.
- For an organism to contract a disease, the host must be susceptible. Susceptibility is determined by factors such as nutritional status, immune status, genetic makeup, living conditions, and exposure.
- Disease can be transmitted directly through inhalation, ingestion, or direct contact with infectious agents, or indirectly via vectors, fomites (eg, contaminated fluids or equipment), or some other complex cycle of interactions.
- For the immune system to protect the body from invading microorganisms, it must be able to distinguish "self" components or cells from "nonself" components or cells; must be both highly specific and general; and must provide protection that consists of several layers so that once one level of immunity has been breached, additional methods of fighting infection remain available.
- Immunity can be either innate (the type of immunity one is born with, which provides protection from invading pathogens despite a lack of prior exposure) or acquired (the type of immunity that develops as a result of interactions between components of the immune system and the invading microbe, which provides improved protection with repeated exposures to specific agents).
- Innate immunity is nonspecific, is activated immediately on invasion, and has no memory. The primary components of innate immunity are the skin, mucous membranes, and their secretions, which provide mechanical and chemical barriers to invasion.
- Nonspecific factors of the immune system help limit growth of microorganisms within the body and include cells such as natural killer cells, neutrophils, and macrophages; proteins such as complement or transferrin; and the body's general responses to invasion with actions such as fever or inflammation.
- Acquired immunity includes both humoral and cellmediated immunity: humoral immunity is provided by B cells through the production of antibodies and complement, and cell-mediated immunity is provided by T cells.
- Cytokines and macrophages are modulators of both cellmediated and humoral immunity.
- Acquired immunity results from the interaction of the agent with the host, is specific, improves with repeated interactions, allows for the development of immunologic memory, and can be either active or passive.
- Active immunity (an ongoing process of developing antibodies and activating T cells in response to invading agents) occurs when an individual either is exposed to microbes through the natural process of infection or artificially stimulated through a vaccine.
- Passive immunity is the process of giving an individual a preformed antibody (from a donor) in the event of an exposure during which the individual has not yet developed immunity.
- Antigens are a complex of proteins and/or sugars that are anchored into the cell membrane and displayed on the cell's surface. An antigen is recognized by the immune system as either self or nonself; in the latter case, it will induce a humoral or cell-mediated response.
- The immune system includes the central lymphoid organs (the thymus and the bone marrow), which are the site of synthesis and differentiation of immunocompetent cells.
- The peripheral lymphoid organs are where immunocompetency is expressed; they include the spleen, lymph nodes, tonsils, intestinal Peyer's patches, and mucosa. Lymph nodes are made up of lymphoidal tissue located throughout the body as single units or in chains of units and are prominent in the neck, axilla, and groin.
- T lymphocytes mature to express phenotypic markers or clusters of differentiation called CD markers.

CD4+ cells (helper T cells) are regulators of the immune system; CD8+ cells (cytotoxic suppressor T cells) kill virus-infected and tumor cells.

- B cells either differentiate into plasma cells that produce specific antibodies on encountering an antigen or become memory cells.
- Antibodies are globulin proteins (immunoglobulins) that react to antigen. There are five classes of antibodies: IgA, IgM, IgG, IgE, and IgD.
- The humoral (antibody-mediated) response is effective against agents that produce toxins, against bacteria that have polysaccharide capsules, and against some viral infections.
- In the primary immune response, antibodies do not appear until 7 to 10 days after the initial encounter. On a second encounter with the same antigen or a closely related antigen, a more rapid secondary response occurs, with antibody being detected in the serum in only 3 to 5 days, and antibody titers being produced that are much higher than those seen in the primary response.
- Cell-mediated immunity plays an important role in defending against intracellular infections, such as TB or gonorrhea, and viral infections, fungal infections, parasites, and tumors. Antibody is not involved in CMI reactions except in the antibody-dependent cellular cytotoxic reactions.
- The process of phagocytosis is performed by macrophages, neutrophils, and monocytes, which engulf and destroy bacteria, foreign antigen, and cellular debris.
- The remaining fragments of the invading cells, known as epitopes or antigen, are displayed by the phagocytic cell in close association with specialized proteins on the exterior of the cell; these proteins are called major histocompatibility complex.
- An inappropriate or exaggerated immune response known as hypersensitivity (allergic) reaction occurs when a first encounter sensitizes an individual to the antigen and induces an antibody response, and then subsequent encounters with the same or closely related antigen elicit the allergic response.
- There are four major types of hypersensitivity reactions: types I, II, and III are antibody-mediated responses, whereas type IV is a cell-mediated response.
- Anaphylaxis is a serious allergic reaction that has a rapid onset of symptoms, has a variable clinical presentation, and, if unrecognized, can lead to respiratory arrest, circulatory collapse, and death. Common triggers for anaphylaxis include foods, drugs, antibiotics, and *Hymenoptera* venom.
- Most cases of anaphylaxis have cutaneous involvement, including flushing, itching, urticaria, or angioedema. Upper airway involvement may include changes in phonation, the sensation of throat closure or choking, cough, wheezing, and shortness of breath.
- The treatments for anaphylaxis focus on early recognition and the use of epinephrine to prevent progression to life-threatening symptoms. Airway management, including intubation, if necessary, and fluid resuscitation are key components of care for a patient experiencing anaphylaxis.
- In biphasic anaphylaxis, the initial resolution of symptoms is followed by a reappearance of symptoms and, if not anticipated, can be the cause of a life-threatening recurrence.
- Immunodeficiency occurs when one or more of the components of the immune system is damaged or is nonfunctioning as the result of illness or lack of functioning immune cells, or when the immune system is intentionally suppressed by various immunosuppressant therapies.
- Critically ill patients have little reserve to fight infections as the result of a decrease in host defenses and loss of innate immunity.
- Features of chronic illness that decrease innate immunity include stress, malnutrition, invasive procedures, loss of physical barriers of skin and mucosal surfaces, and pathogenic bacterial

overgrowth or bacterial growth in normally sterile tissue.

- Management of illnesses and injuries during transport of a transplant patient may be complicated by the side effects of immunosuppressive medications (eg, hypertension, hyperglycemia, hyperkalemia, nephrotoxicity, and neurotoxicity) or by the patient's immunosuppressed condition.
- Normal flora is comprised of colonies of nonpathogenic species that assist the immune system by preventing the overgrowth of pathogenic strains by using up available nutrients, maintaining a certain pH level, and creating bac-teriocins (antibacterial toxins).
- Many individuals requiring critical care transport are immunocompromised, and CCTPs need to be keenly aware that these very sick patients can be inadvertently infected with opportunistic infections (ie, diseases caused by normally nonpathogenic agents in patients with an abnormally functioning immune system).
- Pathogenic organisms cause disease because they possess unique factors that help them gain entry into the body, colonize and overcome host defenses, produce toxins that cause cytopathic effects, or do mechanical damage to the body.
- Properties of microbes that influence their virulence (ie, degree of pathogenicity) include host and tissue specificity (the ability of the organism to gain entry into a host), adherence to specific host cells, invasion of host tissue, evasion of host defenses, and toxicity.
- Virulence can be experimentally quantified by two measures: the ID_{50} and the LD_{50}.
- Typical portals of entry into the body for pathogens are through broken skin, hair follicles, or sweat glands and through the mucous membranes of the respiratory, digestive, and genitourinary tracts, or the conjunctiva of the eye. Once inside the body, the pathogenic organism must be able to adhere to specific cells to begin colonization.
- Bacteria are capable of producing two types of toxins: exotoxins, which are produced inside the cell and are released into surrounding tissues or fluids; and endotoxins, which are part of the gram-negative cell wall and are not released until the bacteria are destroyed.
- The DNA of various bacteria encodes both virulence factors and antibiotic resistance genes. Many virulence factors are carried on circular, extrachromosomal, self-replicating pieces of DNA called plasmids; the uptake of fragments of the chromosomal DNA released on lysis of a nearby cell may also lead to proliferation of the harmful DNA once it becomes part of the recipient cell's genome.
- Bacterial cells are subject to infection by bacterial viruses called bacteriophages. Bacteriophages can cause destruction of a host bacterial cell by growth and lysis of the host bacterium; sometimes, the bacteriophage DNA becomes integrated into the host chromosome and remains there as the bacteria undergo replication.
- Viruses that enter the body bind to host cell surface receptors using viral proteins found on the surface of the virions, leading to receptor-mediated endocytosis that brings the virus directly into the cell.
- Once inside a cell, the virus particle may release its viral nucleic acid, allowing the viral DNA or RNA to direct synthesis of viral-encoded protein and nucleic acid molecules and stimulate the process of new virion assembly.
- Viruses cause illness through three mechanisms: (1) production of viral-specific molecules that deplete the host cell's resources and lead to eventual cell death; (2) induction of programmed cell death (apoptosis); and (3) induction of large inflammatory responses.
- Epidemiology is the study of how disease is distributed within populations and the factors that influence that distribution.

- The incidence of a disease is the number of new cases of disease within a defined population over a defined period of time.
- The prevalence of a disease is the number of cases of disease detected in a specified period of time, regardless of when the illness was contracted.
- Factors such as the incubation period of a disease or the presence of different carrier states may cause the disease to go undetected and unaccounted in an individual, but can place others at risk for contracting the disease. For this reason, CCTPs must use appropriate disease control and prevention practices when providing care to all patients, regardless of whether the patient is currently exhibiting symptoms.
- For a microorganism to infect and reinfect a host, it must have the ability to survive, duplicate or reproduce, and spread to new hosts. Reservoirs of infection provide a supply of nutrients and an environmental niche that enable long-term microbial survival.
- Persons who are colonized by pathogenic species but do not have symptoms of the infection (ie, asymptomatic or latent carriers) can serve as sources of infection during extended hospital admissions.
- Health care providers unwittingly act as a major source of cross-infection when they attend different patients without proper intervening antisepsis.
- The health care environment itself may serve as a reservoir of infection. Some organisms can survive on inanimate objects, including durable medical equipment, for an extended duration of time.
- Direct contact involves person-to-person transmission of a pathogen (ie, no intermediate carrier is involved in the transfer).
- Horizontal transmission (ie, the transmission of infection between members of the same generation) may occur through sexual transmission, exchange of respiratory droplets or secretions, and transmission by contact.
- Vertical transmission is the exchange of an infectious agent between mother and fetus in utero or during the birthing process.
- To guard against direct transmission of infection, health care workers can use protective barriers such as gloves, gowns, masks, and eye shields, which prevent direct contact with infectious materials during invasive procedures or when providing care for an infectious patient.
- Indirect transmission occurs when there is an intervening step in the transmission from reservoir to susceptible host. The intermediate step involves an inanimate object or fomite, such as towels, bedding, thermometers, and contaminated syringes.
- Many infectious diseases are transmitted through the use of a medium, such as water, food, air, or contaminated body fluids. Water can be either the reservoir of disease or a vehicle for the transmission of that disease.
- Vector transmission is the exchange of a pathogen from an infected organism to a susceptible host via an insect or other animal.
- Meningitis (ie, the inflammation of the leptomeninges) is a serious medical condition that can be caused by a bacterial, viral, or fungal infectious agent.
- Bacterial meningitis has an acute onset and is a medical emergency that requires prompt diagnosis and treatment to preserve life and neurologic function. The classic triad of symptoms observed in patients with this disease includes fever, nuchal rigidity, and altered mental status.
- Most cases of bacterial meningitis are observed in adults and can be caused by a variety of bacterial species, including *N meningitidis, S pneumoniae*, and *H influenzae*.

- The severity of the symptoms and the disease is less serious with viral meningitis than with bacterial meningitis, and complete recovery can occur in 2 to 7 days without medical intervention.
- Respiratory syncytial virus causes seasonal outbreaks of acute respiratory tract infections.
- Necrotizing fasciitis is a limb- or life-threatening infection of the soft tissue that affects the subcutaneous tissues, fat, and fascia but usually spares the skin and muscle. Prompt diagnosis and treatment with antibiotic and complete surgical débridement are important to reduce the high mortality rate associated with this disease.
- Epiglottitis (ie, the result of an infected and inflamed epiglottis, aryepiglottic folds, and/or surrounding tissues) typically occurs in children between the ages of 1 and 5 years. It is a potentially life-threatening infection, and patients must be treated promptly with empiric antibiotics.
- Tuberculosis is caused by infection with *M tuberculosis*, which is transmitted via respiratory droplets from the cough of an infected person to the respiratory epithelium of a susceptible person.
- In those with TB, the first site of infection is the lungs, but the pathogen can also spread to the kidney or spine. Most persons infected with *M tuberculosis* are asymptomatic. Persons with full-blown pulmonary tuberculosis typically exhibit five symptoms: cough, fever, weight loss, night sweats, and fatigue.
- The emergence of drug-resistant strains of TB has precipitated the use of a multidrug regimen for cure. The individual drugs used may vary slightly, but the mainstay of therapy is isoniazid.
- Multidrug-resistant TB is TB that is resistant to at least two of the standard anti-TB medications, isoniazid and rifampin. There are limited treatment options for patients with this form of the disease.
- When transporting a patient with suspected or known TB, CCTPs should place a mask on the patient (if tolerated) and wear a mask themselves.
- CCTPs should comply with yearly PPD testing (which identifies antibodies to TB) to determine a personal exposure history to TB.
- If care was provided for a patient known to have TB and exposure was a possibility, providers should get a PPD test 6 weeks after exposure to assess their personal status.
- Pneumonia is an infection of the lung parenchyma that is caused by bacterial, viral, or fungal agents; it is a major cause of death in the United States.
- Many different bacterial species cause pneumonia, including *Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, Chlamydia pneumoniae*, and *Legionella pneumoniae. Mycoplasma pneumoniae* and viruses cause atypical pneumonias.
- Nosocomial or hospital-acquired pneumonia is a pneumonia that occurs in a hospitalized patient within 48 hours or more after admission to the hospital that was not apparent at the time of admission.
- Ventilator-associated pneumonia is a type of hospital-acquired pneumonia that occurs in ventilated patients and appears more than 48 hours after endotracheal intubation.
- Health care–associated pneumonia is a pneumonia that occurs in nonhospitalized patients who have contact with health care facilities or personnel, such as residents of long-term health care facilities, those undergoing hemodialysis, or those who have had a recent admission to an acute care facility.
- *Pneumocystis jiroveci* pneumonia is a fungal infection that is seen in patients with immunosuppression, such as those taking antirejection therapy for solid organ transplantation or those infected with HIV. It is included in the list of AIDS-defining illnesses.
- CCTPs should use standard precautions when caring for patients suspected of or diagnosed as having

pneumonia. If a patient is coughing, place a mask on the patient (if tolerated) and on the CCTP; wear gloves; use good handwashing technique between transports; and clean and decontaminate equipment, including the transport vehicle, prior to undertaking further transports.

- It is especially important to decontaminate equipment such as laryngoscopes and suction equipment after transportation of patients with oral candidiasis (thrush) or patients infected with *P jiroveci*.
- There are few treatments available for influenza except supportive therapy; however, when diagnosed within the first day of symptoms, treatment with an antiviral medication may reduce the severity and duration of symptoms.
- When influenza undergoes a major antigenic drift or a novel combination of hemagglutinin and neuraminidase emerges (antigenic shift), people have little or no antigenic protection from prior infections; pandemics of influenza may then break out and spread quickly.
- Herpesviruses are noted for their ability to cause latent infections, during which the acute viral syndrome is followed by a symptom-free period and the virus is inactive. Reactivation of the virus can occur when the patient is immunosuppressed or through inciting agents.
- Six pathogenic members of the herpesvirus family cause significant disease in humans: herpes simplex types 1 and 2, varicella zoster virus, cytomegalovirus, Epstein-Barr virus, and human herpesvirus 8. Epstein-Barr virus and human herpesvirus 8 are associated with the development of Burkitt's lymphoma and Kaposi's sarcoma, respectively.
- Hepatitis (inflammation of the liver) can be caused by exposure to infectious agents (usually viral), toxins (eg, alcohol), or drugs (eg, acetaminophen). The course of the illness ranges from acute to chronic, and the severity ranges from mild to life threatening.
- Hepatitis A virus (HAV) is usually transmitted via the fecal-oral route, although sexual and parenteral transmission is possible. Large-scale outbreaks can occur, usually the result of contamination of food or drinking water.
- HAV infection can be prevented by active immunization with the HAV vaccine or by passive immunization with immune globulin administered before or after a known exposure.
- Hepatitis B virus (HBV) is transmitted through parenteral routes, or nonoral transmission. Health care providers are considered an at-risk group for this infection and should receive the HBV vaccine series, with immunity confirmed by titer.
- Unlike HAV, HBV can induce other disease states in addition to causing acute infections (namely, acute hepatitis, fulminant hepatitis [severe inflammation of the liver, accompanied by rapid destruction of the liver leading to liver failure], and chronic hepatitis [chronic asymptomatic carriers]).
- The treatment and prevention of HBV infection involves screening the blood supply and removing HBV-contaminated units and donors from the blood pool.
- Hepatitis C virus (HCV) is transmitted parenterally through transfusion or IV drug use, through sexual contact with infected individuals, and from mother to baby. In most cases, acute infection leads to chronic infection, with the disease eventually progressing to hepatitis and fibrotic liver disease (cirrhosis).
- There is no cure for HCV, and there is no vaccine available to prevent infection; the goal of treatment is to prevent the development of cirrhosis and liver failure.
- Hepatitis delta virus (HDV) is transmitted parenterally, but can replicate only with the aid of HBV. All patients with severe HBV infection should be tested for HDV coinfection or superinfection.
- HIV causes AIDS and AIDS-related complex. This retrovirus infects T lymphocytes and other cells that

display the CD4 surface protein, and is notable for causing "slow" infections with long incubation periods.

- Transmission of HIV infection occurs by the transfer of infected cells or free virus from one individual to another. The transmission occurs both horizontally (via sexual contact or by exposure to infected blood) and vertically (from mother to neonate across the placenta or during delivery and from an infected mother through breast milk).
- As a CCTP, exposure to patients with HIV infection is a potential risk for disease contraction. Prevention of exposure (eg, with needlesticks) is the most important method of protection for the health care worker.
- The three stages in HIV infection—acute, latent, and late (period of immunodeficiency)—are largely determined by the CD4 cell count and/or symptoms of the disease.
- Antibodies to HIV are not detected in the blood until 3 to 4 weeks after the initial infection. The person is infected with HIV and is capable of spreading the disease through sexual or blood contacts during this window of time, even though the HIV antibody test result will be negative prior to seroconversion.
- Even while the HIV-infected patient is asymptomatic and symptoms remain latent, the virus continues actively replicating within the lymph nodes.
- Toward the end of the clinical latency period, the HIV-infected patient may begin to experience ARC syndrome, a constellation of symptoms including fevers, unexplained weight loss, fatigue, diarrhea, and generalized lymphadenopathy.
- ARC-related symptoms are often what persuade the patient to seek help in the health care system. ARC syndrome may mark the beginning of the final progression toward AIDS.
- The criteria for the diagnosis of AIDS include HIV infection with a CD4+ helper T-cell count of less than 200 cells/μL and/or the presence of an AIDS-defining condition.
- Patients with HIV often present many years after the initial infection or acute stage of the disease, because in the initial stages the disease is often mild and the symptoms are nonspecific.
- For many patients with HIV, the illness is noticed when the patient begins to experience symptoms; eventually, loss of cell-mediated immunity predisposes the host to many opportunistic infections.
- In HIV-infected patients, the viral load is estimated by determining how much viral RNA is present in the blood. It indicates the magnitude of HIV replication and its associated rate of CD4 cell destruction; is the most accurate indicator of the risk for disease progression; and is used for planning and monitoring antiretroviral therapy.
- Three classes of antiretroviral drugs are currently used to treat HIV infection: nucleoside analog reverse transcriptase inhibitors, protease inhibitors, and non-nucleoside reverse transcriptase inhibitors. A fourth class of drugs, fusion inhibitors, is also under development.
- The goal of current therapies for HIV infection is to prolong life (by preventing opportunistic infections and malignancies, and slowing the rate of virus production) while maintaining the best possible quality of life.
- Emerging infectious diseases (diseases whose incidence has increased dramatically in the last 20 years) are particularly damaging to immunocompromised individuals, such as those living with HIV disease, those receiving immunosuppressive therapy such as the recipients of organ transplants, or those who are immunosuppressed as a result of their treatment for cancer.
- Severe acute respiratory syndrome is an emerging lower respiratory tract illness that is associated with high morbidity and mortality.

- Infection with *Escherichia coli* O157:H7 may occur after eating undercooked, contaminated ground beef; drinking unpasteurized milk and fruit drinks; eating unwashed lettuce or sprouts; eating salami; swimming in or drinking sewage-contaminated water; or having person-to-person contact.
- West Nile virus is a mosquito-borne pathogen that occasionally leads to meningitis or encephalitis; there is no cure for West Nile virus encephalitis.
- *Helicobacter pylori* bacteria infect the stomach and duodenum and are the causative agents of most peptic ulcers. The goal of *H pylori* treatment is the complete elimination of the organism from the body.
- Antibiotics are compounds that are produced by bacteria or fungi that inhibit the growth of bacteriostatic organisms or kill other (bacteriocidal) bacterial organisms.
- All antibacterial agents follow the same basic principle: target bacterial proteins, processes, or cellular components that are not found in human cells.
- The relatively few antiviral treatments available work by interrupting the viral replication cycle at a specific step.
- Antifungal therapies typically bind with components in the fungal cell wall, making the membrane less fluid and more susceptible to rupture and, therefore, leading to cell death.
- Virtually all important pathogenic bacteria have demonstrated resistance to currently available Food and Drug Administration–approved antibiotics.
- Three important factors that contribute to the emergence of resistant bacteria within a given population or community are misuse use of antibiotics, poor infection control, and importation or intrusion of already resistant strains.
- Health care workers are a major source of cross-infection between critically ill patients, and handwashing is the single most important step that a health care provider can take to reduce the spread of infection.
- Methicillin-resistant *Staphylococcus aureus* (MRSA) can colonize a variety of tissues, causing infections such as cellulitis, cutaneous abscesses, wound infections, osteomyelitis, septic arthritis, endocarditis, pneumonia, and septicemia.
- High rates of MRSA are found among residents of long-term care facilities, but serious infections with MRSA are more prevalent in the acute care setting.
- Risk factors for colonization with MRSA include dialysis, diabetes, use of injectable drugs, chronic skin conditions such as decubitus ulcers, and a history of prior antibiotic use.
- The emergence of vancomycin-resistant MRSA poses a serious threat to patients and health care workers. Any patient with this type of infection should be isolated, and the infection should be reported to public health authorities.
- Although antibiotic-resistant species of *Enterococcus* rarely cause illness in healthy people, they can cause serious infections in immunocompromised, postoperative, and other seriously ill individuals.
- When transporting patients infected with vancomycin-resistant enterococci, providers should implement infection control measures such as handwashing, patient isolation, use of protective barriers such as gloves and gowns, and proper disposal of contaminants.
- Rickettsial diseases are transmitted via tick bite and include Rocky Mountain spotted fever, ehrlichiosis, and anaplasmosis.
- Rocky Mountain spotted fever should be considered a possible diagnosis in all patients presenting with

fever and having suspected or known tick exposure. Rocky Mountain spotted fever begins acutely with fever accompanied by one or more of the following: headache (usually severe), rash, muscle aches, nausea and vomiting, and malaise. Treatment is with doxycycline (or a similar antibiotic).

- Knowledge of epidemiologic principles is crucial in differentiating between the presentation of a naturally occurring disease and an unusual, non-natural event that should raise concern that a bioterrorist event has been initiated and that local emergency response systems should be activated.
- In bioterrorism scenarios, the CCTP must maintain an index of suspicion regarding a potential threat because early symptoms may be nonspecific, but early treatment will be required to prevent severe injury or death. Providers must always take steps to protect themselves before approaching patients and should take responsibility for implementing immunologic protection.
- The health risks associated with the job of the CCTP are not limited to blood or body fluid exposures; rather, the greatest risk comes from patients who are actively infectious but are undiagnosed.
- Steps to reduce exposure risks include the use of appropriate protective clothing and personal protective equipment; proper handling of contaminated medical devices; and implementation of isolation precautions to control the spread of infection to others.
- The Centers for Disease Control and Prevention recommends that all emergency medical care providers be vaccinated against the following preventable infectious diseases: measles, mumps, rubella, varicella, hepatitis B, influenza (annual), pertussis, tetanus, polio, diphtheria, pneumococcal vaccine, and meningococcal vaccine.
- By law, all needlesticks and other injuries with sharps contaminated by blood must be reported to the employer.
- Universal precautions are recommended to prevent transmission of bloodborne pathogens such as HIV and hepatitis B and C; they stipulate use of gloves, gowns, or aprons (or uniforms) and masks or other eye protection to reduce exposure of the skin (especially abraded or broken skin) and mucous membranes.
- The first response to a percutaneous exposure should be to wash the wound thoroughly with soap and water or, if water is not available, an alcohol-based hand cleanser.
- After a significant exposure, the source patient and health care worker both should be tested for baseline values, and the exposed health care worker should receive follow-up testing at 6 and 12 weeks and at 6 months.
- Standard precautions are used with all patients and protect against contact with blood, body fluids, and secretions, regardless of the presence of visible blood, and with nonintact skin and mucous membranes.
- Transmission-based precautions are isolation precautions that are designed to be employed during the transport of all patients who have documented infection or who are suspected to be infected with highly transmissible or epide-miological significant infectious agents.
- Airborne precautions include use of an N95 mask by CCTPs, use of a negative-pressure room (airborne infection isolation room) or transport vehicle, or use of the exhaust fan during transport.
- Droplet precautions include isolation of the patient and use of surgical masks by CCTPs (or keeping at a distance of 3′). Contact precautions include isolation of the patient, use of a gown (or uniform) and gloves, and, if warranted, face protection by CCTPs.
- Clean, nonsterile, disposable gloves are standard equipment on critical care transport units and must be donned by all personnel prior to initiating patient care.

- Masks, face shields, and eye protection are worn to protect mucous membranes of the eyes, nose, and mouth during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, or excretions.
- Gowns are used to protect skin and to prevent the soiling of clothing during procedures that are likely to generate splashes of blood or body fluids.
- Proper handling of sharps includes not attempting to bend, remove, or recap needles; not shearing or breaking needles; and disposing of sharps into an appropriate container as soon as possible after use.
- Contaminated work surfaces and all equipment used during the course of the transport must be decontaminated with an Environmental Protection Agency–registered disinfectant on completion of the transport.
- Contaminated laundry should be placed into leakproof bags, labeled, and stored until proper disposal is possible; likewise, regulated waste must be placed in closeable, leak-proof containers designed for disposal.
- Do not allow time constraints between transports to deter proper disinfection.
- In case of a blood exposure, wash the area with soap and water, flush the mucous membranes with copious amounts of water, irrigate the eyes with sterile solutions of saline or water, and report the exposure immediately to supervisory personnel and those managing blood exposure issues.
- Postexposure prophylaxis is available for the prevention of seroconversion after a known exposure to hepatitis B or HIV, but not after exposure to hepatitis C.

Vital Vocabulary

active immunity Production of specific antibody in response to an infection or antigen.

acquired immunity The immunity the body develops as part of exposure to an antigen.

antigen An agent that, when taken into the body, stimulates the formation of specific protective proteins called antibodies.

bacteriocidal Capable of killing bacteria.

bacteriostatic Capable of inhibiting bacterial growth.

decontamination Use of chemical, physical, or other means to remove, inactivate, or eradicate harmful microorganisms from persons, surfaces, or objects.

epidemiology The study of disease distribution within populations and the factors that determine that distribution.

epitope The specific portion of the antigen that is recognized by the antibody or B cell.

etiology The cause of a disease.

fecal-oral route The route of transmitting infectious organisms from one individual to another; commonly, enteric bacteria or viruses are shed in the feces, spread via contamination of food or water sources, and ingested by other individuals.

fomite An inanimate object that is capable of transmitting infectious organisms from one individual to another.

hapten A small-molecular-weight nonprotein molecule that is capable of reacting with a specific antibody but cannot elicit the formation of antibodies unless bound to a carrier protein; also called a

partial or incomplete antigen.

health care–associated pneumonia (HCAP) A pneumonia that occurs in nonhospitalized patients who have contact with health care facilities or personnel.

high-level disinfection Treatment used on inanimate objects to kill all microorganisms but which does *not* kill bacterial spores.

hospital-acquired pneumonia (HAP) Pneumonia that occurs in a hospitalized patient within 48 hours or more after admission to the hospital that was not apparent at the time of admission.

hypersensitivity Occurs when a patient reacts with exaggerated or inappropriate allergic symptoms after coming into contact with a substance the body perceives as harmful.

iatrogenic Any adverse physical condition that results from medical treatment.

immunocompromised Unable to mount a normal immune response as the result of disease (such as AIDS) or chemotherapy treatment.

immunodeficiency An abnormal condition in which some part of the body's immune system is inadequate, and consequently resistance to infectious disease is decreased.

indicator conditions Rare or unusual diseases associated with an immunocompromised state. Also called AIDS-related diseases.

innate immunity Immunity to diseases inherent in the genetic makeup of an individual.

intermediate-level disinfection Treatment used on inanimate objects to kill *M tuberculosis*, vegetative bacteria, and most viruses and fungi, but which does *not* kill bacterial spores.

low-level disinfection Treatment used on inanimate objects to kill most bacteria, some viruses, and some fungi, but which does *not* kill *M tuberculosis* and does *not* kill bacterial spores.

necrotizing fasciitis A limb- or life-threatening infection of the soft tissue that affects the subcutaneous tissues, fat, and fascia.

nosocomial Infections acquired during hospitalization or a nursing home stay.

opsonize To make bacterial cells more susceptible to the action of phagocytosis by the action of binding an antibody to the pathogen's cell membrane.

palpable purpura Larger areas of bleeding under the skin (greater than 3 mm).

passive immunity Short-lived immunity acquired from placental transfer, antibodies in the mother's milk, or antiserum administered IV.

pathogen Any microbe capable of causing a disease state.

petechial lesions Small areas of bleeding under the skin (pinpoint).

prophylaxis Treatment of disease before it occurs (ie, to prevent the disease).

quiescent A latent state as in a dormant virus or bacterium, in which an infected patient will exhibit little to no symptoms.

respiratory syncytial virus (RSV) A labile paramyxovirus that produces its characteristic fusion of human cells in a tissue culture known as the syncytial effect; can affect both upper and lower respiratory tracts but is more prevalent with the lower, causing pneumonias and bronchiolitis.

rickettsial diseases Diseases transmitted via tick bite; the three major diseases in this class include Rocky Mountain spotted fever, ehrlichiosis, and anaplasmosis.

seroconversion Development of antibodies, measured in the serum, in response to an infection or

vaccine.

severe acute respiratory syndrome (SARS) A highly contagious, potentially life-threatening lower respiratory tract illness that usually starts with flu-like symptoms, including fever, headache, and muscle aches, followed within 2 to 7 days by a dry cough and pneumonia.

vector An organism that carries a disease-causing microorganism from one organism to another.

ventilator-associated pneumonia (VAP) A type of hospital-acquired pneumonia that occurs in ventilated patients and that appears more than 48 hours after endotracheal intubation.

viremia The presence of viruses in the blood.

virulence Physical or biochemical properties of a disease agent that determine its pathogenicity.

West Nile virus (WNV) An arthropod-borne flavivirus that is spread to birds and humans by mosquitoes, which may be characterized by sudden onset of fever with malaise, anorexia, nausea, vomiting, eye pain, headache, myalgia, rash, lymphadenopathy, fatigue, and arthralgias.

Toxicologic Emergencies

Authors

Andrew Bartkus, RN, MSN, CEN, CCRN, CFRN, NREMT-P, FP-C

Contributing Authors:

Phillip L. Coule, MD

Dawn Pecora, PA-C, MMS, CCEMT-P

William M. Sherrod, MD, FACEP

Objectives

1. Identify issues that may adversely affect the health and safety of critical care transport professionals during the treatment and transport of patients experiencing a toxicologic emergency (p 800–803).
2. Describe priority interventions and considerations common to all patients following a poisoning or overdose (p 806–809).
3. Discuss the assessment findings associated with the various toxidromes and medication reaction syndromes encountered in the critical care environment (p 804–806).
4. Describe the management of a patient experiencing a toxicologic emergency (p 806–809).
5. Discuss situations in which decontamination is required or indicated following a toxic exposure or overdose (p 806, 829).
6. Identify which chemicals or medications require enhanced elimination (removal of absorbed toxins) from the body (p 812).
7. Discuss the risks and benefits of and the techniques for administration of various antidotes (p 812–828).
8. Identify the clinical presentation, mechanism of toxicity, and treatment of poisoning or overdose situations commonly encountered or requiring specialized management by critical care transport professionals (p 812–828).
9. Discuss hazardous materials response and critical care transport considerations (p 828–830).
10. Discuss radiation emergencies and critical care transport considerations (p 830–831).

Introduction

CCTPs may be asked to transport patients experiencing a toxicologic emergency following a vast array of possible events. Poisons, chemicals, medications, and other toxic substances are found in dangerous quantities in homes, schools, agriculture, industry, commercial establishments, on all modes of transportation, and naturally in the environment. Through accidents, carelessness, intentional misuse, abuse, and the intentional acts of others, people may be exposed to these toxins and experience potentially lethal consequences. CCTPs can dramatically improve patient outcomes through prompt recognition and effective treatment of toxicologic emergencies.

The safety of the transport team and other health care or emergency responders is the highest priority in the approach to a poisoned or overdosed patient. Patients present hazards to rescuers in a variety of ways. Bizarre, aggressive, or violent behavior may accompany or follow a medication overdose. Suicidal patients often jeopardize the safety of others during a suicide attempt. Patients exposed to hazardous

chemicals may contaminate and injure unprotected rescuers if thorough decontamination is not performed before treatment is initiated.

Care for a poisoned patient or one with an overdose is based on maintaining a patent airway, supporting respirations, and promoting effective circulation. Additional steps involve protecting the patient from additional injury through decontamination, prevention of absorption, antidote administration, enhanced elimination, and general patient safety and comfort measures.

Assessment

Safety

Assessment of a patient after poisoning or an overdose ideally should begin well in advance of the first face-to-face contact with the patient. In many situations, if rescuers or health care providers do not use the correct personal protective equipment (PPE) before initial patient contact, it will be too late for this equipment to provide adequate protection **Figure 20-1**. As the transport team receives the initial dispatch or patient report, safety precautions and potential hazards should be considered. CCTPs may encounter hazardous situations during anticipated patient transports between health care facilities, while responding to an emergency in the community, or by happening on a vehicular crash without any warning.

Cues to the presence of toxic substances may include the following:

- The presence of unusual odors, smoke, or vapors
- Signs, placards, or markings indicating chemicals or hazardous materials
- Vehicles known to carry chemicals (such as tank cars and fuel trucks)
- Industrial, manufacturing, agricultural, or laboratory facilities
- Bystanders or rescuers becoming unexpectedly ill or unconscious
- Multiple patients with similar unexpected signs and symptoms

Figure 20-1 Adequate use of personal protective equipment during contact with patients limits the risk to rescuers and health care providers. The four levels of protection include levels A through D. **A.** Level A protection is fully encapsulating, including the self-contained breathing apparatus (SCBA). **B.** Level B protection is worn with an SCBA but is not fully encapsulating. **C.** Level C protection is for a known agent. **D.** Level D protection is sometimes worn in the cold zone, an area where no environmental hazards

should be present.

In addition to chemical hazards posed to health care providers and emergency responders, patients may exhibit violent, bizarre, or aggressive behavior. Hospital security staff, law enforcement personnel, or a sufficient number of trained health care providers may be necessary to restrain an aggressive or confused patient before any real assessment or treatment can begin. Intoxicated patients and patients with psychological or emotional disorders pose a significant risk to health care providers and emergency responders. All patients should be evaluated for the presence of weapons before transport. Physical and chemical restraints should be considered for intoxicated patients and for patients with a psychological or emotional disorder. CCTPs should not approach an unsecured scene without law enforcement involvement when there is an increased likelihood of aggression or violence.

The following are cues to an increased likelihood of aggression or violence:

- Reported suicide attempt or significant mental illness
- History of violent behavior
- Involvement of alcohol, illicit drugs, or medication or chemical abuse
- Altered or confused mental status
- Patients with escape risk (such as prisoners and inpatient psychiatric patients)

Once the safety concerns for health care providers and emergency responders have been adequately addressed, the transport team should evaluate and manage any problems with the patient's ABCs. The overall patient assessment should be focused on identifying immediate threats to life and health, yet be comprehensive enough to disclose the subtle cues that may assist in the diagnosis of a specific type of toxic exposure.

Airway

Maintaining or establishing a patent airway remains the top priority in the management of a patient with a toxic exposure. Transport team members must evaluate whether the patient currently has a patent airway and whether the patient is at significant risk for developing airway compromise during the transport. Patients who are awake, alert, and speaking without difficulty demonstrate a patent airway. Unusual sounds from the airway, such as stridor, snoring respirations, and gurgling noises, indicate that an airway is at least partially compromised. In addition, visual signs such as secretions, blood, edema, and foreign substances in the airway indicate a potentially compromised airway. CCTPs should continually monitor patients, particularly patients exposed to a vaporous toxin, such as anhydrous ammonia. Vaporous corrosives continue to react and may produce progressive airway occlusion over several minutes.

The presence of an endotracheal (ET) tube does not guarantee a patent airway. An ET tube can become clogged, can become dislodged, or may not have been placed correctly. Auscultation of lung sounds and epigastric sounds, continuous observation of end-tidal carbon dioxide ($ETCO_2$), and observation of the clinical status of a patient are necessary to confirm that an ET tube is functioning correctly. Other nontracheal airway devices provide less protection and require greater scrutiny during patient assessment.

A previously patent airway may become compromised during patient transport for a variety of reasons. Any subsequent alteration in mental status or seizure activity may compromise an airway in a poisoned patient or a patient with an overdose. Evolving structural abnormalities from trauma or increasing edema may also compromise a previously patent airway. Obstructions may occur from emesis (especially unrecognized), secretions, and a displaced foreign body during the transport, leading to airway compromise.

Patients who received activated charcoal or syrup of ipecac (agents used for gastrointestinal [GI] decontamination) present an unusual risk of subsequent airway compromise. Syrup of ipecac may induce vomiting as long as 3 to 4 hours after administration. In supine or sedated patients, aspiration may easily occur. Aspiration of activated charcoal from an inadequately protected airway is often lethal. In patients with unprotected airways who have been given ipecac or charcoal, some protection from aspiration can be afforded by maintaining a minimum of 30° elevation of the head of the stretcher at all times. Aspiration is often silent, so if there is any doubt about the patient's ability to protect the airway during transport, the CCTP should secure the airway with an ET tube.

Breathing

Breathing is second only to airway in importance during patient assessment. Patients require effective oxygen delivery and ventilation to supply the body with oxygen and to remove carbon dioxide. Without effective oxygenation and ventilation, tissue hypoxia, acidosis, and cell death will occur.

The CCTP must evaluate whether a patient's oxygenation and ventilation are adequate to meet metabolic needs. Patients who are at risk for subsequent respiratory compromise must also be identified so the appropriate interventions may begin.

A patient's intrinsic or ventilator-controlled rate and tidal volume must provide adequate gas exchange for his or her clinical status. Physiologic stress, acidosis, hypermetabolic states (such as in pediatrics), and many toxic substances require greater oxygenation and ventilation than would normally be required. The CCTP must consider these factors when evaluating a patient's respiratory status.

Clues in the patient's history of present illness and physical examination will alert the CCTP to the increased likelihood of impending respiratory compromise. Many toxic exposures will affect a patient's respiratory status directly or indirectly. Direct toxins, including asphyxiates, organophosphates, and neuromuscular blockers, affect gas exchange, airway diameter, lung tissue, and ventilation. Indirect toxins, such as opiates, benzodiazepines, tricyclic antidepressants (TCAs), and ethanol, inhibit a patient's central respiratory drive. Hypoxia may occur from gases that displace oxygen in the lungs, substances that block cellular oxygenation, and agents that cause cardiogenic or noncardiogenic pulmonary edema. Respiratory compromise may also develop as a result of associated trauma, burns, or aspiration.

Cyanosis, fatigue, or dyspnea indicates that a patient's respiratory status may be compromised. Lung auscultation revealing wheezing, pulmonary edema, and decreased, absent, or coarse breath sounds further indicates unstable respiratory status.

Circulation

The evaluation of a patient's circulation requires assessment of end-organ tissue perfusion and overall cardiovascular functioning. Previously healthy people may experience vast alterations in hemodynamic parameters without losing end-organ tissue perfusion. Conversely, patients with longstanding cardiovascular disease may experience devastating consequences to modest hemodynamic alterations that are normally well tolerated in healthier people.

Patients with intact circulatory functioning will have adequate end-organ tissue perfusion demonstrated by normal mental status and adequate urine output for their age or weight. Patients will have strong distal pulses and "normal" heart rate, blood pressure, and other hemodynamic values for their age and weight. Skin will be warm and dry with a capillary refill time of less than 2 seconds. The electrocardiogram (ECG) will show a normal sinus rhythm (or the patient's baseline rate and rhythm) without signs of conduction abnormality, unusual ectopy, or ischemia. Any deviation from these findings indicates potentially compromised circulation.

Numerous mechanisms may impair a patient's cardiovascular functioning following an exposure to a

toxic substance. During the evolution of a toxic exposure, a patient's circulatory status may decline because of any of the following:

- Direct exposure to cardiotoxic or vasoactive substances
- Fluid volume loss or redistribution
- Electrolyte disturbance
- Airway or respiratory compromise with secondary cardiac dysfunction
- Manifestations of preexisting cardiovascular disease
- Altered oxygen-carrying capacity

A history of exposure to agents with the potential to cause any of the aforementioned events provides a cue that a patient's circulatory status may become impaired before, during, or after transport.

Additional Assessment

Patient assessment is not limited to safety and the ABCs. Every patient transported should ideally be assessed with a thorough history and physical examination. The depth and detail of the additional assessment should be balanced against the needs for prompt transportation and/or immediate clinical interventions.

The history of present illness should include the following:

- The medication(s) or substance(s) involved (including multiple substances, particularly with intentional poisonings)
- Time, quantity, and/or duration of exposure
- Route(s) of exposure
- The patient's initial and subsequent clinical status
- Initial decontamination, stabilization, and treatment performed before arrival of the transport team
- Other contributory information, such as accidental vs intentional event, multiple patients, and the presence of environmental hazards

Interviews of patients, family, and bystanders may provide valuable clues to the nature and severity of a toxic exposure. Through interviews, the CCTP may become aware of **prodromal** symptoms not otherwise discoverable during the physical examination (such as nausea, headache, and dizziness). The interview may be abbreviated or completed during the transport if interventions or transport cannot be delayed.

Knowing a patient's medical and social history, personal medications, and allergies will assist health care providers treating and transporting a patient. Preexisting medical problems may have a profound effect on the severity of a toxic exposure or overdose. Long-term exposures to various substances often present much differently from a single, brief, acute exposure to the same substance. Other factors such as a history of a psychiatric disorder or substance abuse will impact the present treatment plan and the discharge and follow-up options.

The physical examination must be appropriate for the clinical situation. Transport teams must balance the usefulness of a complete head-to-toe physical examination with concerns for patient thermoregulation (hyperthermia or hypothermia), privacy, patient access in confined transport vehicles, and the clinical needs of that patient. It is inappropriate to delay transport of a critically ill patient by performing a time-consuming comprehensive history and head-to-toe examination; it may be equally inappropriate to initiate rapid transport before adequately assessing the patient.

Vital Signs

A vast array of toxic substances will cause altered vital signs. Hemodynamic and respiratory alterations occur from direct action on various organs and tissues or through effects on the central nervous system, which regulates the cardiovascular and respiratory systems. The examples that follow provide only a sample of medications and substances causing alterations in vital signs.

Tachycardia following a toxic exposure may occur from several different classes of medications and chemicals. Sympathomimetics, such as amphetamines, caffeine, and cocaine, produce an increase in sympathetic tone and atrioventricular node conduction, increasing the heart rate. Medications with anticholinergic effects (such as atropine, TCAs, and antihistamines) antagonize acetylcholine and enhance sinus node discharge, causing sinus tachycardia. In addition, any substance causing cellular hypoxia (such as carbon monoxide and cyanide) will cause responsive tachycardia. Various medications and chemicals may also induce ventricular tachyarrhythmias or myocardial ischemia with related tachycardia. The list of chemicals and medications with the potential for causing tachycardia is extensive.

Bradycardia may occur early following exposure to a toxic substance or immediately preceding asystole as the exposure becomes fatal. Central nervous system (CNS) depression causing bradycardia occurs with toxicity from ethanol, benzodiazepines (for example, lorazepam, diazepam, and midazolam), clonidine, and others. Cardiac (digitalis) glycosides, organophosphates, and carbamates cause bradycardia as a result of an increase in vagal tone. Bradycardia may also occur from direct action on myocardial cell membranes produced by calcium channel blockers, beta-adrenergic blockers, tricyclic antidepressants, household poisonings, and others.

Hypertension accompanies tachycardia and bradycardia following exposure to various medications and chemicals. The sympathomimetic agents and anticholinergic agents described in the preceding paragraphs each produce hypertension with tachycardia. Norepinephrine and phenylephrine are examples of agents that can cause hypertension with bradycardia or an atrioventricular block.

Hypotension may also be accompanied by tachycardia or bradycardia. Hypotension with tachycardia may result from fluid loss, third spacing, or blood vessel dilation. Cell membrane depressant agents and agents that depress the CNS can cause hypotension and bradycardia. These include opioids, sedative-hypnotic agents, beta-blockers, calcium channel blockers, and various others.

Temperature regulation is impaired by many chemicals and medications. Hyperthermia occurs from increased muscle activity or seizures, an increased metabolic rate, impaired heat dissipation, and disrupted thermoregulation. Drug withdrawal and reactions to medications at therapeutic doses also precipitate hyperthermia in specific high-risk populations. Examples of medications that may cause hyperthermia include cocaine, salicylates, and phenothiazines. Examples of medications that may cause hypothermia include beta-blockers, benzodiazepines, ethanol, and hypoglycemic agents.

Vasodilators and CNS depressant agents cause hypothermia. In addition to alterations in metabolism, vasodilation, and impaired shivering response, a patient exposed to CNS depressants may lose consciousness in a cold environment, leading to exogenous hypothermia.

Laboratory Assessment

Laboratory analysis can provide great assistance to the CCTP during diagnosis and treatment of a patient with an actual or potential toxic exposure. Analysis of blood and urine samples is routinely available at sending hospitals and clinics. Advances in **point-of-care testing** technology allow CCTPs to measure blood chemistry values, arterial and venous blood gases, and other assorted values during the transport and obtain results almost immediately. CCTPs should be aware, however, that not all chemicals are included in standard toxicology screens.

Certain toxic exposures require a specific approach to laboratory evaluation once the diagnosis is

made. In these circumstances, the toxic substance has a predictable effect on various laboratory values, and the tests are used to guide treatment or monitor patient status. CCTPs do not often have the luxury of a definitive diagnosis before transport and must use available laboratory testing as a screening or an assessment tool.

Patients who are exposed to a chemical or medication and who arrive unresponsive or with altered mental status cannot provide a reliable history and require a thorough screening for life-threatening conditions. In addition, suicidal and psychiatric patients may intentionally provide misleading or incomplete information to health care providers. The laboratory assessment should include the following:

- Urine drug screen, which must include TCAs unless tested for separately
- Acetaminophen level 4 hours after exposure when time of ingestion is known, or immediately when time of ingestion is not known
- Salicylate level (drawn immediately for a baseline and then at least 1 to 2 hours after exposure; repeated testing needed for positive value or a possibility of delayed absorption)
- Serum electrolytes, including glucose and potassium (particularly if paralysis with succinylcholine [Anectine] is a possibility)
- Evaluation of acid-base status through arterial blood gas or serum carbon dioxide testing
- Ethanol level
- Serum levels of any chemicals and medications known to be available to the patient for which tests can be done (for example, digoxin, lithium, phenytoin [Dilantin], and valproic acid [Depakote])
- Anion gap (serum sodium level minus the sum of chloride and bicarbonate; normal level, 8 to 16 mEq/L)
- Osmolar gap if toxic alcohol poisoning is suspected

The listed tests are merely for screening purposes. If any abnormal or positive results are obtained, further investigation is essential. Known exposure to a particular medication or chemical or profound clinical instability may require a more comprehensive laboratory assessment.

Toxic Syndromes (Toxidromes) and Medication Reaction Syndromes

Exposure to certain classes of chemicals and medications will produce a readily identifiable pattern of clinical signs and symptoms, called a **toxidrome**. These patterns aid in diagnosis when the exact nature of the exposure is unclear and permit health care providers to initiate the correct lifesaving interventions. CCTPs should use caution not to overlook other possible causes when making treatment decisions based solely on identification of a toxidrome.

Patients may also experience life-threatening reactions to medications taken at therapeutic doses. Prompt recognition of these rare events is essential and will happen only if health care providers recognize the unusual clues or at-risk patients. Misdiagnosis of these events will adversely affect patient care, with possibly lethal consequences.

Table 20-1 lists some of the most common toxidromes and medication reaction syndromes.

Toxic Syndromes (Toxidromes)

Anticholinergic syndrome occurs following excessive exposure to medications such as antihistamines, atropine, and benztropine (Cogentin), or other substances such as Jimson weed. Poisoning results in muscarinic receptor blockade at the neuromuscular junction. This syndrome is characterized by tachycardia, hyperthermia, dilated (mydriatic) pupils, warm (or hot) dry skin, ileus, delirium, seizures,

psychosis, and urinary retention. A common phrase to remember this syndrome is: "Mad as a hatter (psychosis), red as a beet (hot, flushed skin), dry as a bone (dry mucous membranes and urinary retention), blind as a bat (pupil dilation), and hot as a hare (hyperthermia)." Seizure activity is treated with benzodiazepines (such as lorazepam, diazepam, and midazolam) and phenobarbital. Severe toxicity is treated with physostigmine (Antilirium, Eserine), administered following consultation with a toxicologist.

Cholinergic syndrome (**cholinesterase** inhibitor toxicity) typically occurs following exposure to organophosphate and carbamate insecticides or to certain chemical nerve agents. Cholinesterase inhibitors may affect nicotinic receptors, muscarinic receptors, or both and alter the function of the neurotransmitter acetylcholine. Patients may have two distinct patterns of toxicity, depending on which receptor(s) are involved. Nicotinic receptor toxicity produces tachycardia, hypertension, fasciculations, weakness, hyperglycemia, and dilated pupils. Muscarinic receptor toxicity produces the classic **SLUDGEM** syndrome (Salivation, Lacrimation, Urination, Diarrhea, Gastroenteritis, Emesis, and Miosis) plus bronchorrhea, sweating, and bradycardia. The mnemonic **DUMBELS** can also be used to remember these symptoms (Diaphoresis/diarrhea, Urination, Miosis, Bradycardia/bronchospasm/bronchorrhea, Emesis, Lacrimation, and Salivation). Nicotinic and muscarinic toxicity produce altered mental status, coma, and seizure activity in severe exposures. It is essential that health care providers and rescuers use adequate PPE during evaluation and treatment of exposed patients. Atropine, in doses much higher than in typical Advanced Cardiac Life Support protocols, and pralidoxime are the antidotes for cholinesterase inhibitor toxicity. Seizure activity is treated with benzodiazepines.

TABLE 20-1 Toxidromes and Medication Reaction Syndromes

Toxidromes	Anticholinergic syndrome Cholinergic syndrome Opioid syndrome Sympathomimetic syndrome
Medication Reaction Syndromes	Malignant hyperthermia Neuroleptic malignant syndrome Serotonin syndrome

Signs and Symptoms

Anticholinergic Syndrome

- Tachycardia
- Hyperthermia
- Dilated (mydriatic) pupils
- Warm (or hot) dry skin
- Ileus
- Delirium
- Seizures

- Psychosis
- Urinary retention

Opioid syndrome is frequently encountered by prehospital and emergency department health care providers. This toxicity commonly develops following illicit use or abuse of opioids in the community, or as an adverse consequence of a therapeutic error or accidental ingestion of opioids (for example, morphine, heroin, and fentanyl [Duragesic]). Signs include lethargy and sedation, hypoventilation or apnea, pinpoint pupils, and noncardiac pulmonary edema. Treatment is focused on airway and ventilation support and the prompt administration of an opioid antagonist such as naloxone (Narcan).

CCTPs should be aware that administration of an opioid antagonist may precipitate severe, violent withdrawal symptoms. In addition, many opioids may exert effects much longer than the duration of opioid antagonists, allowing the return of life-threatening symptoms. It is often necessary to use repeated doses of opioid antagonists in severe overdose situations.

Sympathomimetic syndrome involves overstimulation of the adrenergic nervous system, resulting in tachycardia, hypertension, agitation, seizures, hyperthermia, dilated pupils, and diaphoresis. An isolated alpha-adrenergic or beta-adrenergic syndrome may cause bradycardia or hypotension, respectively, but the classic (mixed) syndrome involves the listed symptoms. Amphetamines, caffeine, cocaine, and MDMA (ecstasy) cause sympathomimetic syndrome. Treatment is primarily supportive, with benzodiazepines and aggressive cooling measures. Avoidance or the use of extreme caution is needed with beta-blockers because of the risk of unopposed alpha-adrenergic stimulation causing worsening hypertension.

Signs and Symptoms

Nicotinic Receptor Toxicity

- Tachycardia
- Hypertension
- Fasciculations
- Weakness
- Hyperglycemia
- Dilated pupils

Signs and Symptoms

Muscarinic Toxicity

- SLUDGEM symptoms (Salivation, Lacrimation, Urination, Diarrhea, Gastroenteritis, Emesis, and Miosis)
- DUMBELS symptoms (Diaphoresis/diarrhea, Urination, Miosis, Bradycardia/bronchospasm/bronchorrhea, Emesis, Lacrimation, and Salivation)
- Bronchorrhea
- Sweating
- Bradycardia

Signs and Symptoms

Opioid Toxicity

- Lethargy and sedation
- Hypoventilation or apnea
- Pinpoint pupils
- Noncardiac pulmonary edema

Signs and Symptoms

Sympathomimetic Toxicity

- Tachycardia
- Hypertension
- Agitation
- Seizures
- Hyperthermia
- Dilated pupils
- Diaphoresis

Medication Reaction Syndromes

Malignant hyperthermia is a condition that occurs following administration of succinylcholine or certain inhaled anesthetic agents to genetically susceptible patients. CCTPs may encounter this condition following a rapid sequence intubation (RSI) procedure in the prehospital setting or when responding to a health care facility to perform a patient transport. Patients have muscle spasms, profound muscle rigidity, acidosis (metabolic or respiratory), hyperthermia, tachycardia, tachypnea, myoglobinuria, rhabdomyolysis, and hyperkalemia, beginning up to 12 hours after exposure. Treatment involves aggressive cooling, correction of acidosis, and administration of dantrolene sodium, 2 to 3 mg/kg. Larger patients may require massive quantities of dantrolene for severe reactions; some reports have described the need for more than 36 vials, each containing 20 mg of dantrolene, with 3 g of mannitol. The Malignant Hyperthermia Association of the United States recommends that facilities stock 36 vials of dantrolene to provide initial treatment for a patient weighing 100 to 110 kg, who may require 8 to 10 mg/kg for stabilization.

Neuroleptic malignant syndrome (NMS) is a potentially fatal reaction to antipsychotic and antischizophrenic medications (such as haloperidol [Haldol], prochlorperazine [Compazine], promethazine [Phenergan], and risperidone [Risperdal]), which is not dose dependent and has a 5% to 11% mortality rate overall. Patients often have hyperthermia, profound muscle rigidity, metabolic acidosis, and confusion. Severe manifestations include renal failure, respiratory failure, arrhythmias, and cardiovascular collapse. Supportive treatment involves aggressive cooling and muscle relaxation. Prompt, effective muscle relaxation with nondepolarizing neuromuscular blocking agents, dantrolene sodium, and benzodiazepines will prevent many catastrophic consequences of NMS.

Signs and Symptoms

Malignant Hyperthermia

- Muscle spasms
- Profound muscle rigidity
- Acidosis (metabolic or respiratory)
- Hyperthermia
- Tachycardia
- Tachypnea
- Myoglobinuria
- Rhabdomyolysis
- Hyperkalemia

Signs and Symptoms

Neuroleptic Malignant Syndrome

- Hyperthermia
- Profound muscle rigidity
- Metabolic acidosis
- Confusion

Serotonin syndrome is an unusual response to serotonin-altering medications causing hyperserotoninergic symptoms. Selective serotonin reuptake inhibitors (SSRIs; such as fluoxetine [Prozac], sertraline [Zoloft], and paroxetine hydrochloride [Paxil]), meperidine (Demerol), and monoamine oxidase inhibitors (also called MAOIs; such as phenelzine sulfate [Nardil] and tranylcypromine [Parnate]) are the usual culprits. Amphetamines, TCAs, and lithium are implicated less frequently. Serotonin syndrome may occur following an SSRI (or similar) overdose or when the aforementioned medications are inadvertently combined. Patients have irritability, muscle rigidity, hyperthermia, diaphoresis, headaches, seizures, coma, tachycardia, and hallucinations. Treatment includes aggressive cooling, IV hydration, and seizure control. Muscle relaxation is achieved with sedation and nondepolarizing neuromuscular blocking agents. **Rhabdomyolysis** is treated with sodium bicarbonate and aggressive IV fluid administration. Serotonin antagonist medications have been tested but are not currently recommended for widespread use.

Signs and Symptoms

Serotonin Syndrome

- Irritability
- Muscle rigidity
- Hyperthermia
- Diaphoresis
- Headaches
- Seizures

- Coma
- Tachycardia
- Hallucinations

General Toxicologic Emergency Management

Introduction

Management of toxicologic emergencies includes many interventions common to other areas of critical care transport. Interventions to maintain and enhance the ABCs are discussed in greater depth in Chapter 6. In many toxicologic emergencies, decontamination, enhanced elimination, and antidote administration will not become effective rapidly enough to correct immediately life-threatening problems with the ABCs, although there are a few notable exceptions (such as naloxone for opioid overdose and atropine for acetylcholinesterase toxicity). CCTPs are strongly discouraged from delaying basic ABC interventions while locating, administering, or waiting for a possible antidote to work. Wasted time will prove fatal in many cases.

There are two distinct types of decontamination below, each with a unique purpose. **Primary decontamination** usually is done on a scene or outside a health care facility or transport vehicle to protect rescuers and health care providers from exposure to a toxic substance during patient care or transport. **Secondary decontamination** still requires health care providers to use PPE but is directed at minimizing patient absorption or injury from a toxic substance. The risk to health care providers during secondary decontamination is typically much less than before or during primary decontamination. Gastric decontamination or eye irrigation should be performed well after the ABCs are addressed. Decontamination of a hazardous chemical should occur before an unprotected health care provider makes any contact whatsoever. Both types of decontamination are beneficial to patients, but each must be considered separately to avoid confusion in the following text. Enhanced elimination is the practice of augmenting the body's removal of a toxic substance (or metabolite) once systemic absorption has occurred.

The term *antidote* may be confusing. Certain substances have an identified antidote, which counteracts toxicity through a mechanism clearly related to the particular toxic substance (for example, acetylcysteine [Mucomyst, Acetadote] for acetaminophen overdose). Other toxic exposures cause signs and symptoms amenable to treatment by a variety of medications that treat these symptoms in other situations (for example, benzodiazepines treating seizures caused by a vast array of toxic chemicals or other causes). The line between antidote and other pharmacologic interventions is not important to the outcome but is mentioned to avoid confusion. For many toxic substances, there is a preferred medication to treat a particular sign or symptom, but the term antidote implies a complete reversal of toxicity, which does not usually occur.

Safety

The transport of a patient exposed to a toxic substance should not pose an increased risk to critical care transport personnel if safety considerations are adequately addressed. Potentially suicidal, combative, aggressive, violent, intoxicated, and confused patients should be restrained before transport. Physical restraint includes the spectrum from soft limb restraints, to four-point leather or nylon restraints with additional cross-straps, to handcuffs and shackles for transport of prisoners (prisoners are almost always handcuffed unless they are sedated, intubated, or paralyzed). CCTPs should follow local agency policies when applying or transporting patients in physical restraints.

In addition to physical restraints, CCTPs should consider chemical restraint for patients in the

aforementioned circumstances. Chemical restraint may involve a mild oral sedative and, for extremely high-risk patients, intubation. Local guidelines should be followed for the use of chemical restraint. Air medical crews should consider alternative ground transport if patients cannot be adequately restrained. Ground transport crews should consider taking extra personnel or delaying transport if crew safety cannot be ensured. CCTPs should also be aware of family members, visitors, and prospective passengers who might be carrying weapons or are exhibiting dangerous behavior.

CCTPs risk illness or injury if PPE is not used and adequate decontamination has not occurred before they treat patients exposed to a vast array of toxic substances. Depending on the profile of the critical care transport agency, providers may or may not be actively involved in extrication and decontamination at hazardous material scenes. All transport providers must assess the adequacy of PPE and decontamination before making patient contact or placing the patient in the transport vehicle. Contaminated patients may expose health care providers to potentially lethal substances or incapacitate a pilot or driver, leading to a crash. Decontamination is discussed in greater depth later in this chapter. Crew members should consult a Poison Center at the nationwide number, 1-800-222-1222, Chemtrec at 1-800-262-8200, or a reliable reference source before approaching or transporting a patient exposed to suspected hazardous materials.

Airway

Patients with actual or impending airway compromise require definitive airway management. Endotracheal intubation provides optimal protection for an obtunded or otherwise at-risk patient. If endotracheal intubation is unsuccessful, several additional airway devices will provide varying degrees of protection until endotracheal intubation is performed. Hypoxia and aspiration should be avoided during airway adjunct placement. Devices such as the gum elastic bougie and techniques such as external laryngeal manipulation enhance the likelihood of successful endotracheal intubation. Continuous monitoring of oxygen saturation (SpO_2) and $ETCO_2$ will alert CCTPs to a displaced, clogged, or disconnected ET tube. Laryngeal mask airways and multilumen airways such as the Combitube can be used with continuous $ETCO_2$ monitors and ventilators. Intubated and nonintubated patients require the same degree of observation for airway compromise during critical care transport. Patients exposed to cholinergic or other secretion-producing substances are likely to require frequent ET suctioning.

Breathing

Spontaneously breathing patients may not be oxygenating and ventilating adequately to meet physiologic needs following a poisoning or overdose. Apneic patients require total extrinsic ventilatory support. In either case, oxygenation and ventilation need to be supported externally with positive-pressure ventilation and/or supplemental oxygen.

It is important to provide the correct oxygen concentration and ventilator settings for each patient and clinical situation. In carbon monoxide poisoning situations, for example, patients should receive 100% oxygen, despite normal oxygen saturation readings. The carbon monoxide bound to hemoglobin is misinterpreted as oxygen by conventional pulse oximetry devices, causing falsely elevated readings.

Conventional ventilator settings are often inadequate for a patient's needs following a poisoning or an overdose. Catastrophic consequences may occur if a patient who is hyperventilating to compensate for severe metabolic acidosis is chemically paralyzed and conventional ventilator settings are used. Respiratory compensation no longer protects the body from the devastating effects of the metabolic acidosis, leading to widespread organ, tissue, and cell dysfunction.

Alterations in pH also occur if a patient has underlying metabolic alkalosis and receives aggressive mechanical ventilation, further disrupting the essential pH balance. Any deviations from normal pH

impair the performance of body systems. Pulmonary edema, hypoxia, cardiovascular dysfunction, and hypermetabolic states each require special consideration when initiating and adjusting positive pressure ventilation. Hypermetabolic states require greater ventilation for removal of carbon dioxide than would otherwise be required. Cardiovascular dysfunction, persistent hypoxia, pulmonary edema, and acute respiratory distress syndrome each may benefit from precise adjustment of positive end-expiratory pressure. Chapter 6 provides more discussion on ventilator settings.

Oxygen saturation, blood gas analysis, and $ETCO_2$ provide valuable information when assessing the adequacy of oxygenation and ventilation. Changes in lung sounds, patient appearance, and cardiovascular function (as shown by ECG and assessment of perfusion) indicate improving or worsening respiratory functioning during transport. **Pulse CO-oximetry** is a technology available for noninvasive screening and monitoring for methemoglobinemia and carbon monoxide exposure **Figure 20-2**.

Circulation

Circulatory support for critically ill patients includes managing cardiac function, fluid balance, and vascular tone. Toxic exposures may adversely affect all of these components simultaneously. Impaired circulation may be caused by an airway or breathing problem (resulting in hypoxia and/or ischemia). Impaired airway or breathing may be resolved by a cardiovascular intervention (such as for pulmonary edema).

Figure 20-2 The Masimo Rad-57® Pulse CO-Oximeter™ allows clinicians to noninvasively measure oxygen saturation (SpO_2), carboxyhemoglobin (SpCO) and methemoglobin (SpMet) levels in the blood, as well as total hemoglobin (SpHb) and PVI for fluid responsiveness using a finger sensor.

Cardiac function is managed by medications that increase or decrease the heart rate or contractility. The therapy for an individual patient may be guided entirely by the patient's response or tailored specifically to the toxic substance involved. CCTPs should consult a reliable toxicology reference, a physician, or a Poison Center for precise guidance.

Fluid balance is closely related to vascular tone, kidney function, and electrolyte concentrations. Toxic exposures cause alterations in any of these, requiring corrective action. CCTPs should anticipate fluid volume replacement or diuresis of fluid-overloaded patients when managing circulatory function. In addition, CCTPs may need to remove excess electrolytes, replace them, or change their distribution.

Vascular tone is often managed with IV vasodilator or vasoconstrictor medications. Beta-blockers, calcium channel blockers, catecholamines, and nitrates are used along with specific agents required for peculiar toxic substances to optimize vascular tone. CCTPs should consult a toxicology reference, a physician, or a Poison Center for precise guidance.

Additional General Management

Select patients may require only minimal intervention following a suspected poisoning or drug overdose. A toddler who only possibly ingested a limited quantity of a minimally toxic substance is often managed with only observation for a prescribed period of time. Other patients may become critically ill immediately following a toxic exposure, requiring immediate invasive therapy and exhaustive critical care resources. CCTPs must evaluate the specifics of each situation and weigh the indications, risks, and benefits of each intervention considered for a given patient.

CCTPs must provide continuous assessment and monitoring of any patient being transported. Monitoring must be within the skills of the transport team and adequate for the clinical status of the patient. It is far better to perform excess monitoring (for example, ECG monitoring after exposure to a minimally toxic substance) than inadequate monitoring (for example, no pulse oximetry or capnography on an intubated patient).

Vascular access sufficient for administering emergency medications and fluids should be established in any patient exposed to a potentially harmful substance. Intubated patients require a nasogastric or orogastric tube for stomach decompression and protection from aspiration **Figure 20-3**. Patients who are unresponsive and patients requiring urine output monitoring should have an indwelling urinary catheter inserted and attached to a urine collection device.

Every patient must receive adequate sedation and analgesia while chemically paralyzed and should be prophylactically medicated against seizures. Vital signs (especially following a poisoning or overdose) are *not* a reliable method of measuring patient sedation or comfort. CCTPs frequently encounter unwarranted administration of antihypertensive medications to patients who are chemically paralyzed but lacking adequate analgesia or sedation: Discomfort is a common cause of unexplained hypertension and tachycardia in an intubated, chemically paralyzed patient. Analgesia and sedation should be administered frequently enough to avoid subtherapeutic levels. In addition, patients with increased drug tolerance or hypermetabolic states require significantly more sedation and analgesia while chemically paralyzed. Modern noninvasive commercial devices (such as the bispectral index monitor) that permit monitoring of sedation in intubated and/or chemically paralyzed patients are available.

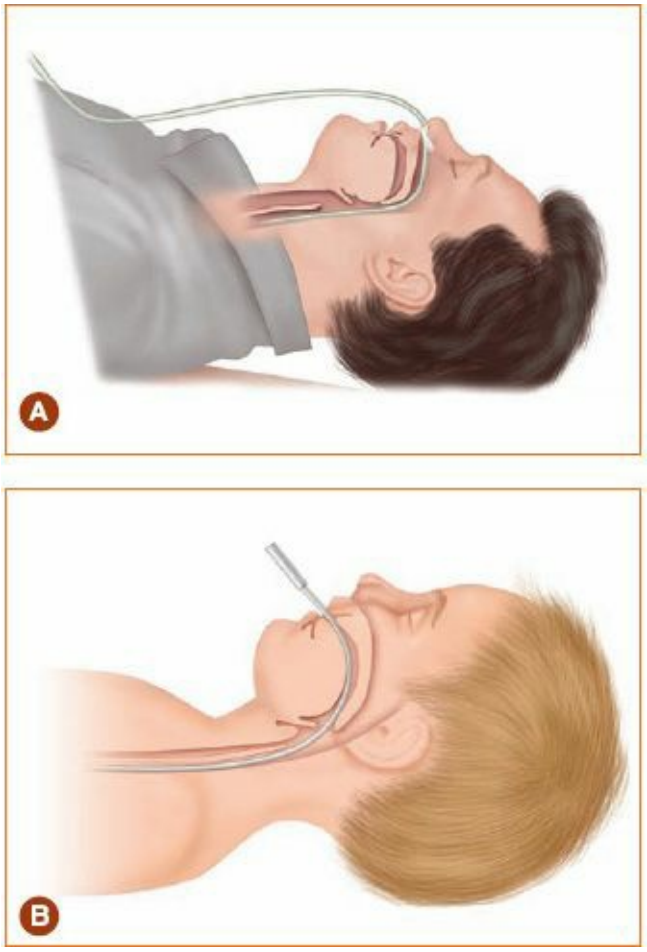

Figure 20-3 A nasogastric **(A)** or an orogastric **(B)** tube is required for stomach decompression and protection from aspiration in intubated patients.

Every patient should experience treatment that provides maximum comfort, privacy, and dignity, within the context of the clinical situation. Patients should be protected from unintentional temperature alterations. Environmental exposure (for example, to hot, cold, moisture, or noise) during transport, while loading or unloading patients, and in health care facilities can adversely impact patient care. Patients experience the same stressors of flight as do air-medical crew members but are frequently more susceptible and lack sufficient reserves to avoid detrimental consequences. Patients in ground transport units traveling through significant altitude changes will experience physiologic stressors similar to those in flight.

Nonintubated patients require **anxiolysis** and analgesia following many toxicologic exposures. Psychiatric and other at-risk patients may require sedative medications to facilitate care and promote comfort. Family members and friends should be assessed for dysfunctional coping during any crisis situation.

Decontamination

Patient decontamination following exposure to a toxic substance is directed at minimizing the quantity of that substance absorbed by the patient and the extent of any local damage. Decontamination may be as simple as providing the patient with fresh air for several minutes or as complicated as whole-bowel irrigation (WBI), taking many hours to perform. Prompt, effective decontamination has the potential to prevent the fatal consequences of an otherwise lethal overdose.

Skin Decontamination

Caustic agents and acetylcholinesterase inhibitors (such as pesticides and chemical weapons) can cause systemic toxic effects from dermal absorption. It is essential that health care providers use the correct PPE during skin decontamination. Numerous other chemicals cause severe local reactions or burns when placed in contact with skin. Skin decontamination, like all other methods of decontamination, is most effective if initiated immediately following exposure and may have no benefit if significantly delayed. Certain agents, such as sodium hydroxide and potassium hydroxide, react violently with water and require a specialized approach to skin and eye decontamination.

Any potentially contaminated clothing must be removed. Dry powders must be gently brushed away **Figure 20-4** and then the affected area should be flushed with copious amounts of water or saline. During irrigation, particular attention should be given to the patient's ears and groin, the area between the fingers and toes, and any skin folds. Hydrocarbon-based products often require a mild soap or shampoo for more effective removal.

No attempt should be made to neutralize chemicals on the skin; frequently, the reaction generates heat and causes additional injury. Only four chemicals are recommended for topical treatment beyond irrigation: hydrofluoric acid treated with calcium, oxalic acid treated with calcium, phenol treated with mineral oil or isopropyl alcohol, and white phosphorus treated with 1% copper sulfate. A reliable reference should be consulted before topical treatment is given.

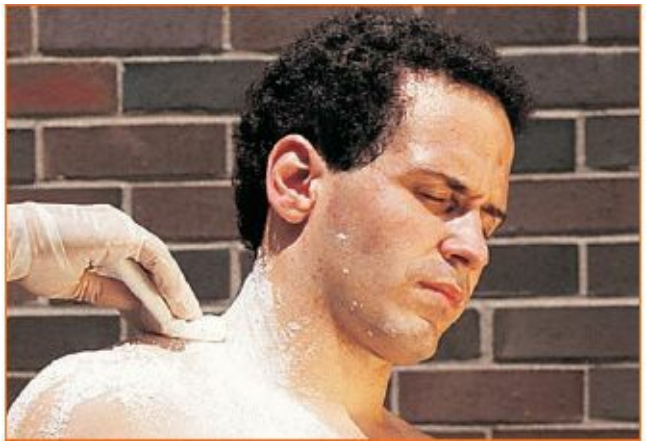

Figure 20-4 To decontaminate skin, gently brush away any dry powders before flushing the area with water or saline. Always ensure protection against hypothermia after decontamination because patients get cold quickly.

Figure 20-5 An irrigation adjunct, like the Morgan Lens, can help flush toxins away from the eye.

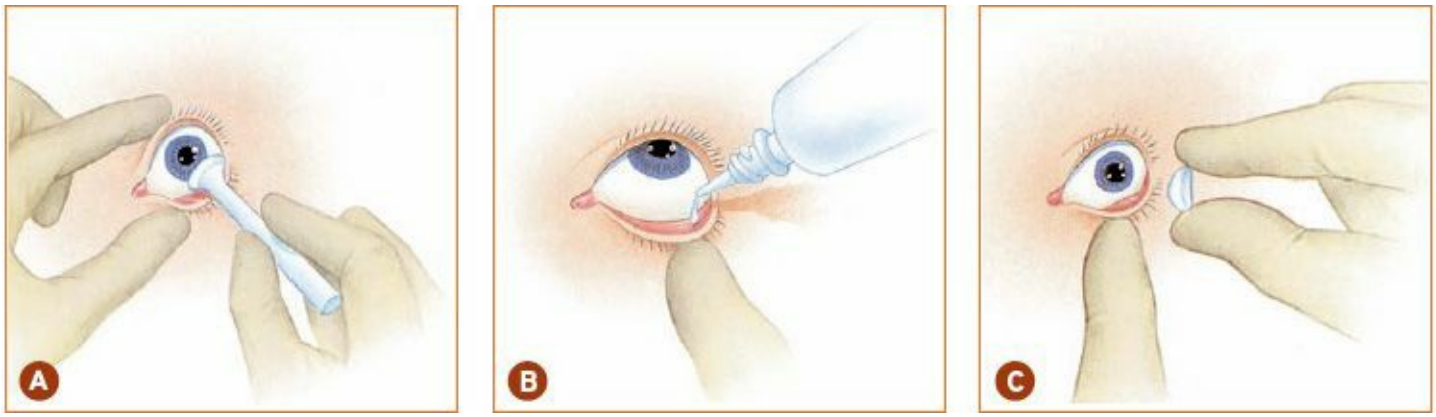

Figure 20-6 Remove contact lenses still in place before irrigation. **A.** To remove hard contact lenses, use a specialized suction cup moistened with sterile saline solution. **B.** To remove soft contact lenses, instill 1 or 2 drops of saline or irrigating solution. **C.** Pinch off the lens with your gloved thumb and index finger.

Ocular Decontamination

Many agents that cause toxicity from skin exposure will also cause damage when in contact with the eyes. The cornea is extremely sensitive to hydrocarbons and corrosive agents.

Each affected eye should be flushed with copious amounts of water, saline, or other approved solution. Local ocular anesthetic drops along with a commercially available irrigation adjunct (Morgan Lens) may be used **Figure 20-5**. Before irrigation, contact lenses still in place need to be removed **Figure 20-6**.

Each eye needs to be irrigated with at least 1 L of water, until the ocular pH is normal following exposure to an acid or base. (Ocular pH is tested by touching the pH paper to the moist surface of the conjunctival cul-de-sac of the affected eye. The pH paper is then compared with the shades on the package.) No attempt should be made to neutralize chemicals in the eye. The neutralization reaction often produces heat, capable of causing devastating injury. Once irrigation is complete, a Poison Center should be consulted for definitive treatment or a thorough ophthalmology exam should be arranged for any significant exposures.

Gastric Decontamination

Patients who have ingested toxic chemicals or dangerous amounts of otherwise therapeutic medications may benefit from gastrointestinal (GI) decontamination. Gastrointestinal decontamination is accomplished through gastric lavage and emptying, activated charcoal administration, and WBI. In each case, the goal is the prevention of systemic absorption of a toxic chemical or medication.

Orogastric Lavage

Pills, pill fragments, and liquid toxins can be removed from the stomach by gastric lavage. This procedure was once widely accepted, but it is now limited to a very small number of clinical situations. In addition, it is not performed in the transport setting. Patients who go to a health care facility within 1 hour of taking a life-threatening ingestion are candidates for gastric lavage. Indications include the following:

- Highly toxic ingestion, likely to remain unabsorbed in the stomach
- Substances poorly absorbed by activated charcoal
- No effective antidote or treatment therapy currently available

Despite the potential to prevent harmful stomach contents from being absorbed, gastric lavage has

several disadvantages. It is a time-consuming, invasive procedure that will delay administration of activated charcoal or oral antidote medications. The amount of actual pill (or fragment) that is removed is limited. This procedure requires cooperation from awake, alert patients. Resistance is common, and sedative medications place patients at increased risk of aspiration. In addition, gastric lavage may propel toxic substances further into the digestive tract and limit the effectiveness of other treatments. The role of gastric lavage following a caustic ingestion is controversial. Contraindications include the following:

- Minimally toxic ingestion
- Significant time since ingestion and absorption has likely occurred
- Highly effective antidote available
- Inability of patient to protect airway during the procedure (ET intubation may be required before gastric lavage)

In terms of complications, aspiration is the main risk during gastric lavage. An injury to the airway, stomach, and esophagus is also possible.

Highly toxic liquids can be evacuated from the stomach using a common orogastric or nasogastric tube much more quickly than by the conventional gastric lavage procedure. For pills or pill fragments, a large (36F to 40F in adults) orogastric tube is inserted. Patients are placed in the left lateral position. After placement confirmation, saline or water is alternately instilled and removed until the effluent is clear (no pills, fragments, or stomach contents visible), or, in adults, until 2 L has been instilled and removed. Patients, especially children, need to be monitored for electrolyte abnormality and hypothermia. At the completion of the procedure, the orogastric tube provides easy access for the administration of activated charcoal. A closed system **Figure 20-7** prevents cross contamination by containing the gastric contents. Some sets include a port for charcoal administration to maintain the closed system.

Emesis induced by syrup of ipecac is no longer a routine treatment of toxic ingestions. Health care providers may encounter patients who received ipecac administered by misinformed members of the public or in one of the rare situations in which ipecac may be beneficial. Ipecac-induced emesis theoretically removes a portion (approximately 28%) of ingested toxins before systemic absorption.

Figure 20-7 A closed system for gastric lavage. The tubes shown range from sizes 32F to 36F and the solution bag holds 3.5 L.

Ipecac is generally limited to home use when patients would have a long delay before access to activated charcoal treatment. Similarly, patients who ingest chemicals or medications not well absorbed by activated charcoal might be candidates for ipecac, although WBI is preferred. Pills with a larger diameter than an appropriately sized orogastric tube are another possible indication for ipecac-induced emesis for gastric emptying.

Ipecac has many contraindications and side effects, almost completely eliminating its usefulness in toxic ingestions. Any patient who is sedated, obtunded, or has a history of seizure activity is not a candidate for ipecac. Ingestion of any medication with the potential for CNS depression or seizures, any hydrocarbon, or any corrosive agent is an absolute contraindication to ipecac. Aspiration is a potentially lethal consequence of inappropriate administration of ipecac. Side effects of ipecac include sedation, vomiting-related trauma (including Mallory-Weiss tear), and delay in the administration of activated charcoal or oral antidote.

Activated Charcoal

Ingestions of numerous medications and chemicals are amenable to absorption with activated charcoal in the digestive tract. **Activated charcoal** is a carbon-based liquid with an incredible absorptive ability **Figure 20-8**. It is typically administered orally or via a nasogastric or orogastric tube to decrease the available quantity of a toxic substance. Activated charcoal also has the novel ability to remove certain toxic substances from circulating blood by "gut dialysis." Orally administered activated charcoal can reduce the available quantity of a purely IV overdose of certain select medications (such as theophylline, carbamazepine, salicylates, digoxin, and some TCAs) or decrease serum drug levels long after systemic absorption has occurred. This ability is also limited to certain select chemicals.

Figure 20-8 Activated charcoal.

Activated charcoal is administered as a single dose for routine ingestions and in repeated doses for select, severe exposures. Adults usually receive 1 g/kg, and children receive 0.5 to 1 g/kg. Activated charcoal is most effective immediately following oral ingestions (within 2 hours) and may have no benefit once systemic absorption of a toxin has taken place. Activated charcoal is indicated in the following situations:

- Ingestion of a harmful amount of a substance known to be adsorbed by activated charcoal within a time frame in which **adsorption** by charcoal is likely to take place (varies dramatically by

substance and situation)
- Unknown substances ingested or presumption of toxic ingestions in high-risk patients

Toxicology reference sources are vague regarding the outer time limits for single-dose activated charcoal administration. Several factors extend the usefulness of activated charcoal beyond the 2-hour window of optimal efficacy:

- Evidence of continued medication absorption demonstrated by increasing serum levels or unexplained continued deterioration in clinical status
- Ingestion of enteric-coated or sustained-release preparations
- Ingested drug packets with likelihood of rupture
- Exposure to substances removed through gut dialysis
- Other conditions that delay toxin absorption (such as food in the stomach and delayed GI motility)

Massive overdoses may require several doses of activated charcoal to adsorb a sufficient amount of toxin in the intestines (see the later section "Multiple-Dose Activated Charcoal").

Sedated patients with an unprotected airway are not candidates for activated charcoal. Unresponsive patients needing activated charcoal require definitive airway protection with an ET tube. Aspiration is often a lethal complication. Vomiting and constipation are frequent side effects of administration. Activated charcoal is also contraindicated following caustic ingestions, because it obscures the views in diagnostic procedures, and hydrocarbon ingestions because of the high aspiration potential. Numerous substances are not well adsorbed by activated charcoal. Lithium, iron, certain heavy metals, hydrocarbons, and alcohols will not be absorbed well. There may still be some benefit to using activated charcoal when these substances are taken simultaneously with toxins that can be absorbed. A careful risk-benefit analysis is essential. Activated charcoal is often combined with a saline or magnesium-containing cathartic agent to decrease the likelihood of constipation and decrease the absorption of toxins unaffected by activated charcoal. A Poison Center or a reliable toxicology reference should be consulted to determine the appropriateness of using activated charcoal in unusual poisoning situations.

Whole-Bowel Irrigation

One additional option exists for treating ingestions of toxic substances that are not amenable to treatment with activated charcoal. **Whole-bowel irrigation (WBI)** involves the patient drinking (or receiving via orogastric or nasogastric tube) large quantities of a nonabsorbable, electrolyte-balanced liquid that propels stomach and intestinal contents through the digestive system. WBI is indicated for significant ingestions of potentially toxic substances not well adsorbed by activated charcoal (for example, iron, lithium, potassium, and heavy metals). It can be given with activated charcoal for large quantities of sustained-release or enteric-coated medications (such as calcium channel blockers and theophylline) and is also indicated when the patient has swallowed capsules containing illicit drugs (as done by body stuffers and body packers) or foreign bodies (such as batteries). This procedure is performed in the intensive care unit.

Body packers (people who swallow carefully packaged capsules for smuggling purposes) and **body stuffers** (people who hastily swallow illicit substances to avoid impending arrest) pose a challenge to health care providers. Body stuffers are at increased risk because of the often unreliable materials and marginal technique used during unplanned packaging. Patients may appear completely asymptomatic, but rapid, unexpected, catastrophic clinical instability develops as the packaging fails and the chemicals are rapidly absorbed by the digestive tract.

Commercial products for WBI are widely available and are used for other purposes, such as preparation for intestinal surgery and diagnostic procedures. Adult patients receive 1.5 to 2 L/h for 4 to 6

hours or until the rectal effluent is clear. Clinicians may use radiography to assist in the diagnosis or monitoring of radiopaque materials.

Enhanced Elimination

Certain, select poisoning and overdose situations are appropriate for **enhanced elimination**. This process replaces or augments the body's normal method of eliminating, modifying, or breaking down toxic substances. If the patient is exposed to lethal quantities of a toxic substance, the ordinary route of elimination from the body is impaired by the overdose or other pathology, or the patient will likely not tolerate adverse effects of the poisoning because of a preexisting medical condition, enhanced elimination should be considered. Substances concentrated heavily in the blood or extracellular fluids and only minimally concentrated in body tissues are more likely to respond to enhanced elimination. Highly protein-bound medications are less likely to be successfully removed. Multiple-dose activated charcoal, urinary manipulation, and various modes of dialysis each enhance elimination of certain toxins. A toxicologist or nephrologist should be consulted when considering these interventions.

Multiple-Dose Activated Charcoal

The unique ability to extract certain toxins from the bloodstream permits activated charcoal to remove chemicals and medications already absorbed into the body. Multiple-dose activated charcoal can reduce the elimination half-life of various chemicals, theoretically improving clinical outcomes. Typically, a reduced dose of activated charcoal is administered every 1 to 6 hours for several doses, or for up to 12 hours total. A toxicologist should be consulted for specific dosing recommendations.

Urinary Manipulation

Alkalinization of urinary pH promotes the increased excretion of weak acids such as salicylates and phenobarbital. Sodium bicarbonate is added to IV fluids to maintain a urinary pH of 7 to 8.5, usually by adding 1 to 2 mEq/kg every 3 to 4 hours. During therapy, fluid volume status, serum pH, and electrolytes (especially potassium and sodium) must be carefully monitored. Hypokalemia is extremely common. Frequent point-of-care testing and/or potassium replenishment during transport, if available, should be considered.

Peritoneal Dialysis, Hemodialysis, Hemoperfusion, and Continuous Renal Replacement Therapy

These modes provide additional options for clinicians managing a severe poisoning or overdose. CCTPs will be called to transport patients who are receiving these treatments. Treatments generally cannot be continued during transport and will need to be discontinued or interrupted to safely transport the patient. Specialized training and equipment is required, and the description is beyond the scope of this text. Patients requiring these services may be transported to tertiary care centers from smaller community facilities and clinics.

Specific Toxicologic Emergencies

Pharmaceutical and Abuse Agents

Acetaminophen

Acetaminophen (Tylenol, Paracetamol, APAP) is the most commonly ingested drug resulting in overdose. It is used widely as an analgesic and antipyretic and often is found combined with narcotic analgesic and cold-symptom ingredients in prescription and over-the-counter preparations. Toxicity from acetaminophen is complicated by other agents when a combination of medications is ingested.

Acetaminophen toxicity is insidious. Toxic signs and symptoms may not manifest until well after it is

too late for any beneficial effects from the known antidote (acetylcysteine). Liver failure results from untreated acetaminophen toxicity and usually requires transplantation or causes death. Ethanol, isoniazid, phenytoin, barbiturates, and carbamazepine predispose patients to increased risk of **hepatotoxicity** following overdose.

The diagnosis of acetaminophen poisoning is based on patient history and laboratory analysis. Documentation of time, duration, and nature of exposure is essential, because signs and symptoms of acetaminophen toxicity evolve in four distinct phases. The acetaminophen (Rumack-Matthew) nomogram is useful only for single, acute ingestions and is not reliable for exposures that have occurred over several hours or days, when gastric motility is altered (such as by anticholinergics or opiates), or for extended-release acetaminophen preparations **Figure 20-9**. A serum acetaminophen level should be obtained at least 4 hours (but < 24 hours) following ingestion and the level and time plotted on the nomogram. The nomogram will indicate whether toxicity is anticipated and treatment is indicated. *Once toxicity is established, future acetaminophen levels will not assist clinical management*. The serum acetaminophen level will continue to decline regardless of toxicity. A metabolite actually causes hepatotoxicity, misleading providers into discontinuing antidote administration prematurely based on a decreasing acetaminophen level. A toxicologist should be consulted for situations not covered adequately by the nomogram or if treatment questions persist.

Figure 20-9 The acetaminophen nomogram. Reproduced from *Pediatrics*, Vol. 55, Pages 871-876. Copyright 1976 by the AAP.

Nausea and vomiting are quite common during acetaminophen toxicity. In addition, patients have anorexia, dehydration, diaphoresis, and elevated liver function test results. During subsequent days, abdominal pain (usually in the right upper quadrant), oliguria, hepatomegaly, coagulopathy, and eventual liver failure develop. A patient who presents with abdominal pain, nausea, and/or vomiting following a probable acetaminophen overdose should be assumed to have toxicity until proven otherwise.

Acetaminophen toxicity is treated with initial GI decontamination with activated charcoal. Acetylcysteine can be given orally or intravenously as the antidote for acetaminophen. Acetylcysteine can prevent serious hepatotoxicity from acetaminophen when initiated within 24 hours of ingestion and can

completely eliminate toxic effects when given within 8 hours.

Signs and Symptoms

Acetaminophen Toxicity

- Phase 1 (0 to 24 h):
  - Nausea and vomiting
  - Anorexia
  - Dehydration
  - Diaphoresis
  - Elevated liver function test results
- Phase 2 (24 to 72 h):
  - Abdominal pain (usually in the right upper quadrant)
  - Continued elevation of liver function test results
- Phase 3 (72 to 96 h):
  - Oliguria
  - Hepatomegaly
  - Coagulopathy
  - Liver failure
- Phase 4 (longer than 4 days):
  - Resolution of symptoms or multiple organ failure

Transport Management

Acetaminophen Toxicity

- Manage the ABCs.
- Perform GI decontamination with activated charcoal.
- Administer acetylcysteine (Mucomyst or IV Acetadote).

Treatment with acetylcysteine should begin immediately for symptomatic patients presenting more than 8 hours after ingestion. Oral acetylcysteine is given with a 140-mg/kg loading dose, followed by 70 mg/kg every 4 hours for 17 additional doses. Patients often require aggressive treatment with antiemetics during oral acetylcysteine therapy. Refractory vomiting, from toxicity or related to oral acetylcysteine, often requires IV acetylcysteine. Patients with uncomplicated acetaminophen poisoning who require IV acetylcysteine generally receive 20 hours of treatment. A loading dose is administered over 15 to 60 minutes followed by an IV infusion. Fluid and electrolyte abnormalities are possible when pediatric patients receive intravenous acetylcysteine. In emergency situations, the oral preparation can be given intravenously through an inline micropore filter. A toxicologist or a Poison Center should be consulted for specific IV dosing recommendations.

Amphetamines

Amphetamines are available as therapeutic medications (such as methylphenidate [Ritalin, Concerta],

amphetamine-dextroamphetamine combination [Adderall], and dextroamphetamine [Dexedrine]); used as illicit stimulants for personal, academic, or professional enhancement; and abused in society for euphoric properties (for example, ecstasy and methamphetamines). These drugs produce many desirable and adverse effects through central and peripheral nervous system stimulation. An amphetamine dose-toxicity paradox exists. A tolerance quickly develops in frequent users, but toxicity may occur when there is only a slight increase in the dose beyond the "therapeutic" range.

Patients have classic sympathomimetic symptoms (also discussed earlier in the "Toxic Syndromes [Toxidromes] and Medication Reaction Syndromes" section). Amphetamine toxicity produces hypertension, tachycardia, hyperactivity (although amphetamines are often used in the treatment of hyperactivity disorders), restlessness, anxiety, diaphoresis, tremors, fasciculations, and rhabdomyolysis. Severe toxicity causes seizures, myocardial ischemia, and cerebral hemorrhage. Amphetamines may cause **methamphetamine washout syndrome** (similar to cocaine washout syndrome, sometimes referred to as a meth-crash) when used in larger quantities over a longer period of time. Amine stores within the body become depleted following prolonged amphetamine use, leading to excessive sleep, hunger, and depression. This syndrome is completely opposite of the typical effects of amphetamine use.

Urine drug screening may identify patients taking amphetamines. Serum drug levels are not clinically useful. The urine output and results of blood tests should be monitored for signs of dehydration and rhabdomyolysis.

Decontamination with activated charcoal or WBI should be considered when clinically appropriate. The treatment is supportive and based entirely on presenting signs and symptoms. Benzodiazepines are used initially for seizure control or sedation and can be supplemented with phenobarbital for seizures and haloperidol for sedation, if needed. Patients with significant hyperthermia should be cooled aggressively. Fluids should be replaced by the IV route as clinically indicated. Hypertension that does not respond to sedative medications is treated with vasodilators. Tachyarrhythmias can be treated with IV esmolol and propranolol.

Signs and Symptoms

Amphetamine Overdose

- Hypertension
- Tachycardia
- Hyperactivity, restlessness, and anxiety
- Diaphoresis
- Tremors
- Fasciculations
- Rhabdomyolysis
- Seizures
- Myocardial ischemia
- Cerebral hemorrhage

Transport Management

Amphetamine Overdose

- Manage the ABCs.
- Perform GI decontamination with activated charcoal.
- Administer benzodiazepines for seizure control or sedation.
- Administer phenobarbital and haloperidol (Haldol), if needed.
- Provide aggressive cooling for significant hyperthermia.
- Replace IV fluids.
- Administer vasodilators for refractory hypertension.
- Administer IV esmolol and propranolol for tachyarrhythmias.

Benzodiazepines

Benzodiazepines (for example, diazepam [Valium], midazolam [Versed], and lorazepam [Ativan]) are a group of medications used therapeutically for anxiolysis, sedation, muscle relaxation, and seizure control. Toxicity occurs following therapeutic error, accidental or intentional ingestion, and illicit misuse and abuse in the community. Judicious administration by health care providers may prevent serious adverse effects when these medications are used therapeutically.

Deaths due to pure benzodiazepine overdoses are rare. Overdoses are often easy to manage conservatively, although sedation and respiratory depression may persist for several days with certain preparations. Benzodiazepine exposure becomes problematic when multiple agents with sedative properties are combined. When benzodiazepines are taken with ethanol, narcotics, and other sedative agents, profound CNS and respiratory depression occurs. Toxic effects also include hypothermia, ataxia, and slurred speech. Most urine drug screens test for benzodiazepines, although clonazepam (Klonopin) and alprazolam (Xanax) often are not detectable in the urine.

Activated charcoal adsorbs orally ingested benzodiazepines, but it is often contraindicated by an unintubated patient's decreased level of consciousness. Intubation should be considered whenever there is significant concern about a patient's ability to protect his or her airway, especially during transport. The majority of patients require only conservative management and careful observation.

Flumazenil (Romazicon) is a benzodiazepine antagonist, only appropriate for a small minority of overdose situations. Benzodiazepines, even in toxic doses, exert sedative and seizure-protective effects, which are desirable during clinical treatment. Reversal with flumazenil places patients at risk for increased intracranial pressure, sedative withdrawal, increased agitation, and potentially untreatable seizure activity. Flumazenil is contraindicated in poisoning or overdose by unknown substance(s); patients with a history of seizures; toxic exposures to chemicals known to cause seizures, increased intracranial pressure, agitation, or CNS stimulation; and patients taking benzodiazepine medications on a long-term basis. The vast array of situations contraindicating flumazenil severely limits its usefulness following benzodiazepine overdose. Flumazenil is useful when a therapeutic error during procedural sedation requires benzodiazepine reversal. The toxic effects of many benzodiazepines last much longer than reversal with flumazenil. Unrecognized resedation will occur in patients not monitored adequately. The adult dose is 0.2 mg IV, increased to 0.3 and 0.5 mg at 30-second intervals for a maximum dose of 3 mg. Children's doses are titrated beginning at 0.01 mg/kg up to a maximum of 1 mg total. Flumazenil still has safe use in situations in which CCTPs are confident of the substances being treated and the clinical status of the patient, such as overmedication during procedural sedation. These types of situations may not occur frequently enough in critical care transport to justify routine use of flumazenil by CCTPs.

Signs and Symptoms

Benzodiazepine Overdose

- CNS and respiratory depression
- Hypothermia
- Ataxia
- Slurred speech

Transport Management

Benzodiazepine Overdose

- Manage the ABCs.
- Perform GI decontamination with activated charcoal unless an unintubated patient has a decreased level of consciousness.
- Intubate the patient.

Beta-Adrenergic Blocking Agents

Beta-adrenergic blocking agents (beta-blockers) are used therapeutically for a wide variety of medical conditions. Toxicity occurs from an intentional or accidental overdose in the community or profound therapeutic error in a health care facility. Atenolol (Tenormin), propranolol (Inderal), and metoprolol (Lopressor) are common beta-blockers. These medications inhibit catecholamines centrally and peripherally. Beta-1 blockers decrease heart rate, myocardial contractility, myocardial conduction, and myocardial oxygen consumption. Beta-2 blockers relax blood vessel walls, constrict bronchi in the lungs, and block catecholamines in the GI and genitourinary tracts. Beta-1 and beta-2 blockers cause hypoglycemia through inhibition of **glycogenolysis** and **gluconeogenesis**. These medications are prescribed based on their beta-1– or beta-2–blocking actions. During overdoses, any beta selectivity is lost, resulting in beta-1– *and* beta-2–blocking effects.

Patient response is largely related to preexisting cardiovascular status. One normal dose for an adult may have catastrophic effects on a small child. An overdose is significantly worse if beta-blockers are combined with other cardiotoxic substances. In adults, two to three times the therapeutic dose has the potential to be fatal.

In addition to hypotension, bradycardia, and hypoglycemia, patients may exhibit bronchospasm, conduction disturbances, pulmonary edema, and, sometimes, seizures, mental status depression, and even tachycardia. Gastric lavage is indicated for recent (< 1 to 2 hours), significant ingestions (but is not performed in the transport setting). Activated charcoal is also administered immediately after lavage or as soon as possible after a toxic ingestion. Some, but not all, beta-blockers can be removed by dialysis for enhanced elimination.

Signs and Symptoms

Beta-Adrenergic Blocking Agent Overdose

- Hypotension
- Bradycardia
- Hypoglycemia

- Bronchospasm
- Conduction disturbances
- Pulmonary edema
- Possible seizures, mental status depression, and tachycardia

Transport Management

Beta-Adrenergic Blocking Agent Overdose

- Manage the ABCs.
- Administer activated charcoal.
- Provide enhanced elimination.
- Administer glucagon.
- Administer IV atropine or use cardiac pacing for bradycardia.
- Administer catecholamines, including dopamine and epinephrine, for refractory hypotension and bradycardia.
- Administer high-dose insulin (given with glucose).
- Administer milrinone when invasive monitoring technology is available.

Glucagon is the treatment of choice for a beta-blocker overdose. When given at increased doses, it exerts a positive inotropic effect. An initial dose of 5 to 10 mg IV is followed by an infusion at 1 to 5 mg/h in adults. This treatment requires a significant amount of glucagon, often more than is available to transport teams. Glucagon is normally reconstituted with phenol. With the quantity of glucagon required, phenol toxicity may occur. To avoid the risk of phenol toxicity, glucagon powder should be reconstituted with normal saline or 5% dextrose in water.

Bradycardia is initially treated with IV atropine (0.01 to 0.03 mg/kg) or cardiac pacing. Some sources recommend an isoproterenol infusion beginning at 4 µg/min and titrated to effect. Catecholamines, including dopamine and epinephrine, are given for refractory hypotension and bradycardia. In addition, high-dose insulin (given with glucose to prevent hypoglycemia) has been shown to improve survival in beta-blocker overdoses. **Phosphodiesterase** inhibitors (for example, milrinone) have an **inotropic** effect in beta-blocker overdoses but should be used only when invasive monitoring technology is available because they often result in hypotension. A toxicologist or a Poison Center should be consulted for guidance during complicated transports.

Calcium Antagonists (Calcium Channel Blockers)

Calcium channel blockers are used clinically to treat hypertension, migraines, cardiomyopathy, and other conditions. These medications include amlodipine (Norvasc), diltiazem (Cardizem), and verapamil (Calan). They act by decreasing intracellular calcium, resulting in vasodilation, decreased myocardial contractility, slowed conduction, and decreased heart rate. Management of calcium channel blocker overdoses is complicated by the widespread availability of sustained-release preparations.

Signs and Symptoms

Calcium Antagonist Overdose

- Hypotension
- Bradycardia
- Nausea and vomiting
- Altered mental status
- Metabolic acidosis
- Hyperglycemia

Transport Management

Calcium Antagonist Overdose

- Manage the ABCs.
- Perform GI decontamination with activated charcoal.
- Administer IV calcium chloride or calcium gluconate.
- Administer glucagon, high-dose insulin, and epinephrine for hypotension and bradycardia.
- Perform cardiac pacing for bradycardia.
- Administer milrinone.

Hypotension and bradycardia are the most common signs of overdose with calcium channel blockers. Other effects include nausea, vomiting, altered mental status, metabolic acidosis, and hyperglycemia. These clinical features may evolve as additional medication is absorbed from sustained-release preparations. One tablet is often enough to cause serious toxicity or death in a small child. Any medication taken beyond the therapeutic dose should be considered potentially toxic.

Gastrointestinal decontamination is accomplished with activated charcoal, often given in repeated doses. Gastric lavage should be considered for recent, severe ingestions. The use of WBI is appropriate for enteric-coated or sustained-release preparations but is not done by CCTPs.

IV calcium is the antidote to an overdose with a calcium channel blocker. *If the overdose includes any cardiac glycoside medications (for example, digitalis), IV calcium should be avoided owing to the risk of lethal arrhythmias*. Adult patients are given calcium chloride 10% (10 mL) or calcium gluconate 10% (20 mL) every 5 to 10 minutes as needed. In severe cases, patients have received more than 15 g of calcium safely. Glucagon, high-dose insulin, and epinephrine are useful in the management of hypotension and bradycardias associated with an overdose with calcium channel blockers. In addition, cardiac pacing may be required for severe, symptomatic bradycardia. Select phosphodiesterase inhibitors (such as milrinone) improve contractility but often result in systemic vasodilation, limiting their usefulness. Atropine is not generally helpful for overdoses with calcium channel blockers.

Cardiac Glycosides

Cardiac glycosides are used therapeutically as digoxin and digitoxin for heart rate control and increased contractility in heart failure and supraventricular arrhythmias. Cardiac glycosides are also found naturally in plants such as foxglove, oleander, and lily of the valley. Peak effects from oral ingestion occur in 6 to 12 hours. Potential ingestions require 12 to 24 hours of observation before discharge of the patient from the health care facility.

Symptoms of cardiac glycoside toxicity are often vague, frequently resulting in misdiagnosis. Patients have nausea, vomiting, and abdominal pain, possibly accompanied by lethargy, confusion, weakness, and/or yellow-green visual disturbance. Almost any ECG change (with the exception of supraventricular

tachycardia) may be present. Bradycardia and conduction disturbances are common. Hyperkalemia is common following cardiac glycoside toxicity. Hypokalemia predisposes to toxicity in patients receiving digoxin or digitoxin. Serum drug levels are extremely valuable in the diagnosis and management of cardiac glycoside poisoning. The therapeutic level of digoxin is 0.5 to 2 ng/mL; and digitoxin, 10 to 30 ng/mL. These levels become falsely elevated during digoxin immune Fab (ovine) (Digibind) treatments, discussed subsequently.

Cardiac glycosides are adsorbed in the intestines by activated charcoal. Severe exposures will benefit from multidose charcoal (discussed in the earlier section "Multiple-Dose Activated Charcoal"). Gastric lavage is not usually indicated.

Symptomatic bradycardia is treated with atropine or cardiac pacing. Hyperkalemia must be corrected promptly, without the use of calcium. *IV calcium may cause lethal arrhythmias in patients with a cardiac glycoside overdose*. Increases in the level of intracellular calcium due to cardiac glycosides are responsible for the increased myocardial contractility (beneficial) and for the development of digitalis toxicity. Calcium can prolong the PR and QRS intervals, significantly worsening digitalis toxicity. Lidocaine and phenytoin assist in the management of ventricular arrhythmias.

Digoxin-specific antibodies (Digibind and Digifab) are the antidotes for cardiac glycoside overdoses and the preferred treatment for ventricular arrhythmias. Dosing is based on the serum drug level and the patient's weight. Severe hyperkalemia, arrhythmias, and renal disease are indications for antidote administration. A toxicologist or a Poison Center should be consulted for specific treatment and dosing recommendations.

Signs and Symptoms

Cardiac Glycoside Overdose

- Nausea and vomiting
- Abdominal pain
- Possible lethargy, confusion, and/or weakness
- Bradycardia and conduction disturbances
- Hyperkalemia

Transport Management

Cardiac Glycoside Overdose

- Manage the ABCs.
- Perform GI decontamination with activated charcoal (single dose or multidose).
- Administer atropine for bradycardia.
- Perform cardiac pacing for bradycardia.
- Administer lidocaine and phenytoin for ventricular arrhythmias.
- Administer digoxin-specific antibodies (Digibind or Digifab) for ventricular arrhythmias.

Cocaine

Cocaine shares many toxic properties with amphetamines and other sympathomimetics. This potent drug is used therapeutically for anesthesia and vasoconstriction of the mucous membranes, but toxic exposures

more often occur following illicit use and abuse. Cocaine is rapidly absorbed from all mucous membranes: the GI tract, lungs, rectum, and vagina. Depending on the route and method, the effects of cocaine peak in 1 to 30 minutes, and it has a half-life of up to 90 minutes. Cocaine handlers may hide cocaine internally for smuggling purposes (body packers) or rapidly conceal cocaine internally when arrest is believed to be imminent (body stuffers), posing a particular challenge to health care providers.

Diagnosis is made by obtaining a patient history and performing urine drug screens and a clinical examination. Chest pain is the most common symptom of cocaine intoxication. In addition to myocardial ischemia and infarction, chest pain occurs from cocaine-induced aortic dissection, pneumothorax, and pneumomediastinum. Young patients, without a cardiac history, who have an acute myocardial infarction or acute coronary syndrome should be assessed for the possibility of cocaine use.

Other symptoms of cocaine intoxication involve many body systems. Ventricular and supraventricular tachycardias are common. Hypoxia, acidosis, and sympathetic stimulation contribute to the development of tachycardias. Bradycardia also occurs from vagal stimulation in select situations. Most cocaine deaths are ultimately caused by arrhythmias. Additional vascular effects include hypertension and renal or intestinal vasospasm.

Cocaine has significant effects on the CNS. Patients may have cerebral hemorrhage or infarction, coma, anxiety, agitation, delirium, and psychosis. Seizures occur following exposure, but status epilepticus suggests continued absorption or concomitant toxicity. Heavy cocaine users also have **cocaine washout syndrome**, profound exhaustion with the ability to regain normal mental status and orientation when aroused. Other harmful effects from cocaine include hyperthermia, muscle rigidity, various movement disorders, rhabdomyolysis, acidosis, pulmonary edema, and exacerbation of asthma. Patients exhibit skin alterations such as tissue necrosis, ulcerations, and scratches, sometimes because of scratching imaginary insects. The aforementioned signs and symptoms are far from a complete list of the effects of cocaine intoxication.

Signs and Symptoms

Cocaine Toxicity

- Chest pain
- Tachycardias
- Cerebral hemorrhage or infarction
- Coma
- Anxiety, agitation, delirium, and psychosis
- Seizures
- Hyperthermia
- Muscle rigidity and movement disorders
- Rhabdomyolysis
- Acidosis
- Pulmonary edema
- Exacerbation of asthma
- Skin alterations (for example, tissue necrosis, ulcerations, and scratches)

Transport Management

Cocaine Toxicity

- Manage the ABCs.
- Perform GI decontamination with activated charcoal.
- Administer benzodiazepines.
- Administer IV hydration.
- Monitor for rhabdomyolysis; alkalinize the urine with IV sodium bicarbonate if evidence of rhabdomyolysis is present.
- Provide active external cooling for hyperthermia.
- Administer vasodilators for hypertension.
- Administer thrombolytics for cocaine-induced myocardial infarction or transport patients to a health care facility capable of prompt percutaneous transluminal coronary angioplasty (PTCA).
- Administer benzodiazepines, phentolamine, and calcium channel blockers to mitigate sympathetic tone or vasospasm.
- Administer nitrates, oxygen, and aspirin for cocaine-induced myocardial infarction.
- Beta-blockers should not be administered to patients with recent cocaine ingestion.

Activated charcoal and WBI are useful for orally ingested cocaine-containing packages. The effects of orally ingested cocaine peak within 60 minutes of consumption. Activated charcoal may theoretically benefit if given immediately after ingestion, but any delay drastically reduces its efficacy. Cocaine-containing packages trapped in the digestive tract may require surgical removal if WBI is unsuccessful.

There is no antidote for cocaine. The treatment is supportive and based on clinical presentation. Benzodiazepines can be administered for agitation, anxiety, muscle rigidity, and seizure control and have a beneficial effect on hypertension. Treatment involves IV hydration adequate to maintain a urine output of at least 3 mL/kg/h, monitoring for rhabdomyolysis, alkalinizing the urine with IV sodium bicarbonate if evidence of rhabdomyolysis is present, and active external cooling for patients with hyperthermia. Various specialists (for example, in cardiology, neurosurgery, or vascular surgery) should be consulted for any cocaine-related end-organ injury.

Hypertension that does not respond to benzodiazepines should be treated with caution. Beta-blockers given for hypertension may cause an increase in blood pressure because of unopposed alpha-adrenergic stimulation. The use of a vasodilator medication should be considered instead of a beta-blocker, or other provision should be made for alpha-adrenergic control.

Cocaine-induced myocardial infarction should be treated with conventional strategies, including thrombolytics (or PTCA in the hospital in certain cases), with the exception that beta-blockers must be withheld to avoid unopposed alpha stimulation leading to severe hypertension. Benzodiazepines, phentolamine, and calcium channel blockers may additionally mitigate sympathetic tone or vasospasm in patients with cocaine intoxication. Care for cocaine-induced myocardial ischemia includes nitrates, oxygen, and aspirin.

Opioids and Opiates

Opioids are the class of chemicals that include naturally derived opiates (for example, heroin, morphine, and codeine) and newer artificial medications with the same properties (for example, fentanyl and meperidine). These chemicals are used heavily for analgesia in modern health care and also are used and abused throughout the world for their euphoric properties. Absorption occurs through oral, dermal, lung, IV, and mucosal routes, resulting in a vast range of times for onset, peak, and duration of effects. Toxicity is highly variable and is determined by the amount, route and rate of administration, and individual

tolerance.

Opioid substances may or may not be detected by routine urine drug screening tests, depending on the particular chemical involved. Prehospital and emergency department health care providers frequently encounter opioid-intoxicated patients. The diagnosis is routinely made by clinical presentation or when symptoms are reversed by an opioid antagonist such as naloxone (Narcan).

In opioid intoxication, patients have profound CNS and respiratory depression. The triad of CNS depression, respiratory depression, and pinpoint pupils offers a presumptive diagnosis. In addition, euphoria, noncardiogenic pulmonary edema, and dermatologic signs of needle marks or subcutaneous ulcerations are often present. Hypoxia and death occur following severe respiratory depression in untreated patients. Patients have more unusual symptoms when exposed to select opioids (for example, seizures with meperidine or propoxyphene; histamine release with morphine). Manifestations of hypoxic brain injury may further complicate the clinical diagnosis in opioid-intoxicated patients.

Signs and Symptoms

Opioid Toxicity

- Profound CNS and respiratory depression
- Pinpoint pupils
- Euphoria
- Noncardiogenic pulmonary edema
- Dermatologic signs of needle marks or subcutaneous ulcerations

Transport Management

Opioid Toxicity

- Manage the ABCs.
- Administer naloxone (Narcan) to reestablish a patent airway and spontaneous breathing.
- Perform GI decontamination with activated charcoal.

Airway and breathing are frequently compromised in severe opioid overdoses. Initial treatment involves establishing and maintaining a patent airway while supporting oxygenation and ventilation. Naloxone, when administered promptly, reverses the opioid effects and often reestablishes a patent airway and spontaneous breathing.

Naloxone is the most common antidote for acute opioid overdose. It can be administered intravenously, intramuscularly, subcutaneously, via ET tube, and intranasally. Dosing is titrated to reverse respiratory arrest or depression without precipitating withdrawal symptoms in long-term users. Because the reversal effects of naloxone do not last as long as the effects of many opioids, careful monitoring is needed following naloxone administration to avoid an unrecognized return of toxic effects. Naloxone can also be administered as an IV drip to maintain CNS and respiratory functioning in patients with long-acting opioid toxicity. Activated charcoal is indicated for recent oral ingestions of opioid substances, especially when they are combined with additional toxic chemicals. Following an oral opioid overdose, patients should be evaluated for the presence of acetaminophen and salicylates.

Salicylates

Poisoning from aspirin (acetylsalicylic acid) and other salicy-late-containing compounds continues to challenge health care providers. In addition to aspirin, salicylates are found in topical analgesics, liniments, and antidiarrheal agents. Toxic exposure occurs from accidental ingestion by children, therapeutic error, and as a suicidal gesture. Ingestion of less than 1 mL of a concentrated topical preparation can cause toxicity in small children.

The diagnosis of salicylate poisoning is made by obtaining a patient history and performing a clinical examination and laboratory testing. Serum salicylate levels can be obtained at most health care facilities; samples should be drawn at least 2 to 4 hours following suspected exposure (longer or with serial testing when delayed absorption is suspected). A urine salicy-late screening test allows providers to determine the presence or absence of salicylates immediately at the bedside.

Presumptive clinical diagnosis often occurs when patients report taking excessive doses of salicylate products and have tachypnea and tinnitus. Any new patient complaint of tinnitus, dizziness, or deafness should prompt an evaluation for possible salicylate poisoning. Salicylate toxicity can cause the spectrum of neurologic changes from mild confusion to coma. Nausea, vomiting, abdominal pain, GI bleeding, and hyperthermia may also be present. In severe cases, salicylates cause pulmonary edema, liver or renal failure, dehydration, electrolyte abnormalities, profound metabolic acidosis (although respiratory alkalosis is also frequently present), and coagulopathy.

Patients require careful attention to the ABCs. Initially, patients exhibit a CNS-driven tachypnea. As the poisoning evolves, the respiratory rate and depth increase to compensate for worsening metabolic acidosis. For patients who require intubation and mechanical ventilation, their rates, tidal volume, and minute volume should be matched carefully to avoid undermining their potentially lifesaving compensatory hyper-ventilation. Fluid volume and electrolyte status should be carefully monitored during treatment and transport. Acidosis and subsequent treatments will alter the elimination and distribution of critical electrolytes such as potassium. Potassium replenishment should be anticipated during patient treatment and transport, especially if urinary alkalinization is performed.

Signs and Symptoms

Salicylate Toxicity

- Tachypnea
- Tinnitus, dizziness, or deafness
- Hyperthermia
- Neurologic changes from mild confusion to coma
- Nausea, vomiting, abdominal pain, and GI bleeding
- Pulmonary edema
- Liver or renal failure

Transport Management

Salicylate Toxicity

- Manage the ABCs.
- Monitor fluid volume and electrolyte status.
- Provide potassium replenishment.

- Perform GI decontamination with ipecac (for children).
- Perform GI decontamination with multiple-dose activated charcoal.
- Perform urinary alkalinization for reduction of the salicylate level.

There is no antidote for salicylate poisoning. Gastrointestinal decontamination may include ipecac for small, accidental ingestions in young children or gastric lavage and WBI for massive ingestions in older children, adolescents, and adults. Depending on the quantity of aspirin or salicylate ingested, patients may require repeated doses of activated charcoal to adsorb the vast quantity of available toxin.

Salicylate toxicity is a candidate for several modes of enhanced elimination. Urinary alkalinization is extremely effective for reducing the salicylate level. This simple procedure can easily be initiated while other interventions are performed or during transport. Salicylate toxicity is also effectively treated in the hospital with hemodialysis and **hemoperfusion**, although hemoperfusion does not provide the same correction of electrolyte levels and acidosis as provided by hemodialysis. Both hemodialysis and hemoperfusion are performed in the intensive care unit; treatments in progress need to be discontinued prior to transport.

SSRIs (and Noncyclic Antidepressants)

This category includes medications such as fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), and a host of others. These medications offer a less toxic alternative to TCAs for the treatment of depression and anxiety and for smoking cessation. In general, toxicity is limited, although severe exposures can cause seizures, serotonin syndrome (discussed earlier in the "Toxic Syndromes [Toxidromes] and Medication Reaction Syndromes" section), cardiovascular alterations, and death. No clear toxic dose is established. Neither urine nor serum drug screening is widely available to assist in diagnosis or management.

Signs and Symptoms

SSRI Toxicity

- Sedation, ataxia, dizziness, and coma
- Nausea, vomiting, and diarrhea
- Headache, restlessness, shivering, and diaphoresis
- Hypotension, QRS prolongation, and sinus tachycardia
- Muscle rigidity, tremors, and hyperreflexia

Transport Management

SSRI Toxicity

- Manage the ABCs.
- Perform GI decontamination with activated charcoal.
- Provide volume resuscitation for hypotension.
- Administer IV benzodiazepines for seizures.

Sedation, ataxia, dizziness, and coma are CNS complications of toxicity due to select SSRIs. Nausea, vomiting, diarrhea, headache, restlessness, shivering, and diaphoresis may also occur. Hypotension, prolongation of the QRS interval, and sinus tachycardia are the usual cardiovascular manifestations of an SSRI overdose.

There is no antidote for SSRI poisoning or overdose. Ipecac is not recommended because of the potential for CNS sedation and seizure activity. Gastric lavage and WBI are not typically indicated unless SSRIs are taken with more toxic substances. Activated charcoal is effective for adsorption in the GI tract if given promptly following ingestion. The treatment for serotonin syndrome is discussed in greater depth in the "Medication Reaction Syndromes" section. In SSRI overdose situations with serotonin syndrome, the treatment is supportive based on symptoms. Hypotension is treated initially with volume resuscitation. Seizures are initially treated with IV benzodiazepines. The ABCs need to be carefully monitored in severe overdoses.

Toxic Alcohols (Ethylene Glycol and Methanol)

The toxic chemicals ethylene glycol and methanol are commonly available in the community and present a significant challenge to health care providers following accidental or intentional ingestion. Each can cause profound, lethal metabolic acidosis following ingestion of very small quantities. Ethylene glycol is the primary component in vehicle antifreeze. Methanol is the primary component in windshield washer fluid and other solvents. Accidental exposure to these chemicals occurs when they are mislabeled or placed in a beverage container. Children may be drawn to the sweet taste of ethylene glycol. People with alcoholism may consume either chemical while searching for an ethanol substitute.

Diagnosis and treatment can be guided by serum methanol or ethylene glycol levels, but these tests are usually only available in larger health care facilities. Even in larger tertiary centers, results for quantitative serum levels may take many hours or several days. The long delay undermines the clinical usefulness of these tests for diagnosis and management.

Clinicians have two additional options to assist with diagnosis. Ethylene glycol often has fluorescein added, which may or may not be visible when urine is viewed under a Wood's (UV) lamp. This method is not entirely reliable but may offer some assistance. Certain types of urinary drainage bag tubing will create the appearance of a false-positive result under a UV light. Hippurate and oxalate crystals in the urine are also highly suggestive of ethylene glycol poisoning.

Each of these chemicals (methanol and ethylene glycol) causes an elevated serum osmolar gap, a finding that is very useful for timely diagnosis in outlying facilities. By comparing the calculated serum osmolality with the measured serum osmolality, clinicians can determine the osmolar gap. When hospital laboratories measure serum osmolality, it is essential that the "freezing point method" be used. Other analysis methods that permit evaporation of alcohols in the specimen will give inaccurate results. This gap is adjusted for the presence of serum ethanol and unreliable when the patient has alcoholic ketoacidosis. This is not an exact test; at least 12 other chemicals or conditions will cause an elevated osmolar gap. When no other useful diagnostic testing is available, this test can assist with diagnosis and guide initial treatment.

Calculated osmolality:

$$2\,(\text{Serum Sodium}) + \frac{\text{Glucose}}{18} + \frac{\text{BUN}}{2.8} = 290\ \text{mOsm/L (Normal)}$$

For a rough estimation of the serum level (mg/dL), the osmolar gap is multiplied by the conversion factor listed in **Table 20-2**. (BUN indicates blood urea nitrogen.)

Toxic signs and symptoms develop following the consumption of 1 to 1.5 mL/kg of ethylene glycol. Patients initially show ataxia, slurred speech, and lethargy, characteristic of ethanol intoxication 3 to 4

hours after ingestion, possibly accompanied by nausea and vomiting. During this time, laboratory analysis reveals an elevated serum osmolar gap. As the toxicity progresses (4 to 12 hours after ingestion), profound anion-gap metabolic acidosis with a drop in the serum bicarbonate level develops (see Chapter 16 for a further discussion of acid-base balance). Seizures, cerebral edema, and coma are common. Respiratory manifestations include tachypnea, hyperventilation, and pulmonary edema. Severe exposures lead to renal failure, cardiac arrhythmias, and conduction disturbances.

TABLE 20-2 Osmolar Gap Conversion Factors

Substance	Conversion Factor
Ethanol	4.6
Ethylene glycol	6.2
Methanol	3.2
Isopropyl alcohol	6.0

Adapted from: Olson KR, ed. *Poisoning and Drug Overdose*, 5th ed. New York, NY: McGraw-Hill; 2007:32.

Patients with methanol poisoning have signs and symptoms somewhat different from those of ethylene glycol exposure. Toxicity occurs when more than 100 mg/kg is ingested. Death can occur after ingestion of 20 to 150 g. During the first several hours, patients exhibit signs of classic ethanol intoxication, possibly accompanied by gastritis. An elevated serum osmolar gap is also present. Toxicity progresses into a severe anion-gap metabolic acidosis. Patients complain of a "snow-field," hazy visual disturbance, or blindness. Renal failure, seizures, coma, and death occur in severe untreated exposures.

Gastric emptying with gastric lavage (or gastric suctioning) is the only effective method of decontamination for ethylene glycol and methanol poisoning. Patients require aggressive treatment for the ABCs following severe exposures. Two antidotes are available for the treatment of methanol and ethylene glycol poisoning: ethanol and fomepizole (Antizol). Either one can be used.

Signs and Symptoms

Ethylene Glycol Toxicity

- Ataxia, slurred speech, and lethargy
- Nausea and vomiting
- Seizures, cerebral edema, and coma
- Hyperventilation
- Pulmonary edema
- Renal failure
- Cardiac arrhythmias and conduction disturbances

Signs and Symptoms

Methanol Toxicity

- Ataxia, slurred speech, and lethargy
- Possible gastritis
- "Snowfield," hazy visual disturbance, or blindness
- Renal failure
- Seizures
- Coma

Transport Management

Ethylene Glycol and Methanol Poisoning

- Manage the ABCs.
- Administer ethanol (oral or IV) or fomepizole (Antizol).

Ethanol, given orally or intravenously, promotes methanol and ethylene glycol excretion through an alternative metabolic pathway, drastically reducing the metabolic acidosis. Serum levels are titrated to approximately 100 mg/dL (which may be measured in serum or tested at the bedside using a breathalyzer device). Many hospital pharmacies carry IV ethanol preparations along with a suitable bottle of spirits from a liquor store. Patients who receive ethanol therapy require close monitoring. Ethanol may cause abnormal behavior, CNS depression, gastritis, pancreatitis, hyponatremia, and hypoglycemia.

Fomepizole is a newer commercial antidote for ethylene glycol and methanol poisoning, creating the same alternative metabolic excretion pathway as ethanol does. It is significantly more expensive than ethanol but does not require the same depth and frequency of monitoring as ethanol therapy. Fomepizole does not cause CNS sedation and does not require specific serum monitoring. In select cases, fomepizole may cause headache, nausea, vomiting, dizziness, fever, or rash.

Tricyclic Antidepressants

These highly toxic medications are frequently prescribed as last-resort antidepressants to patients likely to attempt self-harm. TCAs are also prescribed to patients for the treatment of chronic pain, neuropathy, and migraines. Toxicity usually occurs from accidental ingestions by young children and intentional overdoses in patients attempting self-harm. The toxic dose is approximately 10 to 20 mg/kg. Any TCA overdose should be considered potentially life-threatening.

Signs and Symptoms

Tricyclic Antidepressant Overdose

- Dry mouth and skin
- Dilated pupils
- Seizures (often intractable)
- Delirium, agitation, and hallucinations
- Rhabdomyolysis
- Muscle tremors
- Hyperthermia
- Sinus tachycardia

- Conduction disturbance
- Ventricular arrhythmias
- Hypotension

Transport Management

Tricyclic Antidepressant Overdose

- Manage the ABCs.
- Administer IV sodium bicarbonate for conduction disturbance, ventricular arrhythmia, or refractory hypotension.
- Administer IV barbiturates for seizures.
- Perform chemical paralysis (accompanied by electroencephalographic monitoring) for intractable seizures.

Any patient admitted to a health care facility for an intentional overdose should be screened for the presence of TCAs. Most urine drug screens test for TCAs, and the measurement of serum levels is often available to assist diagnosis and management. Some non-TCA medications may cause false-positive urine screen results (for example, cyclobenzaprine [Flexeril]). A 12-lead ECG should be performed on any patient with a suspected TCA overdose to observe for cardiotoxic evidence or effects.

Prolongation of the PR, QRS, or QT interval indicates serious TCA toxicity. Patients often exhibit sinus tachycardia with ventricular tachycardia or fibrillation, torsades de pointes, and asystole in severe exposures. Hypotension and cardiogenic shock are also possible.

Patients exhibit many anticholinergic signs and symptoms following TCA overdose (see the earlier "Toxic Syndromes [Toxidromes]" section discussion on anticholinergic syndrome). Effects include dry mouth and skin, dilated pupils, seizures (often intractable), delirium, agitation, hallucinations, rhabdomyolysis, muscle tremors, and hyperthermia.

Ipecac is completely contraindicated following TCA exposure. Gastric lavage is appropriate for recent severe ingestions. Activated charcoal is effective. Clinicians should strongly consider multidose activated charcoal for severe exposures.

Patients require aggressive supportive treatment following a TCA overdose. Seizures may require IV barbiturates if initial treatment with benzodiazepines is ineffective. Chemical paralysis should be considered for intractable seizures to avoid hyperthermia and muscle breakdown. Chemical paralysis will stop muscle activity associated with seizures but will not stop brain seizure activity. Electroencephalographic monitoring is essential.

Any conduction disturbance, ventricular arrhythmia, or refractory hypotension is treated with IV sodium bicarbonate. Initial boluses of 1 to 2 mEq/kg are followed by a maintenance infusion to maintain a serum pH of 7.50 to 7.55.

Chemical Agents

Acetylcholinesterase Inhibitor (Organophosphate and Carbamate) Toxicity

Patients may become exposed to acetylcholinesterase inhibitors during unintentional contact with certain pesticides or as victims of a chemical weapon release. **Acetylcholinesterase** breaks down **acetylcholine** at the neuromuscular junction. When acetylcholinesterase is inhibited by these chemicals, excess acetylcholine accumulates in muscarinic, nicotinic, and CNS receptors, causing continued activation of

these receptors. Acetylcholinesterase inhibitors are absorbed through inhalation, dermal contact, mucous membranes, and the digestive tract. Exposed patients pose a major threat to unprotected health care workers during treatment and transport.

Diagnosis is based on patient history, similar illness of multiple people at the same location, and the acetylcholinesterase inhibitor toxidrome. Laboratory measurement of red blood cell acetylcholinesterase has been developed. It is neither widely available nor very helpful in the acute diagnosis and management of exposed patients.

Patients may have two distinct patterns of toxicity, depending on which receptor(s) are involved. Nicotinic receptor toxicity produces tachycardia, hypertension, fasciculations, weakness, hyperglycemia, and dilated pupils. Muscarinic receptor toxicity produces the classic SLUDGE syndrome, plus bronchorrhea, sweating, constricted pupils, and bradycardia. Nicotinic and muscarinic toxicity both produce altered mental status, coma, and seizure activity in severe exposures.

Skin and eye decontamination should be initiated promptly by rescuers or health care providers using appropriate PPE. The potential for rescuer exposure is high. Any potentially contaminated clothing and jewelry should be removed and irrigation begun. Water or saline is used, combined with a mild soap or detergent if these chemicals are combined with hydrocarbons.

Massive recent oral ingestions of acetylcholinesterase inhibitors may be treated by gastric lavage. This procedure should be avoided in patients with an unsecured airway because of the high potential for seizures and aspiration. Activated charcoal is also appropriate when the airway is adequately protected.

Signs and Symptoms

Acetylcholinesterase Inhibitor Toxicity

- Nicotinic receptor toxicity
  - Tachycardia
  - Hypertension
  - Fasciculations
  - Weakness
  - Hyperglycemia
  - Dilated pupils
  - Severe exposures: altered mental status, coma, and seizure activity
- Muscarinic receptor toxicity
  - SLUDGE (Salivation, Lacrimation, Urination, Diarrhea, Gastroenteritis, Emesis)
  - DUMBELS (Diaphoresis/diarrhea, Urination, Miosis, Bradycardia/bronchospasm/bronchorrhea, Emesis, Lacrimation, and Salivation)
  - Bronchorrhea
  - Sweating
  - Constricted pupils
  - Bradycardia
  - Severe exposures: altered mental status, coma, and seizure activity

Transport Management

Acetylcholinesterase Inhibitor Toxicity

- Perform decontamination: irrigation with water or saline (combined with a mild soap or detergent if these chemicals are combined with hydrocarbons).
- Manage the ABCs.
- Perform GI decontamination with activated charcoal.
- Administer atropine.
- Administer pralidoxime (2-PAM, Protopam).
- Administer nondepolarizing muscle relaxants.
- Administer IV benzodiazepines or barbiturates for seizures.

Atropine and pralidoxime (2-PAM, Protopam) are the antidotes for acetylcholinesterase inhibitor toxicity. Atropine decreases airway secretions, reverses bradycardia, and lessens wheezing. The initial dose is 0.5 to 2 mg IV and is doubled every 5 minutes until the patient's condition improves. Severe exposures require vast quantities of atropine, potentially depleting hospital and transport team supplies. Tachycardia is not an indication to withhold additional atropine doses.

Pralidoxime can regenerate acetylcholinesterase activity following certain organophosphate exposures. It is not needed following carbamate exposures. A bolus of 1 to 2 g is administered over several minutes, followed by an IV infusion. The military and other high-risk areas may have supplies of these medications readily available to rapidly treat toxic exposures.

The use of succinylcholine for RSI should be avoided following exposure to acetylcholinesterase inhibitors. Succinylcholine activates the same neuromuscular junction and will cause an extended chemical paralysis. The use of nondepolarizing muscle relaxants is recommended. Otherwise, aggressive management of airway and breathing is used when clinically indicated. Seizure activity is controlled with IV benzodiazepines and barbiturates.

Carbon Monoxide

Carbon monoxide (CO) is a colorless, odorless, tasteless gas that causes serious toxicity through environmental exposures. This substance is created during the incomplete combustion of carbon-based materials. It has an affinity for hemoglobin, 200 to 270 times greater than that of oxygen. Human toxicity occurs in industrial settings, during fires, from indoor heating appliances and generators, from misdirected automobile exhaust, and following intentional exposures by people attempting self-harm.

CO binds to hemoglobin more tightly than does oxygen and prevents the cell from producing energy using oxygen. CO displaces oxygen, normally bound to hemoglobin, resulting in profound tissue and organ hypoxia. In addition, CO exerts direct adverse effects on internal cellular functioning. The cells are forced to conduct anaerobic metabolism to supply energy needs. Anaerobic metabolism results in the accumulation of lactic acid, which results in cell acidosis. The organs that are highly dependent on the supply of oxygen are the first to exhibit signs of CO poisoning. The brain and heart are the primary sites of CO toxicity owing to their large oxygen requirements. The heart may exhibit ischemia as chest pain, shortness of breath, arrhythmia, a drop in cardiac output, and, in severe cases, cardiac arrest. The brain may exhibit its dysfunction as headache, mild confusion, altered mental status, seizures, and coma.

CO poisoning should be suspected in any victim of a fire in a confined space and can be diagnosed by an elevated CO level in an arterial or a venous blood gas sample. Victims who have been removed from a CO-toxic environment for several hours may show low or normal CO levels, despite serious CO poisoning, owing to distribution of the CO in the tissues.

When the index of suspicion is high, clinical diagnosis is easily confirmed with a serum carboxyhemoglobin level. Levels do not directly correlate with severity of symptoms but will aid in

diagnosis when the history of exposure is unclear.

Controversies

Carbon monoxide is the leading cause of poisoning in every industrialized country, yet up to 50% of cases continue to be misdiagnosed. Long-term consequences of CO poisoning include a significantly increased incidence of cardiovascular events and deaths as well as neurologic changes ranging from decreased intelligence to seizures or Parkinson-like syndromes. Up to 10% of patients admitted to hospitals with suspected acute coronary syndromes, seizures, unstable angina pain, and headache are actually victims of CO poisoning. Because symptoms have little correlation to carboxyhemoglobin (blood CO levels), providers must maintain a high index of suspicion and use noninvasive screening technologies whenever available.

The oxygen saturation value is accurate only if it is directly measured on a blood-gas sample. Values calculated from arterial Pa_{O_2} or obtained from conventional bedside pulse oximetry devices are falsely elevated because of CO binding to hemoglobin. If any doubt exists regarding possible CO exposure, aggressive treatment should be started before laboratory results are obtained. CO-oximetry is an emerging technology that uses various wavelengths of light to measure carboxyhemoglobin and other values through a noninvasive skin sensor, similar to a pulse oximeter. This device provides rapid detection of CO and methemoglobinemia at the bedside and during transport.

Mild toxicity results in headache, nausea, vomiting, abdominal pain, and dizziness. Patients without a clear history of CO exposure are at risk of misdiagnosis as having a GI virus or colic. Moderate CO toxicity produces confusion, dyspnea, ataxia, tachycardia, and chest pain. Patients with severe CO toxicity have seizure activity, coma, cardiac arrhythmias, hypotension, and myocardial ischemia. Cherry red skin is an ominous indication of severe toxicity, but it may or may not be present. Hyperthermia, syncope, and incontinence are also possible.

Patients should be removed from any toxic environment. Fresh air needs to be provided until supplemental oxygen is available. CO has a half-life of 3 to 4 hours at room air. If 100% oxygen is administered, the CO half-life decreases to 30 to 90 minutes. In severe exposures, hyperbaric oxygen reduces the CO half-life to 15 to 23 minutes. Any symptomatic patient should receive 100% oxygen immediately if CO poisoning is suspected. Hyperbaric oxygen has the ability to improve patient status up to 3 weeks following exposure to CO.

Special Populations

Fetal hemoglobin interacts differently with CO than maternal hemoglobin, placing an unborn child at greater risk of CO poisoning. Although maternal blood levels of CO will begin to decline immediately after exposure to CO ceases, fetal blood levels of CO continue to rise for several hours. This interaction often necessitates referral of pregnant patients with CO poisoning to hyperbaric oxygen therapy (HBO) to avoid continued fetal CO poisoning.

Signs and Symptoms

Carbon Monoxide Toxicity

- Mild: headache, nausea, vomiting, abdominal pain, and dizziness
- Moderate: confusion, dyspnea, ataxia, tachycardia, and chest pain
- Severe: seizure activity, coma, cardiac arrhythmias, hypotension, myocardial ischemia, cherry red skin, hyperthermia, syncope, and incontinence

Transport Management

Carbon Monoxide Toxicity

- Perform CO oximetry.
- Remove the patient from the toxic environment.
- Provide fresh air.
- Give 100% oxygen immediately.
- Manage the ABCs.
- Perform ET intubation; fill the ET tube cuffs with water if hyperbaric treatment is anticipated.
- Administer IV benzodiazepines or barbiturates for seizures.
- Assess for other possible causes of altered mental status or cardiovascular dysfunction.

The goal of therapy is to displace the CO, under pressure, from the hemoglobin and the mitochondria. Patients with altered mental status, seizures, or serious burns in the setting of CO poisoning should have their airway actively managed by ET intubation. In preparation for hyperbaric therapy, patients who require ET intubation and have CO poisoning should have the ET tube cuffs filled with water.

The remaining treatment for CO exposure is supportive. Airway and ventilator support is needed for comatose patients. Seizures should be controlled with IV benzodiazepines or barbiturates. Other possible causes of altered mental status or cardiovascular dysfunction should be considered.

Caustics and Corrosives

Patients may be exposed to caustic agents through occupational and industrial exposure, household contact, and a vast array of other possible scenarios. Caustics include acids, alkalis, and a host of other chemicals, each causing mucosal, skin, or internal organ damage following exposure.

The duration of exposure, concentration, pH, and particular substance influence the degree of toxicity. Exposure can occur through inhalation, ingestion, or dermal or eye exposure. Systemic toxicity is possible following exposure through any of these routes. Acidic substances cause **coagulation necrosis**, which limits the depth and extent of injury. Alkali substances form **liquefactive necrosis**, allowing extensive tissue penetration. Hydrocarbons and hydrofluoric acid are discussed separately (see the sections “Hydrocarbons” and “Hydrofluoric Acid/Hydrogen Fluoride [HF]”).

Diagnosis is often aided by the patient’s reported history or description of the setting where exposure occurred or symptoms began. The Material Safety Data Sheets (MSDS) and other documents may indicate the particular chemical involved along with suggestions for treatment, decontamination, and PPE needed for rescuers **Figure 20-10**.

Eye and skin exposures require copious irrigation with saline or water. Any basic or acidic substances require a normal mucosal pH before irrigation is discontinued. A reliable toxicology reference should be consulted before beginning any topical treatments other than irrigation.

Patients with an inhalation exposure require immediate fresh air. Symptomatic patients may require supplemental oxygen, bronchodilator medications, humidified oxygen or air, or assisted ventilation in

severe exposures.

The ingestion of caustic agents has the potential to cause devastating injury. Close monitoring for airway compromise, GI bleeding and perforation, and free air in the thorax or abdomen is needed. Patients should immediately be given water or milk to drink, but inducing vomiting and attempting neutralization should not be attempted. A toxicologist or gastroenterologist should be consulted for specific treatment recommendations.

Chlorine, Ammonia, and Asphyxiate Gases

Various gases have the potential to displace oxygen in a patient's lungs; to damage or irritate the mouth, nose, and airway; or to otherwise disrupt effective respiration. These substances exist in gas form or become gases through chemical reactions or when a liquid or solid container is somehow compromised. Exposures occur during a hazardous materials release or when adequate safety precautions are not implemented during the use or storage of these chemicals. Toxicity is highly variable, depending on concentration, duration of exposure, preexisting health of exposed people, and a myriad of environmental factors.

MATERIAL SAFETY DATA SHEET

Syngenta Crop Protection, Inc.
Post Office Box 18300
Greensboro, NC 27419

In Case of Emergency, Call
1-800-888-8372

1. PRODUCT IDENTIFICATION

Product Name: **ENVOKE** Product No.: A9842A

EPA Signal Word: Caution

Active Ingredient(%): Trifloxysulfuron-Sodium (75.0%) CAS No.: 290332-10-4

Chemical Name: 2-Pyridinesulfonamide, N-[[(4,6-dimethoxy-2-pyrimidinyl)amino]carbonyl]-3(2,2,2-trifluoroethoxy)-, monosodium salt, monohydrate

Chemical Class: Sulfonylurea Herbicide

EPA Registration Number(s): 100-1132 **Section(s) Revised: 2, 8, 14**

2. HAZARDS IDENTIFICATION

Health and Environmental

Harmful if inhaled. May be harmful in contact with skin.

Hazardous Decomposition Products

None known.

Physical Properties

Appearance: Light beige to brown granules

Odor: Not determined

Unusual Fire, Explosion and Reactivity Hazards

During a fire, irritating and possibly toxic gases may be generated by thermal decomposition or combustion.

3. COMPOSITION/INFORMATION ON INGREDIENTS

Material	OSHA PEL	ACGIH TLV	Other	NTP/IARC/OSHA Carcinogen
Diatomaceous Earth	80 mg/m³/%SiO2 (20 mppcf) TWA	Not Established	6 mg/m³ TWA **	IARC 3
Surfactant	Not Established	Not Established	15 mg/m³ TWA (total dust) *	No
Sodium Sulfite	Not Established	Not Established	Not Established	IARC Group 3
Trifloxysulfuron-Sodium (75.0%)	Not Established	Not Established	10 mg/m³ TWA ***	No

* recommended by manufacturer

** recommended by NIOSH

*** Syngenta Occupational Exposure Limit (OEL)

Ingredients not precisely identified are proprietary or non-hazardous. Values are not product specifications.
Syngenta Hazard Category: B

4. FIRST AID MEASURES

Product Name: **ENVOKE** Page: 1

Figure 20-10 The Material Safety Data Sheet (MSDS). The MSDS contains a great deal of critical safety information, including product identification, accidental release measures, exposure control/personal protection, and toxicologic information on multiple pages. Be certain to read the entire MSDS.

Transport Management

Caustic and Corrosive Exposure

- Perform decontamination: irrigate the eyes or skin with water or saline (combined with a mild soap

or detergent if these chemicals are combined with hydrocarbons).
- Check the mucosal pH; ensure the pH is normal before discontinuing irrigation.
- Manage the ABCs.
- For inhalation exposure
  - Provide fresh air.
  - Administer supplemental oxygen.
  - Administer bronchodilator medications.
  - Administer humidified oxygen or air.
  - Provide assisted ventilation in severe exposures.
- For ingestion
  - Monitor closely for airway compromise, GI bleeding and perforation, and free air in the thorax or abdomen.
  - Provide immediate water or milk to drink.
  - Do not induce vomiting or attempt neutralization.

Symptoms include lacrimation; coughing; drooling; airway discomfort, swelling, and irritation; and labored, rapid, or absent breathing. Lung auscultation may reveal wheezing, pulmonary edema, and absent or decreased breath sounds. In exposures to simple asphyxiate gases, patients may have only increased breathing, with or without hypoxia.

Immediate fresh air should be provided for patients with an inhalation exposure. Symptomatic patients may require supplemental oxygen, bronchodilator medications, humidified oxygen or air, or assisted ventilation in severe exposures. Pulmonary edema may require specific, aggressive management when present following a toxic inhalation. A toxicologist or a Poison Center should be consulted for customized treatment guidance.

Signs and Symptoms

Chlorine, Ammonia, and Asphyxiate Gases Toxicity

- Lacrimation, coughing, and drooling
- Airway discomfort, swelling, and irritation
- Labored, rapid, or absent breathing
- Wheezing
- Pulmonary edema

Transport Management

Chlorine, Ammonia, and Asphyxiate Gases Toxicity

- Manage the ABCs.
- Provide fresh air.
- Administer supplemental oxygen.
- Administer bronchodilator medications.
- Administer humidified oxygen or air.

- Provide assisted ventilation in severe exposures.
- Administer nebulized normal saline.
- Administer a half-strength preparation of sodium bicarbonate by nebulizer.
- Administer IV corticosteroids in refractory cases.

Patients should receive thorough decontamination before transport. Toxic fumes and residual chemicals pose a risk to unprotected transport team members. Toxic inhalations of chlorine and chloramine (the gas formed from mixing household bleach and ammonia) cause upper airway irritation, coughing, and burning, resulting from the formation of hydrochloric acid on the airway linings. Nebulized normal saline (5 mL) can be effective in alleviating symptoms when humidified air or oxygen is not available in the transport vehicle. In addition, severe symptoms often respond to neutralization of the hydrochloric acid using a half-strength preparation of sodium bicarbonate administered by nebulizer (2.5 mL of 3.75% or 4.2% sodium bicarbonate mixed with 2.5 mL of saline). Administration of IV corticosteroids may also be helpful in refractory cases.

Cyanide Poisoning

Cyanide is used heavily in the manufacturing industry, in laboratory settings, as a chemical weapon, and in homicides and suicides. Cyanide is present in certain fruit pits and seeds, and poisoning may occur from a metabolite during therapeutic administration of sodium nitroprusside (Nipride). The combustion of any carbon- and nitrogen-containing product has the ability to produce cyanide. Cyanide is produced when wool, plastic, and other combustible materials are burned; the combustion of plastics has the ability to produce lethal doses of cyanide. Toxicity may occur through any route: dermal, parenteral, inhalation, or ingestion. Any exposure to cyanide should be considered potentially lethal. Toxicity may be immediate or delayed, depending on the route and manner of exposure.

Cyanide poisons the cellular mitochondria by binding to the last step in energy production in which oxygen is used to produce adenosine triphosphate, or ATP, the energy currency of the cell. Cyanide inhibits the last step in energy production and effectively makes the cell unable to use the oxygen that is present. The clinical result is signs of hypoxia (dizziness, headache, air hunger, and acidosis), but without decreases in pulse oximetry or Po_2. Patients with low-level exposure may have nonspecific symptoms such as weakness and dizziness, whereas large-concentration exposures can result in seizures, coma, cardiovascular collapse, and death in 2 minutes or less.

Cyanide poisoning should be considered in any victim of a fire in a confined space, especially if the patient was in a room in which there was combustion of synthetic- and plastic-containing materials. Any patients potentially contaminated with cyanide require extensive decontamination by rescuers wearing chemical-protective suits with an environmentally isolating breathing apparatus (for example, self-contained breathing apparatus). Health care providers have been injured when patient emesis has released cyanide gas into the treatment room. The patient's skin and soaked clothing may additionally expose health care workers to cyanide during patient treatment if adequate precautions are not taken.

Patient or bystander reports and the location of exposure or manner of onset of symptoms may provide clues to assist in the diagnosis of cyanide poisoning. The classic "bitter almond" smell may or may not be present from hydrogen cyanide. Rescuers should avoid intentionally seeking smells and odors to identify toxic chemicals. Up to 40% of the population is unable to detect the odor of hydrogen cyanide.

Cyanide poisoning is confirmed with serum cyanide and thiocyanate levels. A whole-blood cyanide level greater than 2.5 μg/mL is associated with severe toxicity. A level greater than 3 μg/mL is usually lethal. Thiocyanate is the metabolized form of cyanide, excreted normally in the urine. Thiocyanate toxicity begins at 60 mg/L and becomes potentially lethal at levels above 200 mg/L. In most cases,

thiocyanate poisoning is less severe than cyanide poisoning. In addition, patients have an elevated serum lactate level (> 6 mmol/L or > 10 mmol/L after smoke inhalation); metabolic acidosis; and an elevated, mixed venous oxygen saturation due to decreased tissue oxygen extraction. Laboratory screening should also include a serum carboxyhemoglobin level if there is any potential for a combined exposure (such as during a fire).

Neurologic symptoms include seizures, coma, headache, confusion, anxiety, and weakness. Cardiovascular manifestations include complete cardiovascular collapse, hypertension, hypotension, ST-segment and T-wave ECG changes, asystole, and numerous other conduction blocks and arrhythmias. Patients have hyperventilation, respiratory depression, pulmonary edema, or complete respiratory failure.

Signs and Symptoms

Cyanide Poisoning

- Dizziness
- Weakness
- Headache
- Air hunger
- Acidosis
- No decrease in pulse oximetry or Po_2
- Hyperventilation
- Respiratory depression
- Pulmonary edema
- Complete respiratory failure
- Confusion
- Anxiety
- Seizures
- Complete cardiovascular collapse
- Hypertension or hypotension
- ST-segment and T-wave ECG changes
- Asystole or other conduction blocks and arrhythmias

Transport Management

Cyanide Poisoning

- Perform skin decontamination: copious irrigation with soap and/or shampoo and water.
- Manage the ABCs.
- Gastrointestinal decontamination with activated charcoal.
- Administer amyl nitrite, followed by IV sodium nitrite, then sodium thiosulfate, or administer hydroxycobalamin instead of the amyl nitrite/sodium nitrite/sodium thiosulfate combination.
- Monitor levels of serum electrolytes, blood gases, glucose, and lactate.

Skin decontamination requires copious irrigation by adequately protected rescuers or health care

providers using soap and/or shampoo and water. Activated charcoal adsorbs orally ingested cyanide preparations. Gastric lavage is also appropriate in select situations and may be used to remove old activated charcoal and replace it with fresh activated charcoal following the lavage procedure. Health care providers must use adequate PPE during any gastric decontamination procedures.

Several cyanide antidote kits are commercially available **Figure 20-11**. Industrial, laboratory, and manufacturing settings may have these on site, with or without trained personnel to assist. The treatment of cyanide poisoning is a two-step procedure: (1) removal of the cyanide from the mitochondrial apparatus, and (2) removal of the cyanide from the mitochondria to be excreted by the kidneys. The removal of cyanide from the mitochondria is accomplished by inducing methemoglobinemia. Methemoglobin is the result of oxidation of Fe^{2+} on hemoglobin to the Fe^{3+} state. Cyanide has a higher affinity for methemoglobin than it does for the mitochondrial apparatus and, therefore, leaves the mitochondria and binds to the methemoglobin. Methemoglobin is formed by the administration of nitrites. Amyl nitrite is a time-enhancing inhalation antidote for use until IV access is established. Amyl nitrite is supplied in two perles (small, round, glass ampules) that may be crushed and held in gauze over the mouth and nose of the victim (or bag-valve intake) for 30 seconds of each minute if no IV access is available. Or, it may be placed into a ventilator circuit until IV sodium nitrite is available. IV sodium nitrite is then administered.

Figure 20-11 Cyanide antidote kits are available commercially and may already be present at industrial, laboratory, and manufacturing settings.

Sodium nitrite is administered, 300 mg IV (supplied in 10-mL vials), for 2 to 4 minutes in adults. Children receive 6 mg/kg (or 0.12 to 0.33 mL/kg, with a maximum dose of 10 mL, for 5 to 10 minutes). The dosing may be adjusted based on a patient's hemoglobin level. Health care providers should monitor for nitrite-induced methemoglobinemia (for example, hypoxia, headache, dizziness, and classic "chocolate cyanosis") during therapy.

The second step in the treatment of cyanide poisoning is to remove the cyanide from the body by metabolizing the cyanide to thiocyanate so that it can be excreted by the kidneys. An enzyme called rhodanese normally completes the conversion of cyanide to thiocyanate in the body and requires sulfurs to complete this step. Sulfur is supplied by the administration of one 12.5-g ampule of sodium thiosulfate for 10 to 20 minutes. The pediatric dose is 412.5 mg/kg (or 1.65 mL/kg) for 10 to 20 minutes. The aforementioned medications come packaged together as part of the Lilly Cyanide Kit. More recently, many EMS systems have been replacing this kit with the Cyanokit, which contains 5 g of hydroxocobalamin, that, when administered, binds cyanide to become a form of vitamin B_{12}. Sodium thiosulfate may be given with hydroxocobalamin, simultaneously through a separate IV line or immediately following the hydroxocobalamin infusion for synergistic effect. The two medications should

not be given simultaneously through the same IV line. The hydroxocobalamin may cause hypertension (possibly beneficial) and a reddish discoloration to the skin and mucous membranes. This medication also interferes with CO-oximetry and certain blood chemistry testing. It is important to remember that good supportive care in the absence of antidote, although not optimal, may save many patients.

In addition to supportive, clinically based treatments, monitoring of serum electrolytes, blood gases, glucose, and lactate levels is necessary during treatment.

Hydrocarbons

Hydrocarbons are a class of chemicals widely used in all parts of modern society. This class is divided into aliphatic and aromatic hydrocarbons. The chemicals are used in solvents, fuels, paints, and oils and for many other purposes. Abuse of hydrocarbons is done by "huffing" various highly **volatile** (easily changed from liquid to gas form) hydrocarbons. The toxicity of these substances is highly variable, depending on the nature of the individual chemical and its concentration, as well as the timing, duration, and route of exposure.

Clues to the diagnosis of hydrocarbon exposure often come from information provided by a patient and/or bystander or from containers or markings present at the scene. Many hydrocarbon compounds have a distinctive odor that may remain on a patient or the clothing, assisting in diagnosis. These same odors will adversely affect CCTPs when patients are placed in confined, poorly ventilated transport vehicles. Thorough decontamination is essential before transport.

The ingestion of most hydrocarbons will cause nausea and vomiting with possible gastritis or gastroenteritis. Systemic toxicity can occur following ingestion of selected hydrocarbons.

Inhalation or huffing of hydrocarbons will cause hypoxia, direct brain injury, hypercarbia during rebreathing, and cardiotoxicity and will sensitize myocardial tissues to catecholamines. **Sudden sniffing death syndrome** occurs when people (usually adolescents) are startled while secretly huffing hydrocarbons. The surge of catecholamines on a sensitized myocardium causes ventricular fibrillation or ventricular tachycardia. Vasopressin should be used instead of epinephrine during resuscitation.

Transport Management

Hydrocarbon Toxicity

- Manage the ABCs.
- Administer methylene blue.
- Administer chelating agents.
- Administer acetylcysteine.
- Administer lidocaine or other antiarrhythmic agents for ventricular arrhythmias.

Dermal or ocular exposure to hydrocarbons will cause local irritation, burns, or corneal injury. Patients may experience profound chemical burns when hydrocarbon-saturated clothing or footwear is not promptly removed and skin decontaminated. A mild soap or shampoo should be used when irrigating hydrocarbon-contaminated skin. Systemic toxicity is possible following dermal absorption of certain hydrocarbons.

Toxicity from hydrocarbons is extremely limited in highly viscous (thick) preparations such as motor oil and petroleum jelly. These chemicals do not pose much of an aspiration risk and are not generally believed to cause systemic toxicity. Patients receive observation and general supportive treatments.

Hydrocarbons such as gasoline, kerosene, and petroleum ether are of low viscosity (flow easily) and

pose primarily a risk of chemical pneumonitis following aspiration. Care is supportive, and gastric emptying is contraindicated owing to the potential for aspiration. There is not much risk of systemic toxicity otherwise.

The remaining groups of hydrocarbons have a high potential for aspiration chemical pneumonitis, in addition to the possibility of systemic toxicity. Systemic effects include all of the aforementioned CNS and cardiac manifestations. Patients may also have hypotension, ataxia, headache, altered mental status, seizures, and any variant of respiratory distress.

There is no general antidote for hydrocarbon poisoning, but methylene blue is used when a particular hydrocarbon causes methemoglobinemia. **Chelating agents** and acetylcysteine are also used for treating specific hydrocarbon poisonings. Careful monitoring of the respiratory and cardiovascular status is needed following exposure. Most poisonings require only supportive treatments. Lidocaine or other antiarrhythmic agents should be used instead of catecholamines (epinephrine) for ventricular arrhythmias following hydrocarbon poisoning.

Hydrofluoric Acid/Hydrogen Fluoride

Hydrofluoric acid is HF that has been placed into an aqueous solution. This potent caustic substance can cause devastating local and systemic toxicity from exposure to an extremely small amount of concentrated liquid. The fluoride in HF leaches calcium and magnesium from body tissues, resulting in profound, often lethal hypocalcemia and hypomagnesemia. These electrolyte alterations also prompt a massive release of sequestered potassium into the systemic circulation. Rapid clinical deterioration may occur unexpectedly. Poisoning by ammonium bifluoride has a presentation and treatment approach similar to that of HF. Many interventions following HF poisoning are quite unusual and require individualized guidance. A toxicologist or a Poison Center should be consulted for specific treatment decisions about HF exposure.

Signs and Symptoms

Hydrogen Fluoride Toxicity

- Throat discomfort, bronchospasm, stridor, and local airway injury
- Wheezing, rhonchi, or rales
- Chemical pneumonitis or pulmonary edema
- Hypocalcemia (often severe)
- Hypomagnesemia

Transport Management

Hydrogen Fluoride Toxicity

- Perform eye and skin decontamination: copious irrigation.
- Manage the ABCs.
- For ingestion exposure
  - Provide immediate stomach evacuation with a nasogastric or orogastric tube.
  - Administer a calcium- or magnesium-containing substance such as milk, antacids, magnesium citrate, or magnesium hydroxide.
- For skin exposure
  - Administer calcium gluconate or calcium carbonate gel.

- Administer calcium gluconate or calcium chloride for impending or documented hypocalcemia or hyperkalemia.
- Monitor serum magnesium levels and replenish as necessary.

Hydrogen fluoride may cause throat discomfort, broncho-spasm, stridor, and local airway injury following inhalation. Lung auscultation reveals wheezes, rhonchi, or rales. Serious inhalation exposures can cause delayed chemical pneumonitis or pulmonary edema. Some sources suggest using a nebulized calcium gluconate solution for treatment.

Eye exposure requires thorough, copious irrigation. Early ophthalmologic consultation and evaluation is essential following ocular HF exposure. Dermal exposure also requires copious irrigation. Potentially contaminated clothing should be removed. Rescuers must use adequate PPE to protect against accidental contact with HF during decontamination.

Ingestions of large amounts or concentrated solutions of HF are often lethal. If available, immediate stomach evacuation with a nasogastric tube or orogastric tube should take place. Patients should also immediately ingest a calcium- or magnesium-containing substance such as milk, antacids, magnesium citrate, or magnesium hydroxide. Vomiting should not be induced. There is no benefit to using activated charcoal, and it may obscure endoscopy evaluation. The ingestion of HF may cause vomiting, abdominal pain, and gastritis, in addition to profound systemic toxicity.

Systemic effects from HF poisoning are primarily related to hypocalcemia and electrolyte imbalance. Arrhythmias, tetany, muscle spasm, vasospasm, and acidemia are common. Patients with hypocalcemia and hypomagnesemia also have prolongation of the QT interval.

Calcium is the antidote for HF poisoning. Skin exposure to HF is treated with calcium gluconate or calcium carbonate gel. Distal extremity involvement should prompt consultation with a hand surgeon or other appropriate specialist. Patients may be treated with local IV, intra-arterial, or subcutaneous calcium administration. *Calcium chloride should not be used for subcutaneous or intra-arterial administration.*

Systemic toxicity requires aggressive replenishment of calcium. Calcium gluconate or calcium chloride should be administered to any patients with impending or documented hypocalcemia or hyperkalemia and repeated as necessary; several grams of IV calcium may be required. Monitoring of serum magnesium levels is needed, with replenishment as indicated.

Highly Toxic Substances

A vast array of toxic medications and chemicals are discussed throughout this chapter. The topics in this chapter may appear random, but each substance has been included for one of three reasons:

1. The substance may be frequently encountered in the critical care transport environment.
2. Exposure to the substance may require a specialized or unusual approach to treatment.
3. It may be highly toxic in very small quantities, requiring greater attention when exposure is suspected.

CCTPs should be aware that a variety of substances can cause serious illness or death in very small quantities, especially in children. **Table 20-3** provides a list of these substances, which require special attention when even small quantities are taken by children.

Hazardous Materials (Hazmat) Response

Introduction

Hazardous materials incidents pose challenges to emergency responders and health care providers for a variety of reasons. Scenes may be in remote, almost inaccessible, locations or in dangerous proximity to major population centers, posing an immediate threat to the health and safety of a community **Figure 20-12**. In many cases, numerous chemicals are released simultaneously. Identification, isolation, and mitigation of a hazardous materials release is often hampered by inadequately prepared or a limited number of available emergency responders. Weather, terrain, and other environmental factors complicate conventional disaster response plans. CCTPs should expect involvement in these incidents as emergency responders, through inadvertent contact, or while performing evacuation and interfacility patient transports.

TABLE 20-3 Substances Highly Toxic to Children (1-Pill Killers)

Calcium channel blockers
Beta-blockers
Tricyclic antidepressants (TCAs)
Afrin (oxymetazoline)
Visine (tetrahydrozoline)
Benzocaine
Camphor
Clonidine
Iron preparations
Lindane (for scabies and lice)
Oil of wintergreen and other topical salicylates
Opiates
Sulfonylureas (for diabetes)

Figure 20-12 Hazardous materials scenes pose challenges to providers because of the substances involved and the potential effect on the community.

Role at Hazmat Scenes

Unless CCTPs receive specific training in hazmat response, their role on the scene may be quite limited. Hazmat scenes often involve mechanical extrication, fire suppression, chemical spill containment, population evacuation, crowd and traffic control, the use of complicated PPE, comprehensive primary decontamination, and so forth, which CCTPs may be ill prepared to perform without specialized training and equipment. These skills are well beyond the scope of this text.

CCTPs without specialized training or equipment should remain well outside the "Hot" and "Warm" zones, discussed later, where provider exposure to toxic substances is possible. The area and shape of these zones will vary dramatically based on the chemicals involved, wind direction, topography, and other factors. CCTPs can quickly change roles from rescuer to victim as the wind changes if they are not appropriately positioned.

CCTPs should be prepared to evaluate decontaminated patients delivered by hazmat team personnel. It is imperative that CCTPs collaborate with hazmat team personnel to determine which substances are potentially involved and what PPE is appropriate for health care providers during treatment and transport. Poison Centers and Chemtrec will provide invaluable assistance if reliable, on-site reference materials are not available.

CCTPs may be called on to assist members of the hazmat team or other emergency responders directly. These personnel often become ill or injured during the course of scene operations. Comprehensive PPE can easily cause heat-related illnesses and dehydration, especially when used during unfavorable environmental conditions (for example, on a hot day a long walking distance from the staging area to the working area). Fires, falls, traffic incidents, and equipment-related activities all create the potential for trauma to emergency responders. Inadequate PPE for hazmat personnel and incorrect decisions related to the staging area or evacuation place anybody on the scene at increased risk of toxic chemical exposures.

The main objective of CCTPs at hazmat scenes should be to assess and ensure personnel safety during patient care and transportation. Patient assessment and treatment must occur only after personnel safety has been ensured. Rescuers may needlessly place themselves at risk while attempting to resuscitate a patient who has no chance of being revived. As stated earlier in the chapter, inadequate decontamination on the scene exposes CCTPs to toxic chemicals and compromises the safety of the transport vehicle.

Decontamination

The need, manner, and end point of decontamination are largely determined by the substance involved and

the degree of the patient's exposure to the substance. Many substances are colorless, odorless, and tasteless. Hazardous materials exposures with delayed toxic effects may continue to progress without the awareness of uninformed emergency responders.

A hazmat scene is configured with the chemical source in the center of three concentric circles **Figure 20-13**. The scene may be configured as any other shape if wind, topography, or other factors influence scene access, chemical distribution, and so forth. The inside circle surrounding the chemical source is the **hot zone**, where PPE is essential. The **warm zone** surrounds the hot zone and is where decontamination occurs; PPE is used (often the same PPE as in the hot zone), and extraneous personnel are not present. The **cold zone** surrounds the warm zone. No environmental hazards should be present in the cold zone. Rescuers providing direct patient treatment in the cold zone must still use PPE, but other emergency responders are not at risk. Furtado et al offer the following recommendations for rescuer decontamination at hazmat incidents. Contaminated patients should undergo a similar procedure.

1. Contaminated tools, trash, and clothing are dropped in the hot zone.
2. Primary rescuer garment wash and rinse in the decontamination (warm) zone.
3. Primary garment removal in the decontamination (warm) zone.
4. Secondary garment wash and rinse in the decontamination (warm) zone.
5. Facepiece removal and drop in the decontamination (warm) zone.
6. Boot drop in the decontamination (warm) zone.
7. Inner glove removal in the decontamination (warm) zone; all clothing and gloves should be turned inside out during removal, without shaking.
8. Final shower and clothing change in the cold zone.

This procedure may be modified based on the particular chemical and the other aforementioned factors. Steps should be taken to maintain patient privacy and avoid unintentional hypothermia during decontamination procedures. Specially trained hazmat personnel in appropriate PPE may initiate lifesaving measures before or during patient decontamination. Unless a CCTP has specialized training and adequate PPE, hazmat team personnel should provide all decontamination in the hot and warm zones.

Transport Considerations

Once adequate patient decontamination has been performed and other safety concerns have been addressed, patients should be transported to the closest appropriate health care facility. A small community hospital may be the facility closest to a hazmat incident. These facilities are often unable to provide adequate treatment for a critically ill patient requiring complex interventions. Small community health care facilities may not have sufficient quantities of antidotes or many of the infrequently used antidotes. CCTPs should consider bypassing these facilities in favor of larger tertiary centers when the risks of a longer transport time are outweighed by the benefits of access to greater health care resources.

CCTPs should carefully monitor for the following situations during patient transport:

- Deterioration in the patient's clinical condition as the toxic exposure evolves
- Signs of inadequate decontamination
- Any interventions appropriate for the patient's clinical situation, within the ability of the transport team, that have not been already performed

Any indications of inadequate primary decontamination warrant prompt correction. Unusual smells or fumes in the transport vehicle, unexplained symptoms experienced by transport personnel, and new knowledge about the suspected toxic chemical may require immediate aircraft landing, vehicle

evacuation, and/or additional provider PPE.

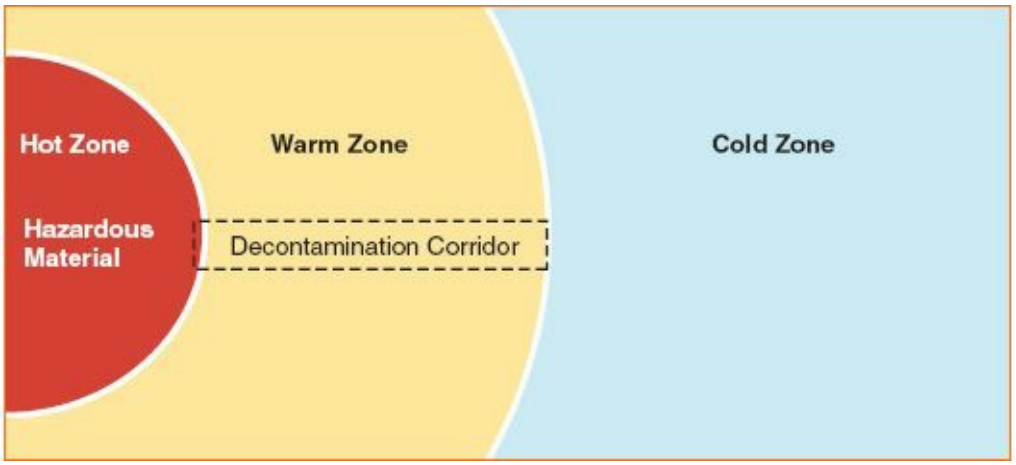

Figure 20-13 Configuration of a hazmat scene.

Patient transport further requires an adequate report to the receiving facility, including the aforementioned elements, and thorough, accurate documentation of the patient condition, interventions performed, and status or events during transport. Crews should weigh the benefits of providing a hazmat container to the receiving facility staff (for substance identification purposes) against any additional risks that transporting this container may pose. A common gasoline container provides minimal benefit with a high risk, whereas a well-sealed container of an unusual substance that is not highly toxic may greatly improve subsequent patient care while posing negligible increased risk. Every situation requires special consideration.

Radiation Emergencies

The threat of radiation exposure or nuclear incident is ever present in society. Ionizing radiation is capable of causing injury from the release of heat generated from a controlled or uncontrolled reaction. It is important to evaluate the nature of a particular radiation event to determine if there is any risk to emergency responders and health care providers. Radiation release may occur in health care, industrial, or laboratory settings; during transportation and disposal of radioactive materials; and following a military or terrorist event. Approach to treatment of a potentially exposed patient hinges on the distinction between **irradiation** and **contamination**. Health care providers and emergency responders are not placed at any risk by irradiated patients. In contrast, patients with radioactive contamination spread this material and expose others to radiation. Continued irradiation occurs until contaminating materials are contained or otherwise removed. The use of a radiation detection device (discussed later) helps identify which patients are contaminated with radioactive particles.

Further radiation exposure occurs during **incorporation**. Devastating individual patient toxicity develops when radioactive materials enter the body, causing ongoing internal exposure.

Figure 20-14 A radiation detection device.

Clues to the diagnosis of radiation exposure may be available by a number of possible methods. A history of radiation exposure through patient report of an isolated event or widespread knowledge of a large-scale event will greatly assist in diagnosis. The military, health care facilities, emergency responders, laboratories, and industrial settings have various radiation detection devices available **Figure 20-14**. Radioactive particles may be present in a patient's mucous membranes or body fluids and tissues. Radiation poisoning (**acute radiation syndrome**) may also be diagnosed clinically in potentially exposed people.

Emergency responders should develop a formal radiation response plan. Providers working in proximity to a radiation release need appropriate protective clothing for the situation and must use respirators to avoid inhaling contaminated material. There is little to no risk to the health care provider when caring for a patient who has been removed from the source of contamination. The patient should be decontaminated before the initiation of care, unless immediate life threats exist. Once decontaminated, no risk exists to the health care provider from radiation.

Patient decontamination involves removing contaminated clothing and jewelry and providing copious irrigation and thorough washing of the skin with soap and water. Providers should also be checked and decontaminated if necessary. Patients who are exposed to only electromagnetic radiation do not require decontamination. Following decontamination, patients should be reassessed for persistent radiation by using a hand-held or similar device. Persistent radiation requires repeated decontamination.

Patients may die within several hours of a massive radiation exposure. Early symptoms include nausea, vomiting, and diarrhea; abdominal pain; fever; mental status changes; coma; and shock. Following the first 1 to 2 days, patients may have a brief recovery period. Subsequent toxic effects include multisystem organ dysfunction, bone marrow depression, sepsis, hair loss, dermatologic injury, and eventual death.

Initial treatment is focused on removal of any accessible radioactive substances in the body. Chelating agents may bind and remove certain radioactive substances. Forced diuresis may also be helpful. Additional treatments are based on presenting symptoms and directed toward minimizing the potential for catastrophic infection.

Radiation burns appear the same as other burns, and their management varies only by the need to decontaminate the wound of radioactive particles. In addition, for massive doses of radiation, the systemic effects of radiation exposure should be considered and treated. Wounds should be dressed in clean, dry dressings.

Flight Considerations

The importance of safety during air-medical transport cannot be overstated when transporting patients following a poisoning, overdose, or toxic exposure. Affected patients pose a serious risk to the lives and health of the transport team.

As stated repeatedly throughout this chapter, patients should not be placed into a transport vehicle, especially a helicopter or airplane, until an effective initial decontamination has been completed. Unlike ground transport vehicles that can stop almost anywhere, helicopters and airplanes require safe areas to land that are often unavailable when conditions in the transport vehicle become unsafe owing to the presence of toxic substances from a contaminated patient. In many cases, effective decontamination requires the removal of all contaminated clothing and adequate cleansing and irrigation for a particular substance before air transport can begin.

Air-medical crews are also at risk from patients (or family members) with bizarre, aggressive, combative, or violent behavior. It is essential to screen patients (and family members) before transport and to use appropriate sedation and restraints. At least one fatal air medical crash has been attributed to a patient interfering with aircraft operation. The risk from patients or family members interfering with safe aircraft or transport vehicle operation should not be underestimated.

During air-medical transport, access to patients is often limited. In the confined space of an aircraft, with environmental variables and loud noises, it is often impossible to perform an adequate patient assessment and many therapeutic interventions. Noise and vibration undermine patient monitoring. Low light conditions in many aircraft make recognizing skin color changes, respiratory alterations, and even subtle emesis difficult to detect. Air-medical crew must be especially prepared to anticipate and manage changes during the flight.

Summary

The management of patients after poisoning or overdose is often a challenging, complicated endeavor. CCTPs must ensure transport team safety while optimizing the chances for patient recovery following a toxic exposure. This chapter serves only as a general overview of various toxicologic emergency situations. During actual patient care, early consultation with a toxicologist, a Poison Center, or a reliable toxicology reference will provide invaluable assistance. CCTPs must never lose focus on safety and the ABCs when treating or transporting patients experiencing a toxicologic emergency.

Case Study

YOU ARE A MEMBER OF A HELICOPTER FLIGHT CREW and you have been called to a rural facility to transport an 18-year-old male who reportedly took his mother's amitriptyline (a TCA) after his girlfriend broke up with him.

On arrival you receive a report from the attending physician. He states that the patient took an unknown amount of the TCA, amitriptyline, 1 hour before his arrival at the emergency department. The patient has been in the hospital for approximately 45 minutes. The patient was administered 60 g of activated charcoal when he arrived. The physician reports that all the patient's laboratory values were normal and he recently received the patient's arterial blood gas measurements, which were as follows: pH, 7.37; Pa_{CO_2}, 43 mm Hg; Pa_{O_2}, 80 mm Hg; and oxygen saturation, 96%. On an ECG, the only other finding was sinus tachycardia at a rate of 118 beats/min with a prolonged QRS interval at 120 ms. The patient has a 20-gauge antecubital IV line in place.

When you obtain the patient's history from his mother, she tells you that she takes 75 mg of amitriptyline at bedtime for depression. She said she receives 2 week's worth of medication at a time,

and she just filled her prescription. She found her son asleep on his bed with an empty pill bottle beside him. She was able to wake him up and then called 9-1-1. The mother states that her son told her that his girlfriend just broke up with him and that he just wanted to "end it all."

On your arrival at the patient's bedside you find an 18-year-old male who appears lethargic and currently lying on his side vomiting black charcoal. His vital signs are as follows: blood pressure, 92/60 mm Hg; temperature, 97°F (36.1°C); pulse rate, 118 beats/min; respiratory rate, 24 breaths/min; and oxygen saturation, 92%. His Glasgow Coma Scale score is 11. He opens his eyes to pain and is able to localize pain. His conversation is confused. The patient has scattered rhonchi throughout consistent with probable aspiration. You are unable to auscultate bowel sounds, and he has diminished reflexes.

1. What are your priorities with this patient prior to transport?
2. What other priorities would be important for the treatment of this patient?

Analysis

One of your most important priorities prior to transport is airway management. Depending on your transport vehicle, some providers might elect to "load and go" and secure the airway en route; however, your patient is already at high risk for aspiration and it would probably be more effective to manage the airway in the more controlled environment of the emergency department prior to transport. This patient needs rapid sequence intubation with both sedative and short-term paralytic medication. Nasogastric intubation would then be accomplished after proper sedation/paralysis was achieved. Cricoid pressure is also important during intubation to prevent any possible further aspiration. Long-term paralysis with a nondepolarizing paralytic should be avoided (unless your service has continuous electroencephalographic monitoring). Patients who have overdosed with TCAs are at high risk for seizures. Patients whose QRS interval is greater than 100 ms have up to a 34% chance of having seizures and up to a 14% chance of having a life-threatening arrhythmia. Once the patient has been paralyzed with a long-term paralytic you would be unable to tell if the patient was seizing.

Sedation is required to enable the patient to tolerate the ET tube. An anxiolytic agent such as lorazepam or midazolam should be used. These agents also protect against seizures. The typical sedative dose for midazolam is 0.025 to 0.05 mg/kg IV. If you are administering midazolam for seizures, the usual loading dose is much higher, 0.1 mg/kg IV or greater. Propofol, a short-acting sedative, can be used if your service carries it and/or the sending agent stocks the medication. The ET tube should be secured prior to transport, and a nasogastric tube should be placed. You would also want to instill 60 g of charcoal into the nasogastric tube and then clamp it prior to transport because the patient has vomited the first dose.

Lastly, you need to secure one or two additional large-bore IV tubes. Because of the anti-alpha-adrenergic effect of TCAs, this patient is at high risk for further hypotension. He will probably require aggressive fluid resuscitation to stabilize his blood pressure while en route. If the patient remains hypotensive despite fluids, vasopressors with an alpha-agonist effect (norepinephrine) would be administered to maintain blood pressure. The additional IVs should be started in flight.

Serum alkalinization with sodium bicarbonate is important in treating patients with a tricyclic overdose. Most Poison Centers recommend serum alkalinization if the QRS duration is 100 ms or greater, if the pH is less than 7.1, or if the patient is hypotensive or having arrhythmias. Alkalinization protects patients from the cardiotoxic effects of TCAs. Correction with sodium bicarbonate promotes protein binding of TCAs and improves myocardial contractility. The goal of therapy is a pH range between 7.5 and 7.55.

Sodium bicarbonate is initially given as a bolus of 1 to 2 mEq/kg IV. You then can begin an IV drip with 150 mEq of sodium bicarbonate per liter of 5% dextrose in water and titrate to keep your pH within

the goal (1 to 3 mL/kg/h). Frequent pH determinations are needed. This is difficult during transport, unless you have point-of-care testing in the helicopter. If the sending institution has started this therapy, it is usually maintained during the flight and it is not titrated until the pH is checked at the receiving facility. If the sending institution has not initiated this, typically the bolus dose is given and the drip would be started at the receiving institution.

Prep Kit

Ready for Review

- Poisons, chemicals, medications, and other toxic substances are found in dangerous quantities in homes, schools, agriculture, industry, and commercial establishments; on all modes of transportation; and naturally in the environment.
- If rescuers or health care providers do not use the correct PPE before initial patient contact, it may be too late for the equipment to provide adequate protection.
- CCTPs may encounter hazardous situations during anticipated patient transports between health care facilities, while responding to an emergency in the community, or by happening on a vehicular crash.
- Patients may sometimes exhibit violent, bizarre, or aggressive behavior, such that chemical or physical restraints may be necessary before effective assessment or treatment can begin.
- All patients should be evaluated for the presence of weapons before transport.
- Once the safety concerns of health care providers and emergency responders have been adequately addressed, the CCTPs should evaluate and manage any problems with the patient's ABCs.
- As with all patients, maintaining or establishing a patent airway is the top priority in the management of patients with a toxic exposure.
- A previously patent airway may become compromised during patient transport owing to alteration in the patient's mental status or seizure activity, evolving structural abnormalities from trauma or increasing edema, or obstructions from emesis, secretions, or a foreign body that becomes displaced during the transport.
- Patients who received activated charcoal or syrup of ipecac have an unusual risk of subsequent airway compromise.
- Breathing is second only to airway in importance during patient assessment. Without effective oxygenation and ventilation, tissue hypoxia, acidosis, and cell death will occur.
- Patients characterized by physiologic stress, acidosis, hypermetabolic states (such as in pediatrics), and exposure to many toxic substances require greater oxygenation and ventilation than would usually be required.
- Cyanosis, fatigue, and dyspnea indicate that a patient's respiratory status may be compromised.
- Lung auscultation revealing wheezing, pulmonary edema, and decreased, absent, or coarse breath sounds indicates unstable respiratory status.
- Evaluation of a patient's circulation requires assessment of end-organ tissue perfusion and overall cardiovascular functioning.
- During the evolution of a toxic exposure, a patient's circulatory status may decline because of any of the following:

- Direct exposure to cardiotoxic or vasoactive substances
- Fluid volume loss or redistribution
- Electrolyte disturbance
- Airway or respiratory compromise with secondary cardiac dysfunction
- Manifestations of preexisting cardiovascular disease
- Altered blood transport ability

- The patient, family, and bystander interviews may provide valuable clues to the nature and severity of a toxic exposure, including information about prodromal symptoms and preexisting medical problems.
- Transport teams must balance the usefulness of a complete head-to-toe physical examination with concerns for patient thermoregulation, privacy, patient access in confined transport vehicles, and the clinical needs of the patient.
- Hemodynamic and respiratory alterations (for example, tachycardia, bradycardia, hypertension or hypotension, and hyperthermia or hypothermia) may occur as a result of direct action on organs and tissues or through effects on the central nervous system.
- Advances in point-of-care testing technology allow CCTPs to measure blood chemistry values, arterial or venous blood gases, and other assorted values during transport and obtain results almost immediately.
- Exposure to certain classes of chemicals and medications produces a readily identifiable pattern of clinical signs and symptoms (toxidrome), which aids in diagnosis when the exact nature of the exposure is unclear.
- Some patients may experience life-threatening reactions to medications taken at therapeutic doses.
- Anticholinergic syndrome occurs following excessive exposure to medications such as antihistamines, atropine, and benztropine, resulting in muscarinic receptor blockade at the neuromuscular junction.
- Cholinergic syndrome (cholinesterase inhibitor toxicity) occurs following exposure to organophosphate and carbamate insecticides or to certain chemical nerve agents. Cholinesterase inhibitors may affect nicotinic receptors, muscarinic receptors, or both and alter the function of the neurotransmitter acetylcholine.
- Opioid syndrome commonly develops following illicit use or abuse of opioids in the community or as an adverse consequence of a therapeutic error or accidental ingestion of opioids (such as morphine, heroin, and fentanyl).
- The administration of an opioid antagonist as a treatment for opioid syndrome may precipitate severe, violent withdrawal symptoms. Many opioids also exert effects much longer than the duration of opioid antagonists, allowing for the return of life-threatening symptoms.
- Sympathomimetic syndrome involves overstimulation of the adrenergic nervous system, resulting in tachycardia, hypertension, agitation, seizures, hyperthermia, dilated pupils, and diaphoresis.
- Malignant hyperthermia occurs following the administration of succinylcholine or certain inhaled anesthetic agents to genetically susceptible patients and is characterized by muscle spasms, profound muscle rigidity, acidosis, hyperthermia, tachycardia, tachypnea, myoglobinuria, rhabdomyolysis, and hyperkalemia.
- Neuroleptic malignant syndrome is a potentially fatal reaction to antipsychotic and antischizophrenic medications in which hyperthermia, profound muscle rigidity, metabolic acidosis, confusion, and, in severe cases, renal failure, respiratory failure, arrhythmias, and cardiovascular collapse develop.
- Serotonin syndrome is an unusual response to serotonin-altering medications causing

hyperserotoninergic symptoms (for example, irritability, muscle rigidity, hyperthermia, diaphoresis, headaches, seizures, coma, tachycardia, and hallucinations).

- Interventions to maintain and enhance the ABCs should not be delayed in favor of interventions specific to toxicologic emergencies (decontamination, enhanced elimination, and antidote administration), which will not become effective rapidly enough to correct immediately life-threatening problems with the ABCs.
- Primary decontamination usually occurs at the scene or outside a health care facility or transport vehicle and is intended to protect rescuers and health care providers from exposure to a toxic substance during patient care and transport.
- Secondary decontamination, which is directed at minimizing patient absorption or injury from a toxic substance, poses much less risk to health care providers than does primary decontamination.
- Decontamination of a hazardous chemical should occur before an unprotected health care provider makes any contact with the material, whether the material is found at the site, on the patient, or on other providers.
- Potentially suicidal, combative, aggressive, violent, intoxicated, and confused patients should be restrained—using physical or chemical restraints—before transport.
- Endotracheal intubation provides optimal protection for an obtunded or otherwise at-risk patient.
- Conventional ventilator settings are often inadequate for a patient's needs following a poisoning or overdose.
- Oxygen saturation, blood gas analysis, and $ETCO_2$ provide valuable information about the adequacy of oxygenation and ventilation; ongoing monitoring of respiration focuses on changes in lung sounds, patient appearance, and cardiovascular function (as shown by an ECG and assessment of perfusion).
- Toxic exposures may cause alterations in vascular tone, kidney function, and electrolyte concentration, thereby disrupting fluid balance.
- Vascular access sufficient for administering emergency medications and fluids should be established in any patient exposed to a potentially harmful substance.
- Every patient must receive adequate sedation and analgesia while chemically paralyzed and should be prophylactically medicated against seizures.
- Patients with increased drug tolerance or a hypermetabolic state require significantly more sedation and analgesia while chemically paralyzed.
- Nonintubated patients require anxiolysis and analgesia following many toxicologic exposures.
- Psychiatric and other at-risk patients may require sedative medications to facilitate patient care and promote patient comfort.
- Patient decontamination following exposure to a toxic substance is directed at minimizing the quantity of the substance absorbed by the patient and the extent of any local damage. Decontamination may be as simple as providing the patient with fresh air or as complicated as whole-bowel irrigation.
- Caustic agents and acetylcholinesterase inhibitors can cause systemic toxic effects from dermal absorption; other chemicals cause severe local reactions or burns when placed in contact with skin.
- Flushing with water or saline (if the chemical is not water-reactive) is the recommended approach for removal of chemical agents from the patient's skin or eyes.
- Methods for gastrointestinal decontamination include activated charcoal administration, gastric lavage and emptying, and whole-bowel irrigation; however, gastric lavage and whole-bowel irrigation are not

done in the transport environment.

- Enhanced elimination may be considered if the patient is exposed to lethal quantities of a toxic substance, the ordinary route of elimination from the body is impaired by the overdose or other pathology, or the patient will likely not tolerate adverse effects of the poisoning because of a preexisting medical condition.
- Acetaminophen toxicity, which can result in liver failure in severe cases, is treated with initial gastrointestinal decontamination with activated charcoal, followed by oral or IV acetylcysteine (Mucomyst).
- In the field, treatment of an amphetamine overdose—which presents with classic sympathomimetic symptoms—is largely supportive.
- The majority of patients who experience benzodiazepine overdose require only conservative management and careful observation.
- Glucagon is the treatment of choice for a beta-blocker overdose.
- One tablet of a calcium channel blocker is often enough to cause serious toxicity or death in a small child. IV calcium is the antidote to an overdose of a calcium channel blocker.
- Symptoms of cardiac glycoside toxicity are often vague, frequently causing misdiagnosis.
- There is no antidote for cocaine; the treatment for overdose of this illicit drug is supportive and based on the clinical presentation.
- Patients who experience an opioid overdose have profound CNS and respiratory depression. Naloxone —which may be administered intravenously, intramuscularly, subcutaneously, via ET tube, or intranasally—will reverse opioid effects and often reestablish a patent airway and spontaneous breathing.
- Any new patient complaint of tinnitus, dizziness, or deafness should prompt an evaluation of possible salicylate poisoning. There is no antidote for salicylate poisoning, but this condition is a candidate for enhanced elimination.
- In selective serotonin reuptake inhibitor (SSRI) overdose situations with serotonin syndrome, the treatment is supportive and based on presenting symptoms.
- Ethylene glycol and methanol can cause profound, lethal metabolic acidosis following ingestion of even very small quantities of these chemicals. Two antidotes are available for the treatment of methanol and ethylene glycol poisoning: ethanol and fomepizole.
- Any patient admitted to a health care facility for an intentional overdose should be screened for the presence of tricyclic antidepressants (TCAs) and given aggressive supportive treatment following a TCA overdose.
- The potential for rescuer exposure is high when the incident involves acetylcholinesterase inhibitors, such as during unintentional contact with certain pesticides or as part of a chemical weapon release. Skin and eye decontamination should be initiated promptly by rescuers or health care providers using the appropriate PPE.
- The brain and heart are the primary sites of carbon monoxide (CO) toxicity owing to their large oxygen requirements. If any doubt exists regarding possible CO exposure, aggressive treatment should be started before laboratory results are obtained.
- The goal of therapy in case of CO toxicity is to displace the CO, under pressure, from the hemoglobin and the mitochondria. Patients with altered mental status, seizures, or serious burns in the setting of CO poisoning should have their airway actively managed by endotracheal intubation.

- Exposure to caustic agents can occur through inhalation, ingestion, dermal exposure, or eye exposure; ingestion of caustic agents has the potential to cause devastating injury.
- Chlorine, ammonia, and asphyxiate gases have the potential to displace oxygen in a patient's lungs; damage or irritate the mouth, nose, and airway; or otherwise disrupt effective respiration. Symptomatic patients may require supplemental oxygen, bronchodilator medications, humidified oxygen or air, or assisted ventilation in severe exposures.
- Cyanide poisoning is confirmed with serum cyanide and thiocyanate levels. Patients have a multitude of neurologic, cardiovascular, and respiratory symptoms. Any exposure to cyanide should be considered potentially lethal. Treatment includes administration of amyl nitrite, administration of IV sodium nitrite, and then administration of sodium thiosulfate. These antidotes are commercially available.
- Abuse of hydrocarbons occurs from "huffing" various highly volatile hydrocarbons. Sudden sniffing death syndrome occurs when people (usually adolescents) are startled while secretly huffing hydrocarbons.
- Hydrocarbons such as gasoline, kerosene, and petroleum ether pose primarily a risk of chemical pneumonitis following aspiration; the care of patients who have toxic exposures to these substances is supportive.
- Hydrofluoric acid is a potent caustic substance that can cause devastating local and systemic toxicity from exposure to an extremely small amount of concentrated liquid. Calcium is the antidote for hydrogen fluoride poisoning.
- A variety of substances can cause serious illness or death in very small quantities, especially in children. The top three include calcium channel blockers, beta-blockers, and TCAs.
- CCTPs without specialized training or equipment should remain well outside the "hot" and "warm" zones where provider exposure to toxic substances is possible.
- Poison Centers and Chemtrec may provide invaluable assistance to health care providers at incidents involving hazardous materials.
- The main objective of CCTPs at hazmat scenes is to assess and ensure personnel safety during patient care and transportation; only then can patient assessment and treatment occur.
- A hazmat scene is configured with the chemical source in the center of three concentric circles: the hot (contaminated) zone, where PPE is essential; the warm zone, where PPE is used and extraneous personnel are not present; and the cold zone, where no environmental hazards should be present.
- Once adequate patient decontamination has been performed and other safety concerns have been addressed, patients involved in hazmat incidents should be transported to the closest appropriate health care facility.
- CCTPs should carefully monitor for the following situations during patient transport:
  - Deterioration of the patient's clinical condition as the toxic exposure evolves
  - Signs of inadequate decontamination
  - Any interventions appropriate for the patient's clinical situation, within the ability of the transport team, that have not been already performed
- Radiation release may occur in health care, industrial, or laboratory settings; during transportation and disposal of radioactive materials; and following a military or terrorist event. Patients may die within several hours of a massive radiation exposure. The use of a radiation detection device will help identify which patients are contaminated with radioactive particles.
- Radiation burns appear the same as other burns; their management varies only by the need to

decontaminate the wound of any radioactive particles. In the flight environment, effective initial decontamination before take-off is extremely important. Other flight considerations for critical toxicologic emergencies include thoroughly screening patients and family members to prevent violence and behavioral problems during flight and anticipating changes in patient condition that may be difficult to detect during flight.

Vital Vocabulary

acetylcholine A chemical neurotransmitter in the parasympathetic nervous system.

acetylcholinesterase An enzyme that breaks down acetylcholine at the neuromuscular junction.

activated charcoal A carbon-based liquid with an incredible absorptive ability that is typically administered orally or via nasogastric or orogastric tube to decrease the available quantity of a toxic substance.

acute radiation syndrome Radiation poisoning.

adsorbtion The process of attracting molecules of a substance to the surface of that substance.

anticholinergic syndrome A syndrome that occurs following excessive exposure to medications such as antihistamines, atropine, and benztropine (Cogentin), or other substances such as Jimson weed, resulting in muscarinic receptor blockade at the neuromuscular junction; characterized by tachycardia, hyperthermia, dilated pupils, warm (or hot) dry skin, ileus, delirium, seizures, psychosis, and urinary retention.

anxiolysis The reduction of anxiety by the administration of an antianxiety agent.

body packers People who swallow carefully packaged capsules for smuggling purposes.

body stuffers People who hastily swallow illicit substances to avoid impending arrest.

chelating agents Chemical substances that bind to heavy metals to remove them from the body.

cholinergic syndrome Cholinesterase inhibitor toxicity.

cholinesterase An enzyme that hydrolyzes acetylcholine to acetic acid and choline.

coagulation necrosis The death of tissue resulting from a blockage of blood flow to that tissue, in which the blockage is caused by clots preventing blood from reaching the tissue.

cocaine washout syndrome Profound exhaustion with the ability to regain normal mental status and orientation when aroused; common with heavy cocaine users.

cold zone The area surrounding the warm zone at a hazardous materials scene. No environmental hazards should be present in this zone.

contamination A state in which a certain substance, such as blood, infectious material, or a toxic substance, is present on an item or surface; in the case of radiation, it is important to distinguish between this and irradiation.

DUMBELS Mnemonic for symptoms of anticholinesterase inhibitor toxicity: Diaphoresis/diarrhea, Urination, Miosis, Bradycardia/bronchospasm/bronchorrhea, Emesis, Lacrimation, and Salivation.

enhanced elimination A process that replaces or augments the body's normal method of eliminating, modifying, or breaking down toxic substances.

gluconeogenesis Glucose formation.

glycogenolysis The breakdown of glycogen to glucose.

hemoperfusion A treatment in which a patient's blood is filtered outside the body through a substance that removes toxic substances from it; a method of removing toxic substances from the blood.

hepatotoxicity Capable of damaging the liver.

hot zone The area immediately surrounding the chemical source at a hazmat scene.

incorporation In the radiologic context, a process in which radioactive materials enter the body during radiation exposure, causing ongoing internal exposure and creating devastating individual patient toxicity.

inotropic Affecting the contractility of muscle tissue, especially cardiac muscle.

irradiation Exposure to radiation; it is important to distinguish between this and contamination because health care providers and emergency responders are not placed at any risk by patients who have been exposed but are not contaminated.

liquefactive necrosis Tissue death caused by bacterial or fungal infections in which cellular destruction has occurred, leaving a lesion filled only with pus and the liquid remains of the tissue.

malignant hyperthermia A condition that may occur after administration of certain inhaled anesthetics and is characterized by muscle spasms, rigidity, acidosis, hyperthermia, tachycardia, tachypnea, myoglobinuria, rhabdomyolysis, and hyperkalemia.

methamphetamine washout syndrome Excessive sleep, hunger, and depression as a result of excessive amphetamine use.

neuroleptic malignant syndrome (NMS) A potentially fatal reaction to antipsychotic and antischizophrenic medications, characterized by patient hyperthermia, profound muscle rigidity, metabolic acidosis, and confusion.

opioids The class of chemicals that includes naturally derived opiates and newer artificial medications with the same properties.

opioid syndrome Toxicity that develops following illicit use and abuse of opioids.

phosphodiesterase An enzyme that helps break phosphodiester bonds, creating smaller nucleotides.

point-of-care testing Laboratory testing that is performed at the point of care, for example, the bedside, so that results can be quickly obtained and considered while decisions are being made about patient care.

primary decontamination A form of decontamination that usually occurs at a scene or outside a health care facility or transport vehicle to protect rescuers and health care providers from exposure to a toxic substance during patient care and transport.

prodromal Referring to the early signs and symptoms that occur before a disease or condition, such as a toxic exposure, fully appears, for example, dizziness before fainting.

pulse CO-oximetry A noninvasive screening and monitoring method for methemoglobinemia and carbon monoxide exposure.

rhabdomyolysis The destruction of muscle tissue.

secondary decontamination A form of decontamination that is directed at minimizing patient absorption or injury from a toxic substance; occurs after initial decontamination has occurred outside a health care facility or transport vehicle.

serotonin syndrome An unusual response to serotonin-altering medications causing hyperserotoninergic symptoms.

SLUDGEM Acronym for Salivation, Lacrimation, Urination, Diarrhea, Gastroenteritis, Emesis, and Miosis, which are symptoms of anticholinesterase inhibitor toxicity.

sudden sniffing death syndrome Occurs when a surge of catecholamines on a sensitized myocardium causes ventricular fibrillation or ventricular tachycardia; can occur when a person is startled while huffing hydrocarbons.

sympathomimetic syndrome A syndrome that involves over-stimulation of the adrenergic nervous system, resulting in tachycardia, hypertension, agitation, seizures, hyperthermia, dilated pupils, and diaphoresis.

toxidrome A group of symptoms, or syndrome, associated with toxicity of a given substance.

volatile Easily changed from liquid to gas form.

warm zone Area surrounding the hot zone at a hazmat incident.

whole-bowel irrigation (WBI) A gastric decontamination method that involves the patient consuming large quantities of a nonabsorbable, electrolyte-balanced liquid that propels stomach and intestinal contents through the digestive system.

Obstetric and Gynecologic Emergencies

Authors

John Bray, BS, NREMT-P, CCEMT-P

Phillip L. Coule, MD

Matthew Lyon, MD, FACEP

Michael D. Shaw, DO, FACEP

Objectives

1. Discuss the anatomy of the female reproductive system (p 842).
2. Recognize the physiologic changes during pregnancy (p 844).
3. Describe the changes that occur in the cardiovascular, respiratory, gastrointestinal, renal, and endocrine systems (p 844–846).
4. Discuss dermatologic changes that occur during pregnancy (p 846).
5. Discuss special areas of concern when performing a critical care transport of a pregnant patient (p 846).
6. Describe the management of the pregnant patient who is in cardiac arrest (p 847).
7. Discuss potential maternal cardiovascular complications exacerbated or induced by pregnancy (p 847).
8. Discuss fetal oxygenation and heart rate, including conditions associated with fetal distress during labor (p 847).
9. Discuss how to assess a fetus during a critical care transport (p 847).
10. Describe several methods of fetal monitoring during critical care transport of a pregnant patient, including electronic fetal monitoring (p 848).
11. Explain how to use a Doppler device (p 847–848).
12. Define the complications of pregnancy, including spontaneous abortion and causes of bleeding (p 849–851).
13. Recognize and treat abruptio placenta, placenta previa, and uterine rupture (p 851–853).
14. Discuss medical conditions that can exist during pregnancy, including pregnancy-induced hypertension, preeclampsia, eclampsia, and HELLP syndrome, and how to manage them during critical care transport (p 853–861).
15. Discuss medications used in treating pregnancy-induced hypertension, including labetalol and hydralizine (p 853).
16. Understand the concerns regarding preterm labor and premature delivery (p 855–858).
17. Discuss the use of tocolytic agents to interrupt labor (p 857–858).
18. Recognize fetal malpresentations of delivery, including frank breech, complete breech, incomplete breech, footling breech, and umbilical cord prolapse (p 858–860).
19. Discuss how to manage fetal malpresentations during a critical care transport, including frank breech, complete breech, incomplete breech, footling breech, and umbilical cord prolapse (p 859–

860).

20. Describe shoulder dystocia and how to manage this complication during a critical care transport (p 861).
21. Discuss multiple-birth deliveries and how to manage these during a critical care transport (p 862).
22. Briefly discuss postpartum care of the mother and infant during a critical care transport (p 862).
23. Describe potential postpartum complications and their management during critical care transport, including amniotic fluid embolism and postpartum hemorrhage (p 862–864).
24. Recognize and discuss how to manage gynecologic issues and emergencies during critical care transport, including ectopic pregnancy, pelvic inflammatory disease, toxic shock syndrome, ovarian cysts, pathologic cysts, ovarian torsion, and gynecologic trauma including vulvular hematoma and sexual assault (p 864–867).
25. Discuss flight considerations that pertain to a critical care transport of a pregnant patient or a patient with a gynecologic emergency (p 867).

Introduction

CCTPs face many challenges when treating female patients, especially if the patients are pregnant. Patient management is difficult when there are competing concerns for the woman and the fetus, physiologic changes induced by pregnancy, and the presence of potential life-threatening pathologic conditions. This chapter provides an overview of the physiologic changes in pregnancy and describes specific emergency conditions associated with pregnancy and postpartum care. Knowledge of the anatomic and physiologic changes that occur during pregnancy is essential to provide effective care to obstetric patients.

Controversies

A common concern when faced with a critically ill or injured pregnant woman is whether the mother or fetus takes priority. In all cases, the priority is resuscitation and stabilization of the mother. The key to a viable fetus, even when a decision is made to expedite delivery, is restoration of adequate perfusion in the mother.

Anatomy and Physiology of the Female Reproductive System

The female reproductive system includes a 28-day cycle that is regulated by a series of hormonal secretions. These hormones prepare the uterus for implantation of a fertilized egg and the start of pregnancy. In the absence of pregnancy, the uterine wall sheds its inner lining, known as the **endometrium**. The mucosal tissues and blood are discharged through the vagina, which is a process known as menstruation. Menstruation lasts approximately 3 to 5 days.

Figure 21-1 depicts the menstrual cycle. At the beginning of the menstrual cycle, there is a rise in the levels of the follicle-stimulating hormone (FSH), which triggers the start of the preovulatory phase, or follicular phase. During the next 7 to 8 days, the uterine wall begins to swell, or proliferate, and the process of creating an ovum begins with follicle stimulation in the ovaries. FSH stimulates the creation of an oocyte in the ovary. As the oocyte begins to mature, estrogen is secreted by the ovary, causing the endometrium to swell with blood. As the follicle matures, the levels of estrogen cause the anterior pituitary to secrete the luteinizing hormone (LH). Introduction of this hormone causes the release of the

oocyte, which is called an ovum now that it is mature, from the ovaries and the start of ovulation. For the next 24 to 48 hours, as the newly formed ovum travels down the fallopian tube to the uterus, the fertility period is at its peak. A hard shell known as the corpus luteum, which begins to secrete more estrogen, testosterone, and progesterone, is left behind in the ovary. As progesterone levels rise over the next 14 days, the endometrium continues to swell and provide a soft shelter for the egg. If there is no conception, the unfertilized ovum travels into the uterus. Progesterone levels drop off as the corpus luteum begins to dissolve in the ovary and menstruation begins, thus ending the cycle.

Conception and Gestation

At this point in the process, if fertilization has occurred and the egg, known as the zygote, implants in the endometrium, blastocytes inside the zygote secrete human chorionic gonadotropin (hCG), which extends the life of the corpus luteum, and progesterone continues to be secreted. The relatively inelastic placenta, which is attached to the wall of the uterus, supplies the fetus with oxygen and vital nutrients and removes waste products such as carbon dioxide. In addition, the placenta continues to secrete the progesterone needed to maintain a swollen endometrium and continue the pregnancy. The placenta and fetus are connected by the umbilical cord, which contains two arteries and one vein that carry the blood of the fetus to and from the placenta **Figure 21-2**.

The placenta is an ephemial, or transitory, organ that is formed early by the implantation of the blastocyst into the endometrium. The placenta grows with the fetus; it contains a thin membrane that separates maternal and fetal blood from coming into contact with one another. Nutrients, oxygen, and carbon dioxide diffuse across this membrane to nourish the placenta. It is important to understand that maternal blood is never shared with fetal blood; a fetal barrier prevents maternal blood from entering fetal circulation, although substances from the blood, such as nutrients, do transfer. CCTPs need to be aware of the medications that are allowed to be given to a pregnant patient, as well as those that should be avoided. The Food and Drug Administration classifies medications as follows: Class B medications are probably safe for the fetus; Class C medications should be used only if the benefit outweighs the risk; Class D medications have known risks to the fetus, but are used in some situations; and Class X medications are known teratogens and should not be used under the circumstance.

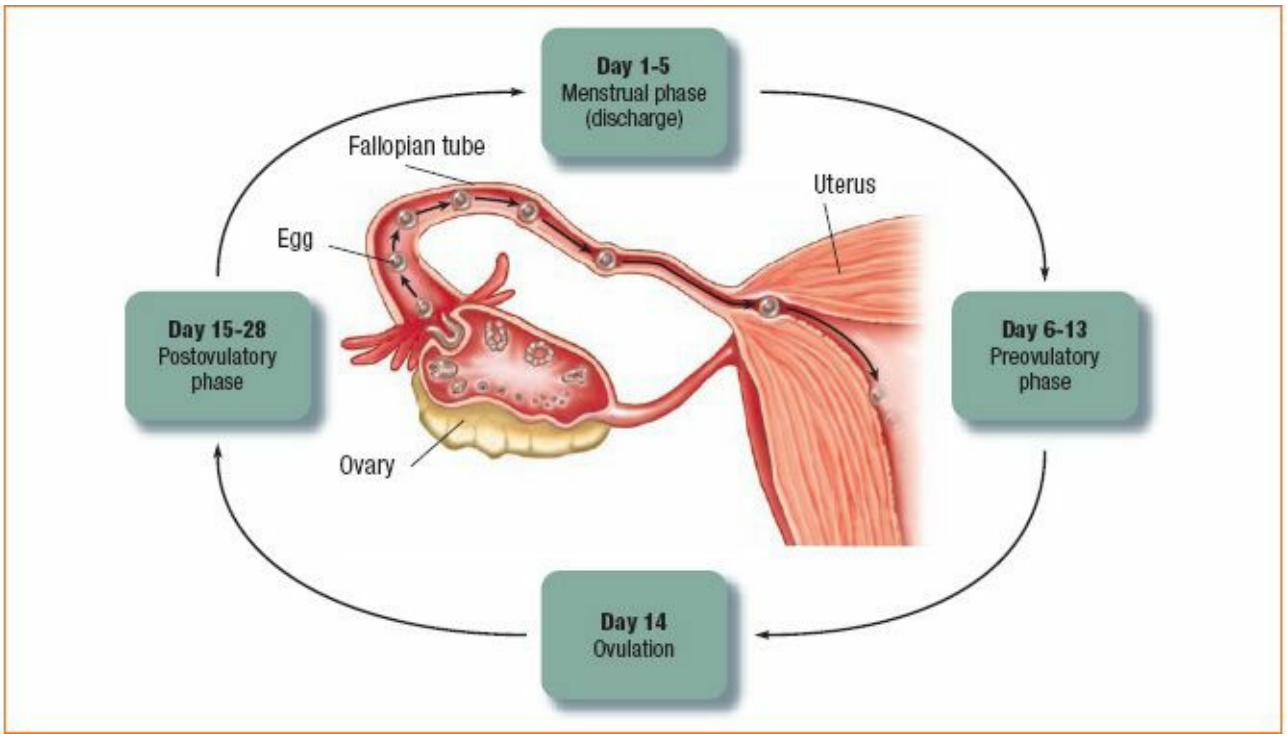

Figure 21-1 The menstrual cycle, based on an average 28-day cycle. The length of the cycle and number

of days in each phase vary from woman to woman, but generally fall within a range of 24 to 35 days.

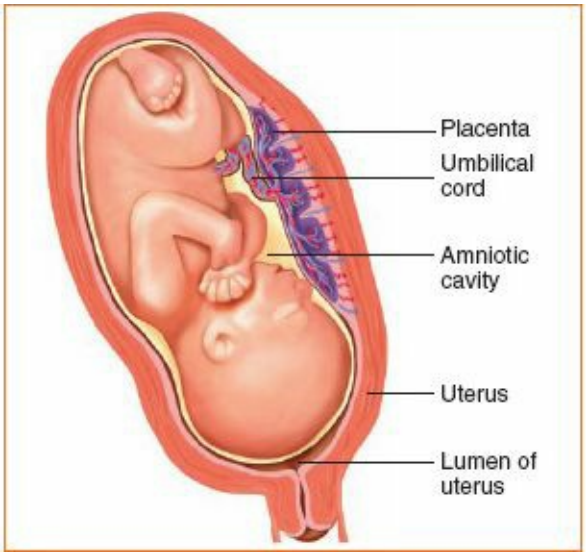

Figure 21-2 The umbilical cord and other structures of the uterus in a pregnant woman.

Early in pregnancy, the uterus is contained entirely within the protective ring of the pelvis. By the 12th week of **gestation**, the enlarged uterus begins to rise out of the pelvis and into the abdomen. By 20 weeks of gestation, the uterus is at the umbilicus, and by 34 to 36 weeks of gestation it reaches the costal margin. This expansion, from approximately 70 to 1,100 g at **term** (38 to 42 weeks' gestation), is due to marked stretching and hypertrophy of existing muscle cells, rather than generation of new cells. As the uterus enlarges, the walls become thin and more fragile. The bowel is pushed cephalad and is somewhat more protected from blunt injury to the abdomen. However, as the uterus rises out of the pelvis, it loses the bony protection provided by the pelvis and becomes more vulnerable to trauma. Also, as the fetus grows, the relative proportion of amniotic fluid to fetal size decreases, making the fetus more vulnerable to trauma. During the last 2 weeks of the pregnancy, the fetal head begins to drop lower into the pelvis in preparation for delivery. As a result, the fundal height, or distance from the pelvic ring to the top of the uterus, decreases by about 2 cm **Figure 21-3**. (To measure the fundal height, use a tape measure from pelvis to epigastrium. The MacDonald's Rule states that the length in centimeters is proportionate to the number of weeks of gestation. For example, a woman who is 15 weeks pregnant would have a fundal height of about 15 cm, give or take 1 to 3 cm. This method is valid from the 12th week until the 38th week of gestation.)

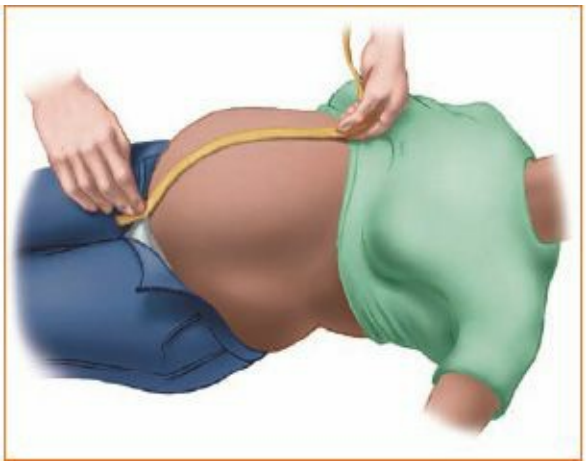

Figure 21-3 Measuring fundal height.

Physiologic Changes During Pregnancy

Pregnancy alters the normal physiology of females, affecting nearly every organ system. These changes may mask well-recognized signs or symptoms of disease, or normal changes may even masquerade as pathologic conditions. A functional knowledge of these alterations is essential to manage a pregnant patient effectively.

Cardiovascular System

Normal cardiac output at rest is approximately 5 L/min, but during pregnancy the cardiac output increases significantly. During the first 10 weeks of pregnancy, the cardiac output increases 20% to 30%, or 1 to 1.5 L/min, and by gestational term the cardiac output could be as high as 43% greater than the cardiac output in a patient who is not pregnant. This increase in the cardiac output is primarily due to an increase in plasma volume and a decrease in vascular resistance resulting from dilation of the uterine arteries. The combination of a greater plasma volume and dilated uterine arteries results in an increase in blood flow to the uterus. At term, the blood flow through the uterine arteries reaches 500 to 700 mL/min. The pregnant patient's pulse rate increases by 10 to 15 beats/min, reaching a maximum in the third trimester of pregnancy (the last 12 weeks [approximately the last third] of pregnancy). This increase in the baseline pulse rate must be considered when you are interpreting tachycardia in response to hypovolemia. The stress on the cardiovascular system is intensified by activation of the renin-angiotensin system during the third trimester of pregnancy, followed by an increase of insulin resistance resulting in high plasma glucose levels. Because these factors can result in gestational hypertension, risk factors that CCTPs must remain aware of include the following:

- Chronic hypertension
- Type 1 and type 2 diabetes
- History of smoking and cocaine use
- Family history of cardiovascular disease and hypertension

Also, the elevated position of the pregnant patient's diaphragm will cause a 2- to 3-cm heart displacement and axial rotation, which can result in a third heart sound and 12-lead abnormalities, such as right or left axis deviation.

Blood Volume and Composition

One of the most significant changes in pregnancy is the marked increase in total plasma volume. Circulating blood volume expands by an average of 40% to 45% as a result of an increase in both plasma volume and the number of erythrocytes. The level of increase depends on such factors as patient size, number of pregnancies **(gravida** [total number of pregnancies], and **parity** [number of pregnancies carried to term of more than 28 weeks' gestation and delivered]), and number of fetuses. The increase in plasma volume is greater than the increase in the level of erythrocytes, giving the appearance of anemia. The hematocrit value decreases, reaching its lowest point between the 32nd and 34th weeks of gestation. This point is referred to as the *physiologic anemia of pregnancy*. The average hemoglobin level in late pregnancy is between 10.5 and 11.0 g/dL, and the average hematocrit value is between 31% and 35%. The leukocyte count is generally elevated during pregnancy and may reach 25,000/µL during labor. However, beginning in the second trimester of pregnancy, leukocyte function is usually depressed and increased susceptibility to infection may occur. The platelet count during pregnancy is relatively stable and therefore **thrombocytopenia** is not usually seen.

Other changes in blood components during pregnancy include a decrease in the level of serum albumin and a lowered total serum protein. Many clotting factors are elevated during pregnancy.

Increased coagulation factors shorten the **prothrombin time (PT)** and **partial thromboplastin time (PTT)**. Fibrinogen levels increase dramatically during pregnancy, nearly doubling by delivery. A pregnant patient is more susceptible to lower extremity deep venous thrombus and pulmonary embolus.

Blood Pressure

At the onset of pregnancy, maternal blood volume increases as much as 30%. During mid-pregnancy, blood pressure often decreases as a result of progesterone, which relaxes the walls around the blood vessels. Lower blood pressures and other clinical signs such as increased jugular vein distention and bi-basilar crackles that can lead CCTPs to believe that the patient is in right-sided heart failure. Treatment should be focused on airway management and oxygen therapy with an understanding that the clinical signs and symptoms are more physiologic than pathologic.

As pregnancy progresses, blood pressure decreases, reaching its lowest point in the second trimester of pregnancy. A lower peripheral vascular resistance allows the diastolic blood pressure to decrease by 10 to 15 mm Hg, whereas the systolic blood pressure normally decreases by 5 to 10 mm Hg. Blood pressure returns to near pre-pregnancy levels at gestational term. During the third trimester of pregnancy, the body position of the pregnant patient may significantly affect her blood pressure and cardiac output. When she is lying supine, the uterus may compress the inferior vena cava, reducing venous return from the lower extremities, causing hypotension. This phenomenon is referred to as **supine hypotensive syndrome**. Displacement of the gravid uterus off of the vena cava by manual manipulation or by placement of the patient in the left lateral position relieves this obstruction and thus restores blood pressure.

For patients with potential spinal injuries, it is important to tilt the backboard to the left to relieve the pressure from the inferior vena cava. This position is accomplished by placing blankets or towels under the right side of the backboard **Figure 21-4**. Note that these materials are placed under the backboard, not directly under the patient.

Venous Pressure

The peripheral venous pressure in the lower extremities also rises progressively during the later stages of the pregnancy due to the compression of the inferior vena cava and pelvic veins by the uterus, which can lead to more bleeding than expected from minor wounds to the lower extremities. CCTPs must be cautious of excessive internal bleeding with minimal clinical signs and symptoms. Pregnant patients involved in blunt trauma must be considered to have internal bleeding even when they are hemodynamically stable.

Figure 21-4 Place pregnant patients with potential spinal injuries on a backboard with blankets and towels under the right side of the backboard to tilt it toward the left and relieve pressure from the inferior vena cava.

TABLE 21-1 Cardiovascular Changes in Normal Pregnancy

	Nonpregnant Patient	Pregnant Patient
Cardiac output	5,000 mL	6,000 mL (20%–40% increase)
Stroke volume	80 mL	110 mL (approximately 30% increase)
Pulse rate	80 beats/min	10%–20% increase
Red blood cell mass	5 million cu mm	33% increase
Systemic vascular resistance	1,500 dyne-sec/cm^{-5}	20% decrease
Mean arterial pressure	85 mm Hg	No change
Systolic blood pressure	120 mm Hg	120 mm Hg
Diastolic blood pressure	70 mm Hg	80 mm Hg

Adapted from: Sodré PM. Maternal physiology changes during pregnancy. *Obstet Gynecol*. Available at: http://www.medstudents.com.br/ginob/ginob5.htm. Accessed February 12, 2009.

Special Populations

The extreme physiologic and hemodynamic changes associated with pregnancy illustrated in this chapter highlight potential consequences resulting from preexisting conditions in the pregnant patient. It is imperative that the CCTP aggressively manage blood pressure, blood glucose, and conditions affecting perfusion in all pregnant patients with cardiac, renal, vascular, or neurologic conditions that may be exacerbated by the changes seen during pregnancy. Failure to do so can result in catastrophic consequences for the mother and infant.

These changes in the cardiovascular system can have a profound effect on any underlying medical condition. CCTPs may be called to transfer a pregnant patient with cardiovascular compromise.

Table 21-1 summarizes cardiovascular system changes during pregnancy.

Respiratory System

During pregnancy, minute ventilation increases due to an increase in tidal volume. The increase in tidal volume is thought to be secondary to increased levels of progesterone. This increased ventilation leads to a lower pCO_2 level of approximately 30 mm Hg (normal, 40 mm Hg). The respiratory rate increases slightly. The body tries to compensate for the increase in pH by creating a state of metabolic acidosis, which results only in a very small change. Arterial blood gas levels tend to be more alkalotic, with the average pH ranging from 7.40 to 7.47.

The increased oxygen demand of the growing fetus results in a significantly reduced oxygen reserve for the patient. Therefore, desaturation occurs more quickly in pregnant patients than in nonpregnant patients. Accessory muscle usage is also difficult in pregnant patients in respiratory distress because the diaphragm is displaced and the abdominal muscles are weakened, resulting in ineffective tripoding. CCTPs must be aware that pregnant patients in respiratory arrest become anoxic faster than nonpregnant patients. Early oxygenation and aggressive airway management with intubation should be primary considerations. Laryngoedema should be expected, with an average Mallampati score of 3 (discussed in

detail in Chapter 6). Consider use of alternate airways if unable to intubate; a bag mask alone will increase the already high risk of aspiration.

Gastrointestinal System

During pregnancy, gastric emptying is delayed and the gastroesophageal sphincter tone is reduced, making gastroesophageal reflux common. These factors combine to increase the likelihood of aspiration during pregnancy when an altered level of consciousness is present. The diaphragm rises an extra 4 cm during pregnancy as a result of the enlarging uterus and cephalad displacement of abdominal contents. The stress placed on the gastrointestinal system results in chronic nausea, vomiting, and, in severe cases, dehydration. Administration of IV fluids and oxygen and patient positioning (position of comfort or on the left side) can help lessen these effects during transport. If a pregnant patient requires placement of a chest tube, a more cephalad location for placement should be considered. The intestines are relocated to the upper part of the abdomen and therefore may be shielded by the uterus from blunt trauma, whereas the liver and spleen remain in their normal location under the diaphragm, but are pushed cephalad somewhat in late pregnancy. In addition, CCTPs must consider intubation early in the pregnant patient because of the higher probability of aspiration.

Renal and Endocrine Systems

During pregnancy, the renal system is stressed; there is a 30% increase in the glomerular filtration rate (GFR) along with **hydroureteronephrosis**. or ureter dilation and obstruction. These conditions lead to frequent urination with hematuria and flank pain. Relief can occur by placing the patient in the left lateral recumbent position. Renal calculi are no more common in pregnant patients than nonpregnant patients, and treatment should remain the same by observation and allowing the stone to pass. Urinary tract infections are also no more frequent in pregnant patients; however, early trimester infections that are left untreated can lead to pyelonephritis in the third trimester of pregnancy about 40% of the time. Patients with chronic renal failure (CRF) can undergo dialysis treatment without any risk to the fetus. Patients with acute renal failure will have issues with compensation of the respiratory alkalosis discussed earlier, so CCTPs must be aware of changes in pH levels and treat them accordingly.

At the beginning of conception, the endocrine system goes into overdrive. The pituitary and thyroid glands enlarge, resulting in the increased production of estrogen, progesterone, cortisol, and thyroxine. These hormones play an important role in fetal development and in preventing the fetus from aborting; however, in some cases, these elevated hormone levels alter the effectiveness of insulin and can result in a condition known as insulin resistance. After 20 weeks' gestation, insulin resistance can lead to elevated blood glucose levels and a condition known as gestational diabetes.

Thyroid conditions (hyperthyroidism or hypothyroidism) may affect fetal development. These conditions therefore should be monitored carefully during prenatal care. CCTPs should expect complications during delivery and a possible distressed neonate if a patient who has a thyroid disorder has had no prenatal care.

Dermatologic Changes

Hormonal changes have an impact on the largest organ of the body—the skin. In addition to acne, pregnant patients can experience linea negra, a darkened line that develops from the navel to the vagina, and chloasma, which causes darkened skin patches to develop on the cheeks and forehead. Finally, some late-term patients present with an itchy rash known as pruritic urticarial papules and plaques of pregnancy (PUPPP) that can be isolated to one region or systemic. Patients can be prescribed topical corticosteroid ointments to treat this condition, but CCTPs must be aware that this can be a life-threatening condition in

patients who have hypothyroidism. Patients will present in anaphylaxis and must be treated with aggressive airway management and beta-agonists.

Critical Care Transport of the Pregnant Patient

The role of the CCTP in any critical care transport is to safely and effectively manage, treat, and transport a patient to the hospital that can best meet the needs of the patient. The pregnant patient's dynamic physiologic changes and the developing fetus can pose a challenge for any hospital, especially those without obstetric services. In addition, pregnancy can lead to exacerbation of chronic diseases such as coronary heart disease, mitral valve prolapse, and aortic stenosis. Treatment needs to focus on maintaining the pregnant woman's hemodynamics. CCTPs need to remember that taking care of the pregnant woman means that the fetus is being taken care of as well. In critical cases, treatment of the pregnant patient is no different than that of the nonpregnant patient; for example, treatment of a pregnant patient with an existing cardiovascular condition does not differ from treatment of a nonpregnant patient with this condition.

The CCTP must perform a complete physical exam, including maternal and fetal hemodynamic monitoring and, if the patient is in labor, external vaginal evaluation for the presence of crowning. If delivery is imminent, the CCTP should assist in the delivery. If you arrive at the initial facility and find that delivery is imminent, delivery should be assisted at that facility; transport should not begin when delivery is imminent.

Transport Management

Cardiac Arrest in the Pregnant Patient

- Administer CPR.
- Provide early oxygenation.
- Place the pregnant woman in the Cardiff Wedge position.
- Defibrillate patients in ventricular fibrillation (but remove fetal monitors).
- Administer resuscitation medications.

Cardiac Arrest Management of the Pregnant Patient

CCTPs need to remember that the pregnant woman's health is the treatment priority. By appropriately treating the pregnant patient, the fetus also benefits. The standard rules of CPR apply, with chest compressions and limited interruptions for ventilation. Because pregnant patients become hypoxic faster, early oxygenation will improve overall outcomes. A late-term fetus can cause circulatory problems, so the following technique can be used. Tilt the patient 15° to 30° to the left or shift the fundus to the left to allow for effective venous return and maximal circulation. If a Cardiff wedge is available, this device is useful in achieving the technique. Defibrillation remains essential for patients in ventricular fibrillation and is safe for the fetus, but fetal monitors (discussed later in this chapter) must be disconnected prior to delivering a shock.

Again, pregnant patients diagnosed with myocardial infarction can be treated with the same medications and procedures as nonpregnant patients; however, delivery will be delayed to reduce stress on the healing myocardium.

Fetal Assessment and Monitoring

Several methods can be used to assess and monitor the fetus. Fetal circulation, oxygenation, and heart rate will be reviewed first.

Fetal Circulation, Oxygenation, and Heart Rate

Fetal circulation occurs through the umbilical vein and umbilical arteries. The umbilical vein carries oxygenated blood from the placenta to the fetus' right atrium via the ductus venosus and the inferior vena cava, and the umbilical arteries carry arteriovenous blood to the placenta. Because the fetus obtains its oxygen via the placenta, the fetal circulation bypasses the lungs until birth.

The oxygen content of the fetus is lower than that of a pregnant woman, even though the rate of oxygen consumption by the fetus is nearly twice that of a pregnant woman per unit weight. The developing fetus obtains its oxygen from the blood of a pregnant woman through the placenta and has only a small reserve of oxygen, usually only 1 to 2 minutes if the supply from the woman is cut off or diminished. During uterine contractions, blood flow through the uterine arteries to the placenta is momentarily interrupted. A healthy fetus with a normal placenta can withstand the stress of labor without having hypoxia develop because there is sufficient oxygen exchange during the interval between contractions.

TABLE 21-2 Conditions Associated With Fetal Distress During Labor

Source	Condition
Umbilical cord	Hematoma Knot in cord Nuchal cord Prolapsed cord Cord compression
Placenta	Infarction Abruption
Uterus	Tetanic contractions Hyperstimulation
Fetus	Anemia Infection
Maternal	Hypertension Hypotension Severe anemia Seizures

The fetal heart is sensitive to the changes in oxygen supply. Monitoring the fetal heart rate gives information concerning the oxygenation status of the fetus. If the heart of the fetus does not receive enough oxygen, the rate will decrease.

Hypoxia may be the result of many causes because fetal oxygenation can be impaired at different anatomic locations within the uteroplacental-fetal circulatory loop. For example, an infarction of the placenta (death of the placental tissue and formation of scar tissue in its place, usually only problematic in extreme circumstances) or a placental abruption (discussed later in this chapter) may lead to impaired

diffusion of oxygen from the maternal circulation to the fetal circulation. **Table 21-2** summarizes the conditions associated with fetal distress during labor.

Fetal Assessment

The true challenge that the CCTP has when transporting a critical pregnant patient is assessing the second patient, the fetus. All patient assessments start with the ABCs. Assessing the ABCs is extremely challenging in the fetus, but this does not mean that assessment and monitoring cannot be done effectively. Prior to transporting a pregnant patient, a fetal assessment needs to be performed.

A pregnant woman should observe a minimum of 10 kicks every 2 hours. As a first step, ask the woman about fetal movement and whether this has occurred. No movement indicates fetal distress and transport should be a priority. Next, auscultate the fundus to detect a heartbeat and any movement not initially felt **Figure 21-5**. It is not recommended to use a normal stethoscope, especially in early term patients; CCTPs should use a Doppler machine starting at 10 weeks' gestation or a fetal stethoscope (Fetoscope) **Figure 21-6** after 20 weeks to detect a heartbeat. The fetus' back is the optimal location to hear the heartbeat; feel for the most rigid part of the fundus to detect the proper location for auscultation. When a hand-held Doppler machine is used, apply conductive gel to the pregnant patient's abdomen at this location to aid in the ultrasound transducer and listen for the heartbeat. To confirm that you are listening to the fetal heart beat, take the pregnant patient's radial pulse and compare the rates; the fetal heart rate should be faster.

Figure 21-5 Checking for fetal responsiveness. After asking the woman about fetal movement, use a Doppler machine or fetal stethoscope, depending on the length of gestation, to feel for the most rigid part of the fundus (the fetus' back) and auscultate that part to detect the heartbeat and any movement not initially felt.

Figure 21-6 A fetal stethoscope (Fetoscope).

The normal heart rate of a fetus is between 120 and 160 beats/min **Table 21-3**. If a patient is in labor, monitor the fetal heart tones for at least 30 seconds every 15 minutes and record the results. The presence of fetal heart tones indicates life, and the absence of fetal heart tones can indicate death. In a noisy environment, however, auscultation of fetal heart tones can be challenging, and it is difficult to determine how the heart rate is changing over time. For this reason, continuous electronic fetal monitoring should be performed during high-risk transports. Continuous electronic fetal monitoring is discussed later in this chapter.

Electronic Fetal Monitoring

Electronic fetal monitoring can be done externally or internally, but during critical care transports it is usually only done externally. **External fetal monitoring** uses an ultrasonic transducer externally applied to the pregnant patient's abdomen **Figure 21-7**. The ultrasonic transducer monitors the fetal heart rate, and a strap around the patient's abdomen monitors uterine contractions. Both of these variables are simultaneously recorded onto a paper chart.

Electronic fetal monitoring is recommended for all high-risk interfacility transports. Monitoring enables continuous reporting of the fetal heart rate and uterine contractions by a 2-channel strip chart recorder that prints the results. The uterine contraction represents a stress on the fetus **Figure 21-8**. The alteration in fetal heart rate correlates with fetal oxygenation.

TABLE 21-3 Heart Rate Parameters

Rate	Beats/min
Normal	120–160
Abnormal • Tachycardia • Bradycardia	< 100 > 160 < 120

Figure 21-7 External fetal monitoring.

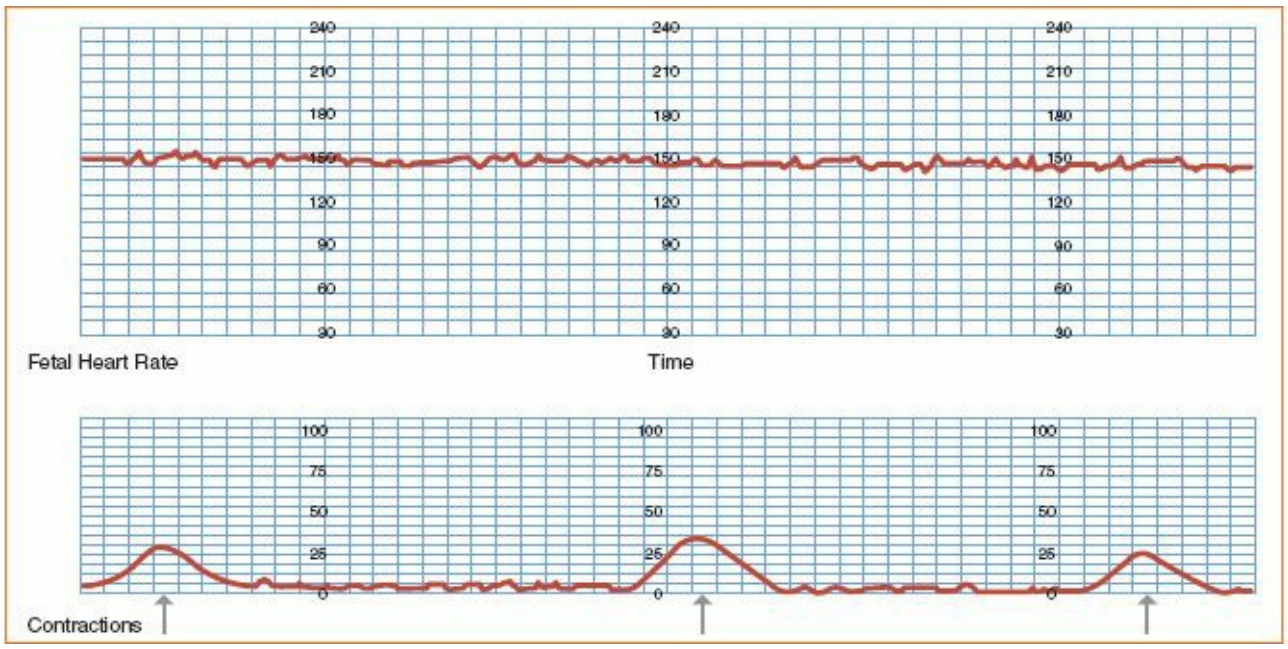

Figure 21-8 A fetal monitoring strip showing uterine contractions.

Equipment

The equipment needed in order to perform external fetal monitoring includes:

- Fetal monitor
- Conducting gel
- Tracing paper
- Ultrasonic Doppler
- External uterine activity Doppler

Steps

Skill Drill 21-1 shows the steps for performing fetal monitoring, which are discussed as follows:

1. Prepare all equipment prior to transport. Introduce yourself and explain the procedure to the patient **Step 1**. Be sure to clarify that this procedure is normal for all transports and that it is essential to monitor the baby's health during the trip.
2. Connect to the power source **Step 2**.

3. Connect the Doppler probe to the patient and adjust the volume **Step 3**.
4. Note that the fetal heart rate should be displayed in green.
5. Make sure that the *Auto Non-Stress Test* switch is in the off position **Step 4**.
6. Manually set the uterine Doppler to zero. Wait for the alerting sound.
7. Press the recording switch.
8. Set the fetal heart tone alarms.

Assessment of fetal monitoring strips rarely occurs during transport, though you may obtain a strip during transport if possible and needed.

Complications of Pregnancy

Spontaneous Abortion

Spontaneous abortion (miscarriage) is the loss of a fertilized developing ovum. Spontaneous abortion is common in early pregnancy with about 30% of all pregnancies ending prior to 20 weeks of gestation. Loss of a fetus after 20 weeks is called intrauterine fetal demise. About 80% of spontaneous abortions occur during the first trimester.

Spontaneous abortions almost always arise from some abnormality in the woman or the fertilized ovum and, in the majority of cases, fetal death occurs before any sign or symptom of the spontaneous abortion. Patients often present with vaginal bleeding or cramping. Assessment of the female patient with vaginal bleeding or abdominal pain focuses on identifying whether the patient is having a spontaneous abortion or whether the symptoms, such as shock, indicate an ectopic pregnancy. With a spontaneous abortion, blood loss is rarely large enough to cause hemodynamic instability. Hypotension should be addressed with volume replacement with isotonic fluids such as lactated Ringer's solution or normal saline. Treatment for women having a spontaneous abortion includes providing comfort and emotional support. Some patients who have a spontaneous abortion may not completely expel all of the products of conception and therefore may require a **dilation and curettage (D&C)**. In this surgical procedure, the physician manually dilates the cervix and scrapes the uterine lining to remove the remaining conception material. Patients having a spontaneous abortion need a D&C procedure to reduce the risk of infection caused by tissue left behind on the uterine wall. The patient should be transported to a facility where this procedure can be performed within 24 hours. CCTPs should maintain documentation of the patient's blood loss by recording the number of sanitary pads that are soaked during transport and relay this information to the receiving facility. Vaginal bleeding that soaks more than one pad every hour should be cause for concern. As with any invasive procedure, there is a risk for infection. CCTPs need to watch for the signs of postoperative infection, including fever, chills, tachypnea, and lethargy.

Signs and Symptoms

Spontaneous Abortion

- Vaginal bleeding
- Cramping
- Abdominal pain
- Hypotension

Skill Drill 21-1

Fetal Monitoring

1 Prepare all equipment prior to transport. Explain the procedure to the patient.

2 Connect to the power source.

3 Connect the Doppler probe to the patient and adjust the volume. The fetal heart rate should be displayed in green.

4 Make sure that the *Auto Non-Stress Test* switch is in the off position. Manually set the uterine Doppler to zero. Wait for the alerting sound. Press the recording switch. Set the fetal heart tone alarms.

Differential Diagnosis

Spontaneous Abortion

- Abruptio placenta
- Ectopic pregnancy
- Placenta previa

Transport Management

Spontaneous Abortion

- Provide volume replacement with isotonic fluids.
- Provide comfort and emotional support.
- Place sanitary pads.

Bleeding

Vaginal bleeding in the third trimester of pregnancy is often associated with significant pathologic conditions that may endanger the life of the fetus and woman. In one third of cases of vaginal bleeding after 20 weeks of gestation, the fetus will die.

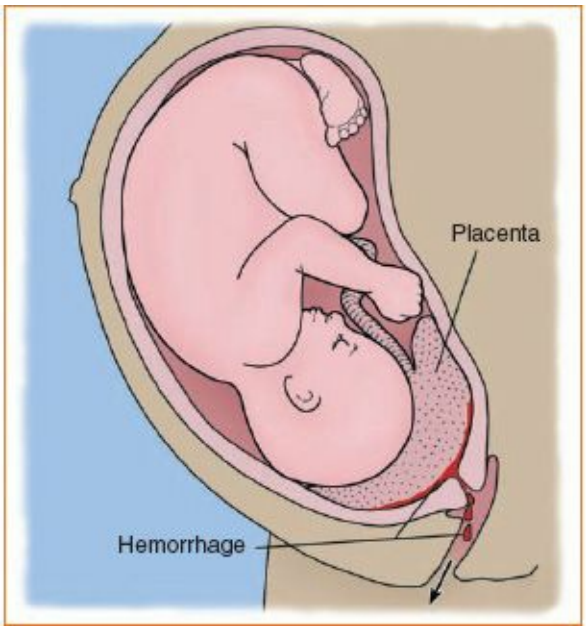

Figure 21-9 Placement of the placenta in abruptio placenta.

As the pregnant woman approaches term, there is an increased possibility of life-threatening hemorrhage associated with vaginal bleeding. Three major causes of life-threatening bleeding are abruptio placenta, placenta previa, and uterine rupture. Because of the high risk of maternal and fetal death associated with any of these clinical entities, any vaginal bleeding during the third trimester of pregnancy must be regarded as a dire medical emergency until proven otherwise. As a general rule, labor is not associated with significant vaginal bleeding. Therefore, you should suspect placenta previa or

abruptio placenta in any patient with third-trimester abdominal pain or vaginal bleeding.

Regardless of the cause of the vaginal bleeding, patient management is the same. The woman should be placed on her left side in a recumbent position to maximize blood return to the heart by preventing supine hypotensive syndrome. High-flow oxygen should be administered along with at least one large-bore IV Lactated Ringer's solution is the optimal treatment, but treatment with 0.9% normal saline as an alternate can be given in 250-mL boluses and titrated to the patient's hemodynamic status. Blood pressure should be maintained at no less than 90 mm Hg systolic. Rapid transport is required, with the receiving hospital notified of the nature of the problem as well as any changes in the condition of the patient en route. ***Under no circumstances should an internal vaginal exam be performed by the CCTP.***

Abruptio Placenta

Abruptio placenta is the premature separation of a normally implanted placenta from the uterine wall **Figure 21-9**. This condition accounts for 30% of vaginal bleeding in the second half of pregnancy. Abruptio placenta can be either spontaneous or a result of trauma.

Signs and Symptoms

Abruptio Placenta

- Vaginal bleeding
- Abdominal pain
- Back pain
- Uterine tenderness
- Signs of shock
- Lack of fetal heart sounds

Differential Diagnosis

Abruptio Placenta

- Ectopic pregnancy
- Placenta previa
- Preterm labor
- Spontaneous abortion

Transport Management

Abruptio Placenta

- Place patient on her left side, in recumbent position.
- Provide bleeding control.
- Provide oxygenation.
- Administer IV fluids.
- Provide rapid transport.

Spontaneous abruptio placenta is primarily associated with maternal hypertension but is also associated with increased maternal age, multiparity, smoking, cocaine use, and previous history of the condition. Bleeding from spontaneous abruptio placenta usually occurs late in the third trimester of pregnancy as the cervix begins to dilate in preparation for delivery.

Abruptio placenta associated with trauma is less common and is usually due to direct trauma to the abdomen. However, it is a complication in 1% to 5% of minor injuries that occur during pregnancy and up to 40% to 50% of major trauma injuries that occur during pregnancy. Because the placenta is less elastic than the uterus to which it is attached, when a pregnant woman is involved in trauma in which the uterus is stretched or deformed, the relatively inelastic placenta separates from the uterine wall, causing abruptio placenta.

Regardless of the cause, the presenting signs and symptoms of abruptio placenta include vaginal bleeding, abdominal pain, back pain, and uterine tenderness. Abruptio placenta can be concealed, however. The separation may occur in such a way that the bleeding is contained by the part of the placenta attached to the uterine wall. The amount of vaginal bleeding may be small or no blood is evident, and the diagnosis may be easily mistaken for premature labor. However, shock may ensue from the concealed blood loss.

On physical exam, the abdomen is usually tender and the uterus is rigid on palpation. When vaginal blood is present, it is usually dark red. Fetal heart sounds are often absent, because the fetus is either partly or completely cut off from its blood supply. The pregnant patient may exhibit signs of shock that may be out of proportion to the amount of vaginal bleeding.

Important factors in the management of the pregnant patient with suspected abruptio placenta are fetal status and the presence or absence of labor. Most women who experience abruptio placenta spontaneously go into labor. The same procedures for all vaginal bleeding in the third trimester of pregnancy should be followed, with a focus on bleeding control, oxygenation, and IV fluids to maintain hemodynamic stability. Again, those procedures are to place the patient on her left side in a recumbent position, administer high-flow oxygen, administer at least one large-bore IV of lactated Ringer's solution or normal saline, and provide rapid transport. Ultrasound should be used when a pregnant woman has experienced blunt force trauma in order to determine if the fetus has life-threatening injuries.

Placenta Previa

In placenta previa, the placenta is implanted low in the uterus and partially or completely covers the cervical canal **Figure 21-10**. Placenta previa accounts for 20% of bleeding episodes after 20 weeks of gestation. Bleeding usually occurs late in the third trimester of pregnancy as the cervix begins to dilate in preparation for delivery.

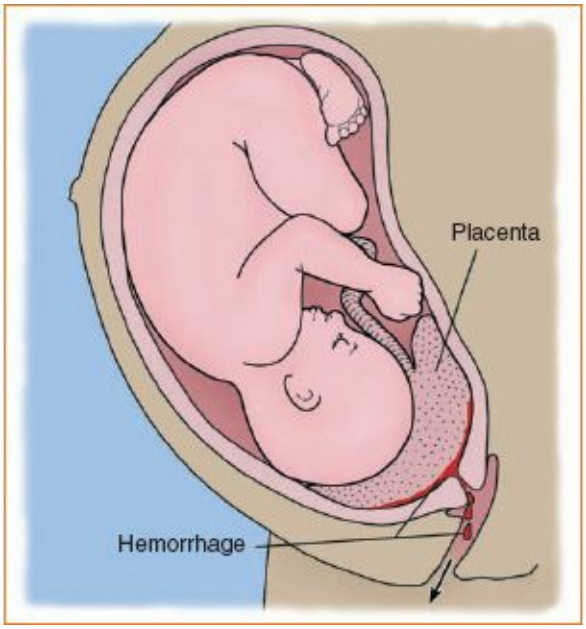

Figure 21-10 Placement of the placenta in placenta previa.

Signs and Symptoms

Placenta Previa

- Bright red vaginal bleeding
- Lack of abdominal pain
- Detectable fetal movement and heart sounds

Differential Diagnosis

Placenta Previa

- Abruptio placenta
- Ectopic pregnancy
- Preterm labor
- Spontaneous abortion

Transport Management

Placenta Previa

- Administer IV fluids.
- Administer oxygen.
- Allow minimal movement.
- Perform electronic fetal monitoring.

The usual presenting complaint of the woman with placenta previa is bright red vaginal bleeding. In

contrast to abruptio placenta, the bleeding in placenta previa is painless and the uterus remains soft. Fetal movement is detectable and fetal heart sounds remain audible because the blood supply to the fetus is not compromised.

Treatment of the patient with suspected placenta previa remains the same as with all patients with third-trimester bleeding. CCTPs need to make the mother the priority. Maintaining her hemodynamics with IV fluids and oxygenation will benefit the fetus as well. However, one must be cautious when examining the patient with placenta previa. Because the placenta is precariously placed over the cervical opening, minimal maneuvers to the cervix or uterus may induce heavy bleeding. Treatment should be accomplished with minimal movement; CCTPs should avoid palpating the fundus, which would cause fetal movement and possible placental tearing. Electronic fetal monitoring should be performed with minimal patient movement as well.

Uterine Rupture

Uterine rupture is a cause of catastrophic bleeding in the second half of pregnancy. Rupture associated with trauma is relatively uncommon. Maternal mortality of trauma-induced uterine rupture is about 10%. In contrast, the fetal mortality approaches 100%. Uterine rupture should be suspected in the pregnant trauma patient who has lost the palpable uterine contour, has easily palpated fetal parts, and has severe abdominal pain. As with any trauma in the pregnant patient, initial management is directed at the resuscitation and stabilization of the pregnant patient because fetal life depends on the patient's condition.

Signs and Symptoms

Uterine Rupture

- Loss of palpable uterine contour
- Easily palpated fetal parts
- Sharp, tearing abdominal pain
- Weakness
- Dizziness
- Thirst with signs of shock

Transport Management

Uterine Rupture

- Perform electronic fetal monitoring.
- Provide volume resuscitation.
- Administer oxygen.
- Provide rapid transport.

Uterine rupture can occur without trauma and is almost always associated with labor. A weakened portion of the uterine wall is at risk for rupture at any time during the gestational or delivery phase. Women who are most at risk have had many children or have had a previous cesarean section.

Some incomplete ruptures go unnoticed; however, complete ruptures are very dangerous to the health of the pregnant patient and fetus. The signs and symptoms of a complete rupture include sudden onset of

sharp, tearing abdominal pain. The diagnosis of uterine rupture should also be suspected in a pregnant patient in labor who reports weakness, dizziness, and thirst with signs of shock. Significant vaginal bleeding in this case may not be present. Fetal monitoring shows **long-term variability** as the fetal distress causes high fluctuations in heart rate. In some cases, the fetus and placenta exit the uterus into the abdominal cavity.

Treatment of spontaneous uterine rupture consists of volume resuscitation, oxygen, and 20 to 40 units of oxytocin in a 1,000-mL solution given IV. CCTPs need to prepare the patient for surgery because definitive care involves surgery and cesarean section. During transport, consider IV fluids and whole blood transfusions for hemodynamic stability along with oxygenation and advanced airway management.

Medical Conditions During Pregnancy

Pregnancy-Induced Hypertension

Pregnancy-induced hypertension (PIH), which occurs in about 8% of pregnancies, can have dangerous if not fatal consequences for the woman and fetus if left untreated. Risk factors include multiple gestations (twins, triplets), first-time pregnancies, and maternal chronic hypertension. In addition, women younger than 20 years or older than 40 years are at risk for PIH. PIH develops after 20 weeks of gestation, and there have been instances where PIH extends into the postpartum period, especially with patients who have a history of Guillain-Barré syndrome. CCTPs must take note that patients with a history of prior or chronic hypertension are at the greatest risk for PIH.

Although most PIH is managed effectively with diet and bed rest, uncontrolled hypertension can lead to eclampsia. Treatment must be focused on keeping the diastolic pressure below 90 mm Hg; effective medications are as follows:

- **Labetalol:** A beta-blocker that decreases systemic vascular resistance without affecting cardiac output. Administer a 20-mg IV push over 2 minutes. This administration may be repeated every 10 minutes with a 40- to 80-mg IV push until the maximum dose of 300 mg has been given.
- **Hydralazine:** A smooth-muscle relaxant that causes arteriolar relaxation, decreases vasospasms, and reduces blood pressure and cardiac output. Hydralazine is administered when the diastolic blood pressure is greater than 110 mm Hg. Administer 5 to 10 mg IV every 15 to 30 minutes up to 20 mg per hour until the diastolic blood pressure is 90 to 100 mm Hg.

Signs and Symptoms

Pregnancy-Induced Hypertension

- Blood pressure above 140/90 mm Hg
- **Proteinuria** (greater than 500 mg of protein in urine)
- Peripheral edema

Transport Management

Pregnancy-Induced Hypertension

- Administer medication such as labetalol and hydralazine to keep diastolic pressure below 90 mm Hg.

Preeclampsia and Eclampsia

Preeclampsia is the presence of the triad of hypertension, **pathologic edema**, and proteinuria (protein in the urine) due to pregnancy or recent pregnancy. Preeclampsia usually occurs after 20 weeks of gestation and may present within the first few weeks of the postpartum period. As discussed previously, blood pressure generally declines during pregnancy and therefore the definition of hypertension is different in pregnant patients and is defined as a blood pressure greater than 140/90 mm Hg or a systolic blood pressure 30 mm Hg above baseline.

The cause of preeclampsia is not known. Generally, the rise in blood pressure is the result of **vasospastic disease** of unknown cause. The proteinuria and subsequent edema is the result of vasospasm of the renal arteries, leading to decreased renal blood flow. In response to this decreased blood flow, the kidneys retain sodium and subsequently retain body water, which contributes to and aggravates the hypertensive state.

Signs and Symptoms

Preeclampsia

- Hypertension
- Edema or pathologic edema
- Proteinuria
- Headache
- Visual disturbances
- Abdominal pain
- Seizures
- Coma

Transitioning to Eclampsia

- Severe headache
- Scotomata (visual changes)
- Hyperreflexia (overactive reflexes)
- Epigastric pain
- Anxiety

Eclampsia

- Seizure

Differential Diagnosis

Preeclampsia

- Preexisting hypertension **Eclampsia**

Eclampsia

- Preexisting seizure disorder

Transport Management

Preeclampsia/Eclampsia

- Place the patient on her left side.
- Prevent/control seizures.
- Administer oxygen.
- Administer magnesium sulfate if seizures occur.

Presenting complaints of preeclampsia include headache, visual disturbances, edema, and/or abdominal pain. As preeclampsia progresses, evidence of end organ damage is seen. Hemodynamically, an increased D-dimer concentration (discussed in Chapter 8) leads to a condition known as hypercoagulative disorder, which causes increased clotting in the vasculature. Central nervous system (CNS) effects commonly include headache, visual changes, and, most importantly, seizures or coma.

Once seizures develop in the patient with signs and symptoms of preeclampsia, the condition is defined as **eclampsia**. Warning signs for the transition from preeclampsia to eclampsia are severe headache, scotomata (visual changes), **hyperreflexia** (overactive reflexes such as ankle clonus), epigastric pain, and anxiety. Preeclampsia may progress rapidly to eclampsia before, during, or after delivery, particularly during the first 48 hours postpartum, but occasionally the progression may be as long as 10 days after delivery. A change in diastolic blood pressure of 15 mm Hg above baseline, an increase in urine protein in a 24-hour period, or an increase of 100 mg/dL in random urine analyses 6 hours apart indicates the potential for eclampsia. The only true treatment for eclampsia is delivery. Maternal complications from eclampsia include permanent CNS damage, renal insufficiency, and death.

The management goals for the CCTP in preeclampsia and eclampsia include the prevention of seizures. If seizures do occur, rapid control of the seizures and the administration of magnesium sulfate are vital. Eclampsia should always be considered in a pregnant patient who is having a seizure or in a patient who has recently delivered an infant who is having a seizure. A pregnant patient with edema, hyperactive reflexes, and an elevated blood pressure requires no specific prehospital treatment other than prophylactic venous access. The patient should be lying on her left side. Oxygen may be administered.

Seizures may occur suddenly and should be anticipated. If seizures occur, routine seizure management and protection of the patient should be initiated. Treatment of seizures caused by eclampsia includes the administration of a 1- to 6-g IV bolus of magnesium sulfate, which is believed to act as a vasodilator and thereby reduces cerebral ischemia. Magnesium sulfate is a poor antihypertensive medication, but is an effective anticonvulsant that preserves uterine blood flow. If the patient already has an IV established, the dose for magnesium sulfate should be 2 g IV for 3 to 5 minutes. If no IV has been established, the loading dose is 4 g for 5 minutes IV If seizures continue, administer 2 g for 3 to 5 minutes.

Controversies

Practitioners may be reluctant to use large doses of benzodiazepines to terminate active seizures in a pregnant patient for fear of inducing respiratory depression in the infant if emergent delivery becomes necessary. The benefits of terminating seizure activity in the mother outweigh any concerns for the effects of benzodiazepines on the fetus. Should emergent delivery be performed, side effects observed in the infant are easily managed.

The administration of magnesium sulfate should be considered according to the transfer orders or upon consultation with medical direction. The administration of magnesium sulfate should always be accompanied by clinical observation for loss of reflexes, respiratory depression, and, if the patient is not currently experiencing a seizure, CNS depression. The antidote for magnesium sulfate toxicity is calcium gluconate. If magnesium sulfate is not available, standard seizure therapy may be followed, which includes the use of diazepam or other benzodiazepines. Even though benzodiazepines are effective anticonvulsants, they are not as effective as magnesium for the treatment of eclampsia. The administration of medications to lower blood pressure should be delayed until you reach the hospital because a careful titration of an antihypertensive medication is required to prevent a precipitous fall in blood pressure. Rapid lowering of blood pressure can result in uterine hypoperfusion and fetal morbidity or death.

HELLP Syndrome

A hemolytic disorder, **HELLP syndrome** occurs during the latter stages of pregnancy, usually after the 20th week of gestation. HELLP syndrome is named after its clinical findings, namely, hemolytic anemia, elevated liver enzyme levels, and a low platelet count.

The cause of HELLP syndrome is unknown, but a condition develops with the clotting cascade similar to end-stage shock patients with multiorgan dysfunction syndrome (discussed in Chapter 9).

Signs and Symptoms

HELLP Syndrome

- Hemolytic anemia
- Elevated liver enzyme levels
- Low platelet count
- Abdominal pain
- Blurred vision
- Headache
- Edema

Differential Diagnosis

HELLP Syndrome

- Cholecystitis
- Hepatitis
- Idiopathic thrombocytopenia

Transport Management

HELLP Syndrome

- Perform a blood transfusion.
- Administer magnesium sulfate (to prevent seizures).

As in preeclampsia, patients with HELLP syndrome will present with blurred vision, abdominal pain, headache, and edema. Treatment can include blood transfusions to combat the anemia and the administration of 1 to 6 g of magnesium sulfate to reduce the likelihood of having seizures. However, definitive treatment can only be accomplished with delivery of the fetus. CCTPs need to be aware that HELLP syndrome can occur postpartum 10% of the time.

Complications During Labor

Delivery includes a prodromal stage plus three distinct stages, the durations of which depend partly on whether or not it is the patient's first pregnancy (nullipara). **Table 21-4** provides a review of the stages of labor.

Transition of Fetal Circulation at Birth

Prior to birth, the fetus receives oxygenated blood from a pregnant woman via the umbilical vein, the ductus venosus, and the inferior vena cava of the fetus, which ultimately leads to the right atrium of the fetus. Prior to birth, the fetal lung is collapsed and filled with fluid, and most of the fetal blood flow is diverted away from the lungs. As the baby is delivered, fetal transition occurs—a process that enables the baby to breathe **Figure 21-11**. During fetal transition, the newborn's lungs must expand with air within seconds. As the baby's lungs become filled with air, the pulmonary vascular resistance decreases and systemic vascular resistance increases. Blood begins to flow to the lungs, picking up oxygen. The change in pulmonary pressure results in closing of the foramen ovale, the opening that allows blood to flow from the right atrium to the left atrium of the fetus, bypassing the lungs prior to birth.

Anything that delays this decline in pulmonary pressure during fetal transition can lead to delayed transition, hypoxia, brain damage, and, ultimately, death.

Preterm Labor

Preterm delivery represents 8% to 10% of all births and results in 60% of all perinatal morbidity and mortality. In critical care medicine, the emphasis is on interrupting preterm labor. **Preterm labor** is defined as the onset of labor before 36 weeks of gestation, as evidenced by rhythmic uterine contractions and cervical **dilation**. This presentation is cause for concern and often requires intervention such as specialized care at a facility capable of managing preterm labor and **premature** infants (infants born before 36 weeks of gestation or weighing less than 5 lb at birth).

Of all pregnant patients, 25% to 50% will experience contractions without being in preterm labor, known as Braxton-Hicks contractions. Treatment includes lowering anxiety levels in the pregnant patient along with bed rest and supportive care.

TABLE 21-4 Stages of Labor

Stage of Labor	Average Time (Nullipara)	Average Time (Multipara)	Frequency of Contractions	Characteristics
Prodromal stage	Varied	Varied	N/A	Bloody show (mucus mixed with blood) expelled from the vagina
First stage	8 to 12 h	6 to 8 h	5- to 15-min intervals	Labor pains and contraction of the uterus begin. Pain may radiate into the small of the back. Amniotic sac often ruptures toward the end of this stage, signified by a gush of fluid from the vagina. This stage lasts until the cervix is fully dilated.
Second stage	1 to 2 h	30 min	2 to 3 min apart	Begins as the baby's head enters the birth canal. Woman's pulse rate increases, sweat appears on her face. Cervix becomes fully dilated and effaced. Crowning occurs (presenting part of baby becomes visible). Delivery is imminent. This stage concludes when the baby is fully delivered.
Third stage	5 to 60 min	5 to 60 min	N/A	Placental stage Lasts from delivery of the baby until the placenta has been expelled and the uterus has contracted. Uterine contraction is necessary to squeeze shut all of the tiny blood vessels left exposed when the placenta separates from the uterine wall.

The use of critical care transport for a pregnant patient in preterm labor can be critical if the transferring facility is incapable of managing these patients. Knowledgeable CCTPs provide the critical link between the local hospital and the tertiary care facility. Careful patient monitoring, being prepared to treat changes in the patient's condition while in transit, and a smooth transfer of care to the receiving hospital will improve patient outcomes. Emphasis on continued bed rest and limiting physical activity are vital to extend gestation, and CCTPs need to be aware that during a stressful transport, sedatives may need to be administered. Discuss with the receiving physician the use of proper sedative agents to reduce anxiety and ease in the transfer. Also consider IV hydration, which increases intravascular volume and uterine blood flow, decreases pressure on the cervix, and inhibits release of pitocin.

Premature or preterm labor and fetal immaturity are the leading causes of neonatal mortality. Precipitous delivery may occur with premature labor. On presentation, the patient should be asked about the frequency and duration of contractions as well as the passage of blood-stained mucus and whether there has been rupture of membranes signaled by a gush of fluid or constant fluid leakage. This condition, known as premature rupture of membranes, accounts for up to 50% of all preterm deliveries. Knowledge of these signs and symptoms allows CCTPs to understand the stage of labor the patient is entering. Although all prehospital deliveries are considered emergencies, the way to reduce risk to the pregnant woman and fetus is to be prepared to deliver at any time. In preterm delivery between 26 and 34 weeks' gestation, the administration of glucocorticoid therapy such as betamethasone and dexamethasone results in stronger fetal lung tissue and increased surfactant fluid production, resulting in decreased cases of fetal respiratory distress syndrome. CCTPs can discuss beginning this course of treatment during transport to the receiving facility.

Signs and Symptoms

Preterm Labor

The following, occurring prior to 36 weeks' gestation:

- Rhythmic uterine contractions
- Cervical dilation
- Rupture of membranes
- Passage of blood-stained mucus

Differential Diagnosis

Preterm Labor

- Abruptio placenta
- Ectopic pregnancy
- Placenta previa
- Spontaneous abortion

Transport Management

Preterm Labor

- Provide or continue therapy to prolong gestation (fetal maturation therapy) or interrupt labor.
- Provide or continue bed rest.
- Consider hydrating the patient.
- Consider administration of tocolytic agents.

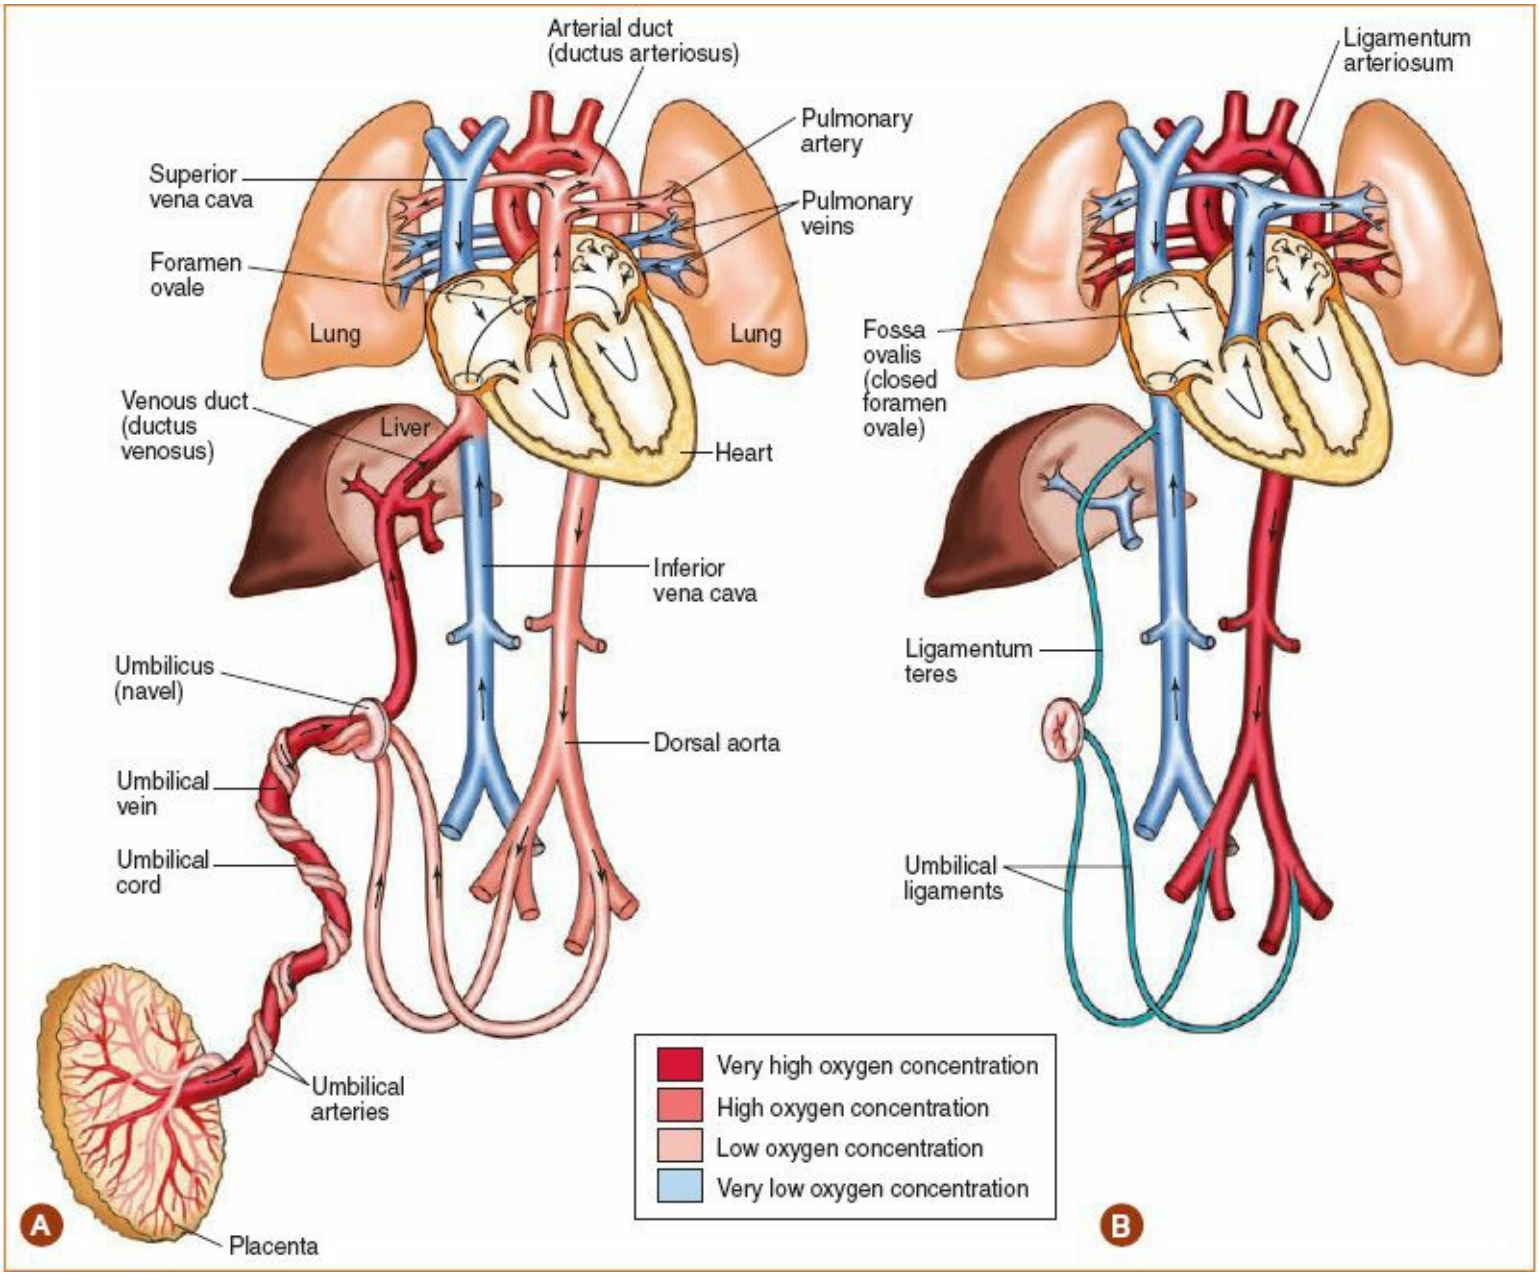

Figure 21-11 Fetal circulation. **A.** Oxygenated blood from the placenta reaches the fetus through the umbilical veins. Blood returns to the placenta via two umbilical arteries. **B.** Fetal circulation following transition.

Viability of the fetus is possible at 23 weeks of gestation, but fetal mortality and morbidity rates are extremely high. If a viable fetus is present and the woman is relatively healthy, the medical management is directed towards prolongation of gestation if possible. Treatments to prolong gestation include fetal maturation therapy, bed rest, hydration, and the administration of pharmacologic agents, termed **tocolytics**, to interrupt labor.

Inversely, prolonged pregnancy over 40 weeks can lead to instances of fetal hypoxia during labor and a higher percentage of meconium production. CCTPs need to be aware of these risks and have meconium suctioning equipment available prior to delivery **Figure 21-12**.

Tocolytic Agents

The ideal tocolytic agent effectively antagonizes myometrial (uterine) muscle contraction and has no systemic effects. Unfortunately, the complexity of the physiology behind smooth-muscle contraction makes this task difficult. The uterus is composed of smooth muscle, under the control of the auto-nomic nervous

system, and requires sufficient concentrations of calcium to contract. The beta-2 receptors located on the myometrial cell membranes control the intracellular calcium concentration. These receptors activate an enzyme called aden-ylcyclase, which is responsible for the conversion of adenosine triphosphate to cyclic adenosine monophosphate, which causes a decrease in the intracellular calcium concentration.

TABLE 21-5 Premature Labor Therapies

Class	Drug	Use	Bolus Dose
Tocolytic	Magnesium sulfate	Stop uterine contraction	1–6 g IV, then 2–4 g/h infusion
	Terbutaline	Stop uterine contraction	0.25–1 mg SC every 2–4 h

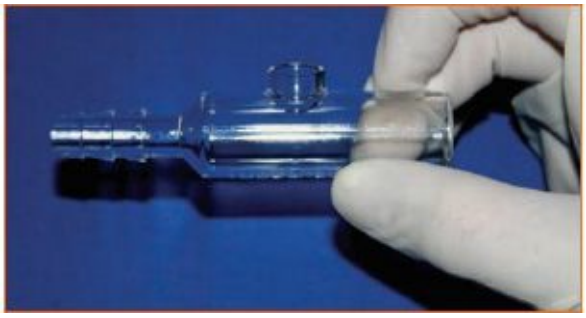

Figure 21-12 A meconium aspirator.

Tocolytics are only marginally effective in stopping preterm labor. The two most commonly administered tocolytic agents are terbutaline (up to 1 mg) and magnesium sulfate (1 to 6 g). Terbutaline is a beta-2 agonist that, when used in sufficient doses, can be successful in reducing uterine contractions. The doses used to reduce contractions, however, can result in side effects by stimulating beta-2 receptors elsewhere, such as in the myocardium. Stimulation of myocardial receptors can result in tachycardia or frank myocardial ischemia in patients with underlying coronary artery disease. Thus, the patient should have continuous cardiac and fetal monitoring during transport and be frequently assessed for signs and symptoms of myocardial ischemia, such as chest pain and pulmonary edema. Terbutaline should not be administered if the maternal pulse exceeds 140 beats/min.

The effects of beta-2 stimulation of the pancreas can result in hyperglycemia, which can be monitored in the pregnant patient using finger stick glucose checks. If the patient's baby is delivered during transport, the baby could have hypoglycemia as well. Fetal hypoglycemia results secondary to the need for increased insulin production by the fetus to compensate for high maternal glucose levels. Other less significant effects of terbutaline treatment include headache, tremor, vomiting, fever, and hallucinations.

Another common drug effectively used to arrest preterm labor is magnesium sulfate. This medication is usually administered as a 1- to 6-g bolus followed by a continuous infusion at 2 to 4 g/h. The mechanism by which magnesium inhibits uterine contraction is not completely clear, but it asserts its effects through the antagonism of calcium in muscle cells. The doses required to achieve this effect are close to toxic. Symptoms of magnesium toxicity are decreased patellar reflexes and, ultimately, respiratory depression and respiratory arrest. In a patient receiving magnesium, the patellar reflexes should be monitored frequently, urine output should be at least 25 mL/h, and there should be no signs of respiratory depression. If any signs or symptoms of toxicity are noted, the infusion should be stopped and medical control contacted for further instruction. Magnesium is cleared by the kidney, thus making the accurate measurement of urine output using a Foley catheter important. If the patient's urine output falls,

the serum magnesium level will rise. Therapeutic levels of magnesium are between 4 and 7 mEq/L. Patellar reflexes become diminished when magnesium levels are between 8 and 10 mEq/L, and respiratory depression and failure occur when levels rise above 12 mEq/L. If the patient exhibits a toxic reaction such as respiratory depression, the infusion should be stopped; 1 g of calcium gluconate should be given by *slow* IV push, and oxygen should be administered to maintain a saturation of greater than 90%. In the face of respiratory failure, the patient should be intubated.

Table 21-5 lists premature labor therapies.

Delivery

Vertex, or head-first presentation, is the ideal presentation for all deliveries; crowning is observed as the second stage of labor begins. The role of the CCTP is to ensure that the delivery proceeds without any complications. It is the responsibility of the CCTP's trained eye to note unexpected events when the baby is presenting.

Normal crowning and normal shoulder presentation are shown in **Figure 21-13** and **Figure 21-14**, respectively.

Malpresentations

Breech presentation is the most common malpresentation, occurring in 4% of all deliveries. With this presentation, there is an increased risk of asphyxia and fetal mortality, though one third of these are considered preventable. Breech presentations are more common in the premature infant and in those with a low birth weight, although two thirds of breech infants weigh more than 2,500 g.

There are four common variants of breech presentation:

1. **Frank breech**: both of the infant's hips are flexed and the feet are near the infant's head **Figure 21-15**.
2. **Complete breech**: the hips are flexed and the legs are flexed at the knees and oriented transversely to the birth canal; the buttocks present with the legs flexed and the feet along the buttocks **Figure 21-16**.
3. **Incomplete breech**: similar to complete breech except one foot extends into the birth canal **Figure 21-17**.
4. **Footling breech**: both feet extend into the birth canal

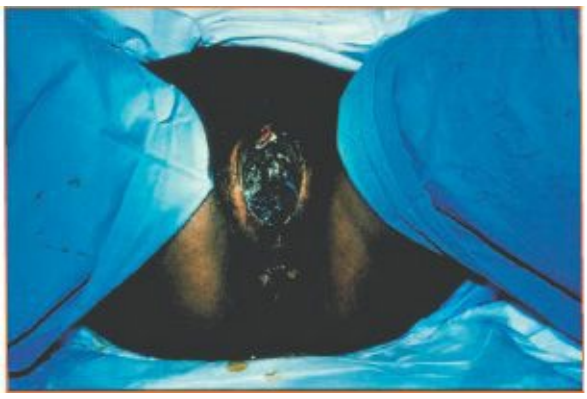

Figure 21-13 Normal crowning.

Figure 21-14 Normal shoulder presentation.

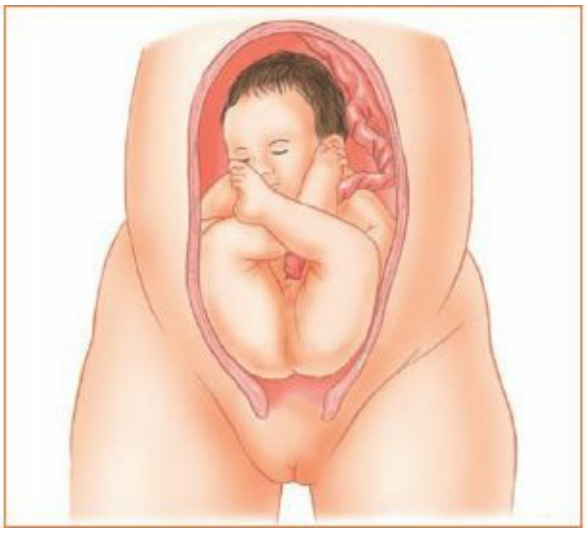

Figure 21-15 Frank breech presentation.

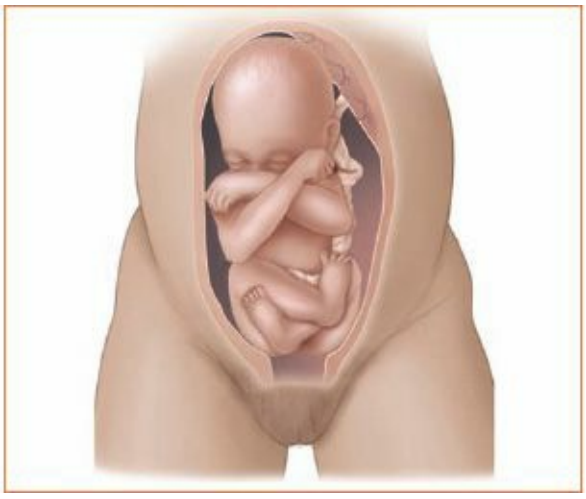

Figure 21-16 Complete breech presentation.

Figure 21-17 Incomplete breech presentation.

The footling breech is the only malpresentation in which field delivery should be considered. All other limb presentations cannot be manipulated in the field and must be transported to the nearest appropriate facility.

To deliver a footling breech baby, the patient is usually positioned supine with hips flexed, as in a normal delivery, or maybe on her hands and knees. As the baby (ie, the feet) emerges from the birth canal, the body of the infant should be supported and directed toward the mother's anterior.

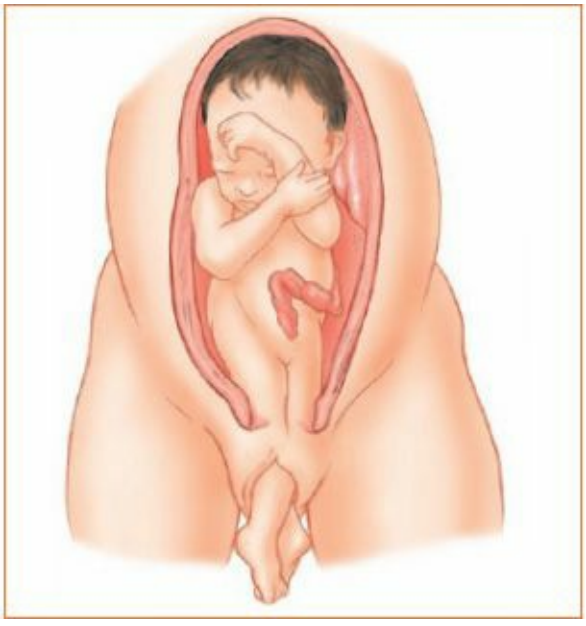

Figure 21-18 Footling breech presentation.

Special Populations

In breech delivery, the cervix is less than completely dilated, which will likely delay delivery of the head.

- Maintain the infant's airway with the index and middle finger on either side of the infant's mouth and nose, pushing the vaginal wall away.
- Suction as soon as the head delivers. If the head does not quickly deliver, continue transport.
- With a footling breech delivery, support the baby toward the mother's anterior as he or she emerges.

The head will likely be the most difficult to deliver because it is the largest body part. In a normal delivery, the head fully dilates the cervix and allows for easy passage of the remainder of the body. However, in the case of a breech delivery, the head delivers last and the cervix is less than completely dilated. In this case, the head is likely to be delayed in its delivery as the cervix dilates maximally. Once the umbilicus has cleared the birth canal and is visible, this means that the head has cleared the cervix and the infant can be held. With one hand supporting the infant, place the index and middle finger of the other hand in the birth canal against the birth canal wall on either side of the infant's mouth and nose, pushing the wall away from the airway. This maneuver should provide a route for the infant to breathe and should be maintained en route to the hospital or until delivery is complete. Disengage the legs from the birth canal if they have not yet been delivered. As the shoulders present, the arms are delivered by hooking the index finger over each of the baby's shoulders. As the shoulders clear, rotate the baby so that its chest is facing upward and apply gentle traction until the hairline is visible. During the entire process, if there is an extra provider available, he or she can assist the delivery by applying suprapubic pressure. Suctioning can be performed as soon as the head delivers, but if the head does not quickly deliver, transport should continue.

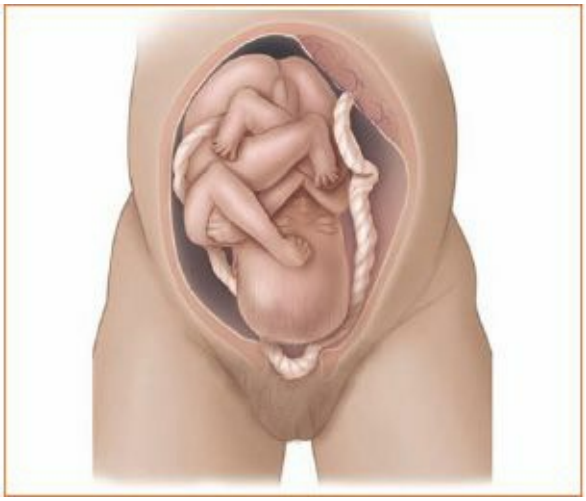

Figure 21-19 A prolapsed cord.

Umbilical Cord Prolapse

Occasionally the presenting part may be the umbilical cord **Figure 21-19**. This condition, in which the umbilical cord passes through the birth canal in advance of the infant, is known as a prolapsed cord and can have serious consequences for the infant.

The cord may be compressed between the bony pelvis of the mother and the head of the infant, thus decreasing blood flow to the infant. Low blood flow to the infant can cause fetal distress or death.

In the event of a prolapsed cord, the patient should be placed on 100% oxygen by nonrebreathing mask and placed in the knee-chest position on the stretcher. This involves the patient being prone on her elbows and knees with buttocks elevated **Figure 21-20**. If the patient cannot tolerate this position, an alternate is the Trendelenburg position. Once the patient is positioned correctly, encourage her not to push. Insert two gloved fingers into the vagina to gently elevate the presenting part to relieve pressure on the cord and restore umbilical pulse. *Do not push the cord back in*. To prevent umbilical cord drying that may result in atrophy of the vessels, gently cover any exposed cord with sterile saline gauze. Continue rapid transport and notify the receiving hospital as soon as possible.

Figure 21-20 The knee-chest position should be used in the event of a prolapsed cord.

Transport Management

Umbilical Cord Prolapse

- Administer oxygen.
- Position the patient in either the knee-chest position or the Trendelenburg position.
- Insert two gloved fingers to relieve cord compression.
- Encourage the patient not to push.
- Cover any exposed cord with a sterile saline gauze to prevent drying.
- Provide rapid transport.

Shoulder Dystocia

In about 1 of every 100 vertex deliveries, there exists a condition in which the infant is too large (macrosomia) to travel through the birth canal without additional clinical maneuvering. This is **shoulder dystocia**. CCTPs will know this condition exists after seeing a feature known as "turtle sign"; the fetal head will begin to protrude and then withdraw back inside as the shoulders, being too large, are prevented from exiting the uterus. Because the head is now stuck back inside and the face is pressing against the walls of the birth canal, there is a high risk for neonatal anoxia. CCTPs must now assist the mother with the next contraction; most contractions are no more than 30 seconds apart so there must be a rapid decision and treatment plan.

One common technique to assist the patient is known as the McRoberts maneuver. The patient is instructed to hyperflex her legs to her abdomen **Figure 21-21**; this will widen the pelvis and lower the lumbar spine, thus enlarging the birth canal. This procedure has been proven effective in 40% of deliveries. Pressing against the suprapubic region will increase the percentage of success. *Do not apply fundal pressure;* this can cause the stuck shoulder to rupture the uterus. *Do not pull on the baby's head;* pulling on the head can cause a brachial plexus injury, which can cause permanent disability or death of the infant.

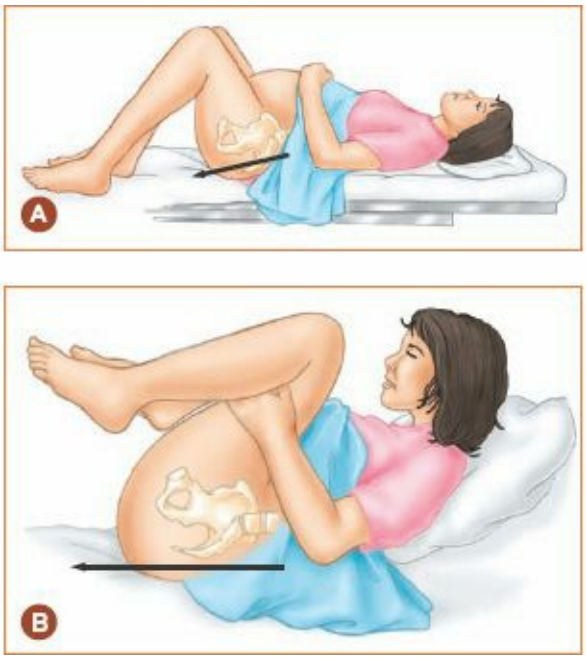

Figure 21-21 If the fetal head begins to protrude and then withdraws back inside (a sign of shoulder dystocia), the first step is to have the mother hyperflex her legs to her abdomen to help enlarge the birth canal.

If there is still no delivery, insert a gloved hand into the vagina and locate the humerus. Gently rotate the infant's arm towards its sternum; this action will displace the shoulder away from the vaginal wall in an attempt to shorten the diameter of the baby's axial skeleton.

Signs and Symptoms

Shoulder Dystocia

- "Turtle sign" of infant's head protruding and withdrawing into the birth canal

Transport Management

Shoulder Dystocia

- Perform the McRoberts maneuver.
- With a gloved hand, rotate the baby's arm toward its sternum.
- Provide rapid transport.

Figure 21-22 Tie or clamp the cord in two places (approximately 3″ and 4″ from its insertion into the baby). Cut the cord between the two ties or clamps.

CCTPs need to be aware that they are limited to what their scope of practice dictates. In extreme cases of shoulder dystocia, obstetricians perform episiotomies, perform shoulder dislocations, or push the head back into the uterus and perform a cesarean section. None of these procedures are performed by CCTPs, so it is important to have a plan of action such as diverting to the nearest obstetric facility if faced with an extreme case that cannot be corrected within your scope of practice.

Multiple Births

Single gestations are most common, although invariably many CCTPs will encounter a multiple-gestation pregnancy and potential delivery. The incidence of twin gestation is 1:100; and triplets, 1:10,000. The presence of a multiple-gestation pregnancy should be identified by history obtained from the patient. Twins may share a placenta and a gestational sack or they may each have their own individual sack and placenta.

After the first infant is delivered, his or her cord should be double-clamped to prevent bleeding (in the case of a shared placenta) and allow for identification of each infant's cord. Place one to two clamps close to the infant and one to two clamps 3 cm from the first set of clamps, then cut the infant's cord between the four clamps **Figure 21-22**.

There is usually a delay of about 15 minutes between deliveries. During this delay, transport should continue and should only be interrupted if the next infant begins to emerge from the birth canal. If the subsequent infant is malpresenting, take the appropriate measures previously described and continue transport. The orientation of each infant at the time of birth should be accurately documented and relayed to the hospital. The presentation is documented as, for example, vertexbreech, with the first term referencing the first infant. Be sure to monitor each infant separately once delivered.

Postdelivery Care

Once delivery is complete, care for both the mother and infant should continue. The newborn's ABCs and APGAR score should be determined (further discussed in Chapter 22). The mother's perineum should be examined for tears. If large tears are actively bleeding, apply direct pressure. Significant postpartum hemorrhage is defined as greater than 500-mL blood loss within 24 hours after delivery of the infant. Often the source of bleeding is not easy to identify; thus, the uterus should be massaged and one or two large-bore IVs established with a crystalloid solution running open. High-flow oxygen should be applied, and, if extended transport time is anticipated, orders for pitocin may be given by medical control. Pitocin will aid in uterine contraction and should be given as 10 to 20 U/L of fluid.

The infant should be thoroughly cleaned and dried, wrapped in warm blankets, and placed next to the

mother if possible. The APGAR score should be taken at 1 and 5 minutes after delivery. If the APGAR score is below 7, repeat every 5 minutes. Continue with any supportive measures applied as needed while transporting.

Postdelivery Complications

Amniotic Fluid Embolism

Amniotic fluid embolism, although rare, can present antepartum and postpartum in 1 of every 8,000 patients and occurs when fetal tissue crosses over the placental barrier into maternal circulation. The most frequent routes of entry include lacerations to the placenta site, the endocervical vein, or areas in the lower portion of the uterus. Amniotic fluid leakage into maternal circulation can cause obstruction to the mother's organs with organ failure or respiratory and cardiovascular compromise. Causes of this pathophysiology are abdominal trauma with amniotic and uterine vein rupture, twins, older gestational periods (longer than 40 weeks), and older patients (older than 40 years). The mother presents with sudden onset of shortness of breath and hypotension. Other signs and symptoms include chest pain, restlessness, anxiety, coughing, vomiting, pulmonary edema with pink, frothy sputum, seizures, coma, and sudden death.

Signs and Symptoms

Amniotic Fluid Embolism

- Sudden onset of shortness of breath
- Sudden onset of hypotension
- Chest pain
- Restlessness
- Anxiety
- Coughing
- Vomiting
- Pulmonary edema with pink, frothy sputum
- Seizures
- Coma
- Sudden death

Transport Management

Amniotic iluid Embolism

- Manage the airway.
- Provide fluid resuscitation.
- Provide rapid transport.
- Administer positive end-expiratory pressure.
- Administer blood.

Amniotic fluid embolism carries a 50% mortality rate; therefore, the CCTP must recognize the signs

and symptoms early and treat with airway management, fluid resuscitation (it is recommended to establish two IV lines), and immediate transport. Additionally, positive end-expiratory pressure may be required.

Postpartum Hemorrhage

Bleeding is common during delivery; blood loss of over 500 mL, however, is considered to be serious and is the leading cause of maternal death. Causes of postpartum hemorrhage are listed as follows:

- **Trauma:** Tearing away of the placenta prematurely or a ruptured placenta
- **Tone:** Inability of the uterus to contract, leading to extended bleeding
- **Tissue:** Any unexpelled fetal product or placenta can cause increased bleeding
- **Thrombin:** Bleeding disorders of the mother can prevent clotting

Management should include padding to produce clotting (do *not pack*, just place a pad), fundal massage **Figure 21-23**, and, after the placenta has been delivered, administering an oxytocin IV drip. If bleeding persists, the CCTP can perform bimanual uterine compression, providing it is within the local scope of practice. In this procedure, one hand, wrapped in a dressing, is clenched as a fist in the vagina while the other hand presses down on the uterus. After about 2 to 5 minutes, release pressure and re-examine for continued bleeding. Repeat as needed.

Signs and Symptoms

Postpartum Hemorrhage

- Severe bleeding after delivery

Transport Management

Postpartum Hemorrhage

- Place padding to absorb the blood.
- Perform fundal massage.
- Administer oxytocin after the placenta has delivered.

Figure 21-23 Fundal massage should be performed if the patient experiences postpartum hemorrhage.

Rh Incompatibility and Erythroblastosis Fetalis

In some cases, Rh factors in red blood cells in the mother and child can be different. Although this is a well-managed condition prenatally, during delivery blood may mix, resulting in an antibody reaction and inflammatory response. Signs and symptoms include maternal fever, nausea, vomiting, and shortness of breath. Treatment of the mother includes oxygenation and administration of antipyretics.

Erythroblastosis fetalis, a condition caused by the mother's antibodies attacking fetal red blood cells, can develop in the fetus, leading to in utero anemia. Upon delivery, newborns with this condition can appear jaundiced, swollen, and pale. Treatment includes addressing the anemia with blow-by oxygen and admission to a neonatal intensive care unit for treatment of the high bilirubin count.

Signs and Symptoms

Rh Incompatibility in a Mother

- Fever
- Nausea
- Vomiting
- Shortness of breath

Transport Management

Rh Incompatibility in a Mother

- Administer oxygen.
- Administer antipyretics.

Uterine Inversion

Usually 10 to 30 minutes after delivery, the placenta will detach from the uterine wall and deliver vaginally. In rare cases, the placenta will remain attached and as the uterus contracts to expel the afterbirth, the uterus inverts and protrudes from the vagina. Risk factors for this condition include pulling on the cord to induce placental detachment and use of magnesium sulfate during the delivery. Surgical intervention is the most definitive treatment, but CCTPs (if within the local scope of practice) can attempt to correct this complication by flushing the vagina with saline. This procedure, known as hydrostatic correction, will cause the uterus to re-inflate and return to the proper position. Oxytocin can also be given to prevent any further contractions and more profound inversion and protrusion.

Transport Management

Uterine Inversion

- Flush the vagina with saline (hydrostatic correction).
- Administer oxytocin.

Ectopic Pregnancy

A n **ectopic pregnancy** is an extra-utero conception and is not considered a viable fetus, because development in the tubules is a life-threatening condition to women. Most ectopic pregnancies occur in the fallopian tubes, although a small percentage can gestate in the peritoneum, in an ovary, in the cervix, or interstitially. When the fertilized egg implants on the uterine wall, it will begin to burrow by degrading tissue on the wall lining. In the tubules, where there is no build-up of tissue that would be normally found in the uterus, this degradation can lead to vessel rupture and bleeding. For this reason, all women of childbearing years with sudden onset of abdominal pain or uncommon vaginal bleeding must be considered to have an ectopic pregnancy. The greatest risk factor for the occurrence of an ectopic pregnancy is pelvic inflammatory disease. Severe pelvic inflammatory disease can cause tubule scarring, which destroys the cilia hairs that guide the ovum to the uterus. Other risk factors include tubal ligation, reversed ligation, current intrauterine device use, and smoking.

Signs and Symptoms

Ectopic Pregnancy

- Abdominal pain (sudden onset)
- Vaginal bleeding

Differential Diagnosis

Ectopic Pregnancy

- Abruptio placenta
- Placenta previa
- Preterm labor
- Spontaneous abortion

Transport Management

Ectopic Pregnancy

- Continue supportive therapy.
- Continue the administration of methotrexate (for specific cases that meet defined criteria).

Treatment for ectopic pregnancy is primarily surgical; however, early inhospital treatments include the antimetabolite methotrexate in certain cases that meet defined criteria (less than 2 cm in size, and an hCG of less than 15,000 mIU/mL). Methotrexate disrupts the growth of the embryo and causes pregnancy termination.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) causes inflammation to the reproductive system, including the uterus, fallopian tubes, and ovaries, and is most commonly the result of sexually transmitted diseases. If left

untreated, the inflamed tissue scars and loses much of its functionality. Of the one million women who are diagnosed with PID each year, 10%, or 100,000, will become infertile as a result.

Patients with PID will complain of back and abdominal pain with painful urination and have a low-grade fever. In addition, the inflammation sometimes makes it difficult to ambulate without pain, and patients sometimes present with signs and symptoms that mimic appendicitis.

Treatment is done with IV antibiotics; CCTPs must be aware of any drug interactions when transporting patients on an antibiotic regimen.

Signs and Symptoms

Pelvic Inflammatory Disease

- Back and abdominal pain
- Painful urination
- Low-grade fever
- Difficulty ambulating without pain

Differential Diagnosis

Pelvic Inflammatory Disease

- Appendicitis
- Urinary tract infection

Transport Management

Pelvic Inflammatory Disease

- Continue the administration of IV antibiotics.

Toxic Shock Syndrome

During menstruation, the presence of protein-rich blood and a neutral pH creates a fertile environment for the gram-positive bacteria *Staphylococcus aureus* and *Streptococcus pyrogenes*. Super-absorbent tampons can aid in bacteria colonization, as was first discovered in the 1980s. The Centers for Disease Control and Prevention now reports that only 10 in every 100,000 menstruating people will have bacterial infections leading to toxic shock syndrome. Signs and symptoms include high fever, body rash, headache, and hypotension. Treatment includes airway management, fluid resuscitation, and IV antibiotics such as cephalosporins or vancomycin.

Signs and Symptoms

Toxic Shock Syndrome

- High fever

- Body rash
- Headache
- Hypotension

Transport Management

Toxic Shock Syndrome

- Manage the airway.
- Provide fluid resuscitation.
- Continue the administration of IV antibiotics.

Ovarian Cysts

Ovarian cysts occur in about 7% of the female population annually, typically as a result of follicular maturation during the normal female menstrual cycle. Ovarian cysts are often unde-tectable and self-resolving, although a small percentage may continue to grow and may cause lower abdominal pain. These functional cysts are divided into two categories: follicular cysts (also called graafian cysts) that result from nondegenerated graafian follicles, and corpus luteal cysts from nondegenerated corpus luteum. Follicular cysts commonly occur during the first 2 to 3 weeks of the menstrual cycle.

Most ovarian cysts are benign and asymptomatic and are usually discovered only in a routine checkup. If the cyst exceeds a diameter of 4 cm, however, pelvic discomfort begins, either from distention of the pelvic and lower abdominal structure or from ovarian torsion. Symptoms of a cyst include abdominal pain, nausea, vomiting, and frequent urination from bladder pressure.

Pain management with nonsteroidal anti-inflammatory drugs or, in severe cases, morphine and fentanyl is recommended; however, CCTPs need to remember that all abdominal pain must be considered to be caused by an ectopic pregnancy until definitively diagnosed otherwise.

Laboratory Assessment

There is no specific laboratory technique to test for an ovarian cyst **Figure 21-24**. Instead, diagnosis is made through ultrasonography and Doppler flow studies that can monitor blood flow as well as cyst size and location. A computed tomographic scan and magnetic resonance imaging are useful alternatives, although usually not required.

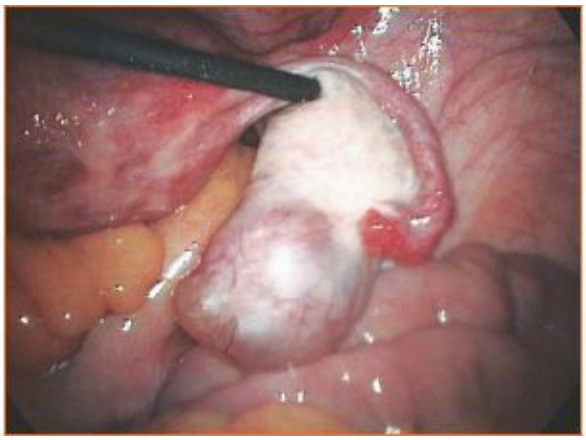

Figure 21-24 An ovarian cyst.

Underlying and resultant conditions related to the cyst may be detected with blood tests. A complete blood count, for example, can detect leukocytosis relating to an infectious process. A decreased hematocrit value may indicate anemia, and prolonged PT and PTT times can detect clotting abnormalities that may complicate the healing process. Cancer antigen 125 (CA-125) levels greater than 35 U/mL suggest carcinoma as the origin of the cyst. CA-125 is a surface protein that is found on normal ovarian tissue cells and carcinomas; its level increases following abnormal excessive tissue growth. Blood and cervical cultures should be monitored for signs of infection. Last, a urinalysis is helpful in determining whether any blood is present in the urine.

Ruptured Ovarian Cyst

Occasionally, ovarian cysts may rupture spontaneously or following trauma. Mild to severe hemorrhaging frequently occurs when a cyst ruptures. If a rupture with hemorrhaging has occurred, patients may present with increased lower abdominal and pelvic pain, vaginal bleeding, and hypovolemia leading to shock. The rupture of an ovarian cyst causes severe **mittelschmerz pelvic pain** to the affected side. Corpus luteal cysts occur during the final 1 to 2 weeks of the menstrual cycle, and their rupture can lead to pelvic inflammation and hemorrhage.

Treatment for patients with a ruptured ovarian cyst includes controlling any immediate life threats. Evaluation for hypovolemic shock is paramount and should include testing for orthostatic changes. Isotonic fluid boluses through large-bore IVs are indicated to maintain an adequate blood pressure for patients in shock.

Signs and Symptoms

Ruptured Ovarian Cyst

- Increased lower abdominal and pelvic pain
- Vaginal bleeding
- Hypovolemia leading to shock

Differential Diagnosis

Ruptured Ovarian Cyst

- Hematuria
- Appendicitis
- Diverticulitis
- Bowel obstruction
- Ovarian tumor
- Ovarian torsion
- Ectopic pregnancy
- Salpingitis (inflammation of the fallopian tube)
- Inflammatory bowel disease
- Pelvic inflammatory disease

Transport Management

Ruptured Ovarian Cyst

- Control any immediate life threats.
- Evaluate for hypovolemic shock.
- Test for orthostatic changes.
- Administer isotonic fluid boluses through large-bore IVs if patient is in shock.

Definitive management occurs at the hospital and normally involves laparoscopic surgery to control bleeding and remove the cyst.

Pathologic Cysts

Neoplasmic cysts of the ovary arise from unchecked tissue growth and are related to a carcinoma, most frequently to ovarian cancer. Endometriomas, another type of mass, fill with blood from ectopic endometrium. Ovarian carcinomas occur in about 15 of every 100,000 patients; treatment involves removal of the cyst or ovaries, or a complete hysterectomy.

Signs and Symptoms

Pathologic Cysts

- Abdominal pain
- Vaginal bleeding
- Infertility

Transport Management

Pathologic Cysts

- Manage pain (administer morphine or fentanyl).

Another more common type of malignant cyst is a polycystic ovary; this is the case of an enlarged ovary with multiple cysts noted on the exterior. Insulin resistance (leading to diabetes), obesity, and hirsutism are associated signs and symptoms of polycystic ovary syndrome. Other signs of polycystic ovary syndrome include abdominal pain, vaginal bleeding, and infertility. Patients have little tolerance for extended transports, and CCTPs should consider pain management with morphine or fentanyl.

Ovarian Torsion

In some cases, an enlarged ovary, either by itself or as a result of another condition, will twist into a nonfunctional state; this is called **ovarian torsion**. Ovarian torsion is often a cause of lower abdominal pain in females that initially presents similar to appendicitis or an ectopic pregnancy **Figure 21-25**. Possible causes include increased ovarian weight secondary to blood retention from impaired venous drainage and congenital deformities. When not rapidly treated, this condition can lead to ovarian

infarction and loss of function. Pregnant, nonpregnant, and postmenopausal women are all at risk for ovarian torsion.

A gradual onset of diffuse lower abdominal pain, biased toward the affected side, is often seen in cases of ovarian torsion. Nausea and vomiting are common, along with either constipation or diarrhea. In approximately 50% of cases, a tender mass can be palpated at the torsion site.

It is important to immediately rule out the possibility of pregnancy and ovarian cysts prior to proceeding with specific treatment. The CCTP can initiate this process by taking a thorough history, including sexual history and the date of the patient's last menstrual cycle. Some clinicians may prefer that pain medications be withheld until diagnosis. Whether the CCTP can administer pain medication based on field impression will depend on local protocols. Pelvic ultrasonography is the preferred method of diagnosis, in which an enlarged ovary is typically observed. A computed tomographic scan and magnetic resonance imaging can serve as secondary diagnostic techniques when a sonogram is nonspecific. Laparoscopic oophoropexy is the most common treatment, in which the ovary is moved out of the distorted position.

Transport Management

Ovarian Torsion

- Manage pain (administer morphine or fentanyl).

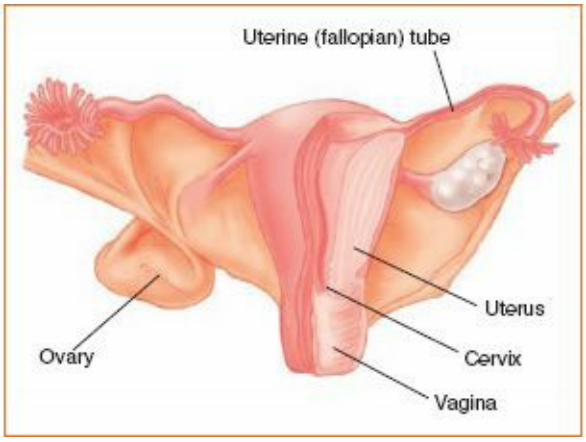

Figure 21-25 Ovarian torsion.

Pain management with morphine or fentanyl should be considered for long transports.

Gynecologic Trauma

Vulvular Hematoma

A hematoma can result from blunt trauma to the vulva, also known as a straddle injury. Purplish swelling occurs that is treated with ice and compression. Foley catheterization should be considered if the hematoma expands to compress the urethra, causing bladder outlet obstruction.

Signs and Symptoms

Vulvular Hematoma

- Purplish swelling of the vulva

Transport Management

Vulvular Hematoma

- Administer ice.
- Provide compression.
- Monitor the indwelling catheter, if one is placed.

Sexual Assault

After the patient's ABCs have been addressed, CCTPs must treat patients who have been sexually assaulted as a living crime scene. The focus should be on evidence preservation; do not allow patients to void or shower and limit any unnecessary treatments. Cover the patient with a sheet to capture trace evidence and ensure that a rape kit is requested.

Transport Management

Sexual Assault

- Address the ABCs.
- Preserve evidence: do not allow patients to void or shower and limit unnecessary treatments.
- Cover the patient with a sheet.

Flight Considerations

Delivery of an infant is absolutely the last procedure that you want to perform while in flight; therefore, a full patient assessment must be performed prior to launch to ensure that the patient is not showing signs of imminent delivery. In addition, the stress and noise of flight can cause anxiety to a pregnant patient and also result in long-term variability and fetal distress. Flight CCTPs should consider analgesics for these patients to ease the anxiety.

Summary

The dynamic changes that occur with pregnant patients are challenging for the CCTP. For a pregnant patient, each day is different physiologically as inside her a new life grows. Gynecologic emergencies do not require significantly different treatment during critical care transport, but as always, are important to treat properly and with sensitivity.

Case Study

A PREGNANT WOMAN AT 25½ WEEKS' GESTATION PRESENTED to a local hospital with a headache and complaints of extreme sensitivity to light and sound. The patient's vital signs were as follows: blood pressure, 154/104 mm Hg; pulse rate, 104 beats/min; and respiratory rate, 18 breaths/min. The patient was placed on the fetal heart monitor, an IV line was inserted, routine lab values were obtained, and a

24-hour urine protein test was ordered. The laboratory results were obtained and were unremarkable with the exception of the uric acid level, which was 7.2 mg/dL (normal, 2.5 to 6.2 mg/dL). The 24-hour urine protein determination was alarming at a total protein count of 333 mg/d (normal, 44 to 225 mg/d). The attending obstetrician informed the expectant mother that he thought she had a moderate case of preeclampsia. Because of its early onset, the patient needed to be transferred to a tertiary care center that specializes in high-risk obstetrics for further evaluation.

Your mobile intensive care unit is dispatched to the referring hospital to transport the patient to a tertiary care center located 70 miles away. Your report from the referring facility indicates that the patient's condition is stable. The patient has no complaints, has a saline lock in place, and is currently on room air. The hospital requests that you bring a fetal heart monitor with you because the fetus has experienced sporadic episodes of bradycardia. Your expected total transport time to the tertiary center is 90 minutes.

Upon your arrival at the referring facility, you are met by the staff nurse outside the patient's room. The nurse gives you a more detailed patient report. Your partner enters the room to begin assessment of the patient while you obtain more information from the nurse. The nurse tells you that this patient is a gravida 1, para 0, who is currently 25½ weeks' pregnant. At 18 weeks' gestation, mild elevations in her blood pressure developed accompanied by swelling in her face, feet, and hands. She was admitted to the obstetrics unit 24 hours ago after complaining of a headache associated with a blood pressure of 154/104 mm Hg, which was the highest reading so far during her pregnancy. Urinary output, between 35 and 55 mL/h, was positive for proteins and negative for blood. The glucose level was normal. The attending obstetrician initially suspected PIH. The patient was given one dose of dexamethasone intramuscularly shortly after admission to the labor and delivery unit to help develop the lungs of the fetus in the event of a preterm delivery. The fetal ultrasound showed an anterior placenta and no placenta previa. The patient reported having no drug allergies, taking only prenatal vitamins, and having a medical history of *Helicobacter pylori*, cytomegalovirus infections, and leukopenia.

Patient assessment reveals marked edema of the face, hands, ankles, and feet, which the patient reports has gotten progressively worse since the onset. The abdominal exam reveals a symmetric abdomen that is free from surgical scars with minor striae gravidarum noted and a normal fundal height of 26 cm. The patient tells you that a decrease in her urinary output began around the 20th week of pregnancy. The edema to the lower extremities is symmetric, and the patient denies having any pain associated with the swelling. An 18-gauge IV catheter is noted in the patient's left antecubital fossa with a saline lock. Deep tendon reflexes are normal without any signs of clonus. The fetal heart rate is noted to be 162 beats/min with the last deceleration 3 hours ago. Maternal vital signs are as follows: blood pressure, 121/70 mm Hg (mean arterial pressure, 87 mm Hg); heart rate, 78 beats/min with sinus rhythm; respiratory rate, 20 breaths/min; and SpO_2 98% on room air. Lung sounds are clear and equal bilaterally with symmetric chest wall expansion. Peripheral pulses are easily palpated bilaterally. The patient has been accepted by the obstetrician at the tertiary care center, and bed availability has been confirmed. You and your partner place the patient on the ambulance stretcher and prepare for transport. Prior to departure, you contact your online medical control to discuss the case. Your medical control physician is comfortable with the current treatment and does not recommend additional interventions. If changes are noted in the patient's condition or if frequent fetal decelerations are noted, the crew is to contact medical control for orders.

Approximately 25 minutes into the 90-minute transport, the patient begins to complain of nausea associated with mild frontal headache and dizziness. Vital signs are as follows: blood pressure, 98/52 mm Hg (mean arterial pressure, 67 mm Hg); pulse rate, 84 beats/min with sinus rhythm; respiratory rate, 20 breaths/min; and SpO_2, 98% on room air. You instruct your patient to lie on her left side and you place

her on 3 L/min of nasal oxygen while your partner administers 4 mg IV of ondansetron (Zofran) and begins a crystalloid infusion of 0.9% normal saline at 100 mL/h. Approximately 10 minutes later your patient reports that the nausea has subsided, but she still complains of a mild headache and is resting quietly in no apparent distress on the stretcher. No significant changes are detected on the fetal heart monitor.

Approximately 60 minutes into the 90-minute transport, your patient begins to complain of a sharp stabbing pain in the center of her chest that radiates to the right upper quadrant of her abdomen. She rates the severity of pain at onset as only a 5/10; however, you notice that she is getting anxious and is difficult to calm. Repeat vital signs are as follows: blood pressure, 164/110 mm Hg (mean arterial pressure, 128 mm Hg); pulse rate, 112 beats/min with sinus tachycardia; respiratory rate, 24 breaths/min; and Spo_2, 99% on 3 L of nasal oxygen. No obvious changes are noted on the fetal heart monitor, with a current heart rate of 170 beats/min. You place your patient on 15 L of oxygen via a nonrebreathing mask. Approximately 10 minutes later, your patient is writhing in pain and is barely able to stay secured to the stretcher as a result of her extreme anxiety. Your patient says, "It hurts so bad.… I just can't get comfortable." She now rates the severity of her headache and her chest and abdominal pain as a 10/10. Vital signs are as follows: blood pressure, 210/112 mm Hg (mean arterial pressure, 144 mm Hg); pulse rate, 121 beats/min with sinus tachycardia; respiratory rate, 28 breaths/min; and Spo_2, 98% on 15 L of oxygen via nonrebreathing mask.

You immediately contact online medical control and give them an update on your patient's condition. The physician requests the administration of 20 mg of nifedipine orally, but you advise him that nifedipine is not available to you. Orders are then received for 10 mg IV of labetalol with another dose of 20 mg IV in 10 minutes if the mean arterial pressure remains greater than 130 mm Hg. You are also ordered to administer 4 g of magnesium sulfate IV over 5 to 10 minutes and then begin an infusion of 2 g/h. All orders are read back and verified. You advise online medical control that you are 20 minutes from your destination, and you request that a patient update is passed along to the receiving facility.

Five minutes after administering labetalol, your patient's condition remains unchanged. She is still extremely anxious with the following vital signs: blood pressure, 222/120 mm Hg (mean arterial pressure, 154 mm Hg); pulse rate, 124 beats/min with sinus tachycardia; respiratory rate, 28 breaths/min; and Spo_2, 97% on 15 L of oxygen via nonrebreathing mask. Your partner establishes a second IV line with an 18-gauge needle in the right antecubital fossa and begins the magnesium sulfate loading dose of 4 g. It is now 10 minutes after her first dose of labetalol was administered and her condition remains unchanged. Her vital signs are as follows: blood pressure, 218/122 mm Hg (mean arterial pressure, 154 mm Hg); pulse rate, 128 beats/min with sinus tachycardia; respiratory rate, 28 breaths/min; and Spo_2, 97% on 15 L of oxygen via nonrebreathing mask. You administer 20 mg IV of labetalol for persistent hypertension related to severe preeclampsia; after 10 minutes, there is no change in your patient's condition.

You arrive at the receiving facility where a team of obstetricians and neonatologists who specialize in high-risk pregnancies are waiting for you. You and your partner provide a detailed report to the awaiting team along with a copy of the patient's health care record. The patient is quickly assessed by the team, and it is determined that an emergency cesarean section is needed.

1. What was the likely cause of this patient's deteriorating clinical picture and severe pain during transport?
2. What is the most common complication associated with preeclampsia?
3. Does the presence of pregnancy-induced hypertension in this patient make her more likely to have a recurrence in future pregnancies?

Analysis

The patient was diagnosed with preeclampsia after testing positive for proteinuria, hypertension, and elevated uric acid levels. The conditions of a small percentage of women (10%) who are diagnosed with preeclampsia worsen, resulting in a condition that is referred to as HELLP syndrome, which carries a high mortality rate. The patient's symptoms developed rapidly without warning and required an emergency cesarean section. The only cure for HELLP syndrome is the immediate delivery of the fetus.

In this case, the transport crew immediately contacted the medical control physician to obtain orders for the patient's worsening condition. Most transport programs should already have an aggressive set of protocols available that allows them to begin treatment of this condition without first contacting medical control. In order to save time during transport, the transport personnel should have asked for "what if" orders from the control physician while at the referring facility to eliminate the delay in treating the patient, therefore giving the patient and fetus a better chance of survival.

The goal of preeclampsia treatment is to avoid the progression and worsening of the symptoms related to the disease process. The patient's symptoms became markedly worse, requiring immediate treatment of life-threatening hypertension. Prompt treatment of the patient's signs and symptoms is the key as disease progression increases morbidity and mortality rates. The interventions performed were only temporary measures because an immediate cesarean delivery was indicated.

The most commonly seen complication associated with preeclampsia is eclampsia. Eclampsia is a disorder marked by the occurrence of seizures during pregnancy that are directly related to hypertension. Eclampsia is also known for having a high mortality rate and often requires a magnesium sulfate infusion to assist in stopping the seizure activity. In the case study, a magnesium sulfate infusion was initiated prophylactically in order to prevent seizures from occurring and was continued throughout the remainder of the transport. The magnesium sulfate infusion should be maintained until the blood pressure returns to normal and the threat of seizures has diminished.

The presence of pregnancy-induced hypertension does make a woman more susceptible for recurrence in future pregnancies. After this patient recovered from her emergency cesarean section, an array of laboratory tests were performed on an outpatient basis to determine a cause for the preeclampsia. Studies have shown that the exact cause of preeclampsia is unknown, but some of the likely suspects are clotting disorders and chromosomal abnormalities. The detailed laboratory studies revealed that the patient had a thrombophilia disorder called factor V Leiden. This disorder often causes small clots to form inside the placenta, which in turn causes the HELLP syndrome and accounts for a 60% recurrence of preeclampsia in future pregnancies.

Prep Kit

Ready for Review

- The physiologic changes induced by pregnancy and the presence of potential life-threatening pathologic conditions can make management of obstetric patients difficult.
- The female reproductive system, regulated by hormonal secretions, undergoes an approximately 28-day menstrual cycle.
- The placenta provides the fetus with oxygen and vital nutrients. It grows with the fetus and includes a thin membrane that separates maternal and fetal blood.
- As the fetus grows, it is more vulnerable to trauma as the ratio of fetal size to amniotic fluid decreases.
- Pregnancy alters the normal physiology of females, affecting nearly every organ system.

- During pregnancy, cardiac output increases, circulating blood volume expands, and peripheral venous pressure increases. Blood pressure and levels of serum albumin and serum protein decrease as pregnancy progresses.
- The fetus increases the demand for oxygen and reduces the oxygen reserve in the pregnant woman.
- Gastroesophageal reflux is more common during pregnancy, and the likelihood of aspiration in a pregnant patient with an altered level of consciousness is greater.
- Pregnancy places increased strain on the renal and endocrine systems.
- Hormonal changes in the pregnant patient can cause dermatologic changes, including acne, linea negra, chloasma, and rashes.
- Obstetric patients require a complete physical exam, including maternal and fetal hemodynamic monitoring and, if in labor, external vaginal evaluation for the presence of crowning.
- If delivery is imminent, CCTPs should choose to assist in the delivery at the hospital rather than during transport.
- To ease anxiety caused by the stress and noise of transport, analgesics may be administered to patients in labor.
- When necessary, CPR may be performed on pregnant patients, following standard guidelines with constant chest compressions and limited interruptions for ventilation and gas exchange.
- If defibrillation is necessary, fetal monitors should be removed before administering a shock.
- The developing fetus has only a small reserve of oxygen, usually only 1 to 2 minutes, if the supply from the mother is cut off or diminished. If the heart of the fetus does not receive enough oxygen, the heart rate decreases.
- The well-being of the fetus may be assessed by auscultation for heart rate and movement, use of a hand-held Doppler or fetal stethoscope, and electronic fetal monitoring.
- Electronic fetal monitoring records the fetal heart rate and uterine contractions on a fetal monitoring strip. Late or variable decelerations in the heart rate are abnormal and may indicate fetal distress.
- The normal heart rate of a fetus is between 120 and 160 beats/min. Fetal heart tones should be at least 30 seconds long and performed and recorded every 15 minutes during labor. During high-risk transports, electronic fetal monitoring should be performed continuously.
- Any vaginal bleeding during the third trimester of pregnancy must be regarded as an emergency.
- Bleeding may indicate a spontaneous abortion (miscarriage), ectopic pregnancy, abruptio placenta (premature separation of the placenta from the uterine wall), placenta previa (placenta that covers the cervical canal), or uterine rupture.
- CCTPs should be aware of the warning signs of dangerous medical conditions, such as pregnancy-induced hypertension, preeclampsia, eclampsia, and HELLP syndrome, and the appropriate treatment protocols.
- Labor includes three distinct stages as the cervix dilates, the baby descends through the birth canal and is born, and the placenta is delivered.
- During delivery, a crucial fetal transition occurs as the baby begins to breathe independently of an oxygen supply from the mother. Anything that delays the decline in pulmonary pressure during fetal transition can lead to delayed transition, hypoxia, brain damage, and death.
- Preterm labor and fetal immaturity are the leading causes of neonatal mortality.
- Tocolytic agents such as terbutaline and magnesium sulfate may be used to help stop preterm labor.

- The baby may present in vertex, Frank breech, complete breech, incomplete breech, or footling breech positions for birth. Only with vertex and footling breech presentations should CCTPs consider delivery in the field.
- In the event of a prolapsed cord, the pregnant patient should be given oxygen, placed in the knee to chest position, and transported rapidly.
- If shoulder dystocia occurs (the infant is too large to travel through the birth canal unassisted), a rapid treatment plan is needed, which may include positioning the pregnant patient using the McRoberts maneuver or rotating the infant's arm toward its sternum during delivery.
- During the delay between multiple births (such as twins or triplets), transport should continue. Transport should only be interrupted if the next infant begins to emerge from the birth canal.
- Once delivery is complete, care for both the mother and infant should continue by examining the mother's perineum for tears and monitoring the infant's APGAR score.
- CCTPs must examine the antepartum patient for possible postpartum hemorrhage, amniotic fluid embolism, complications arising from Rh incompatibility, or uterine rupture.
- All women of childbearing age with sudden onset of abdominal pain or uncommon vaginal bleeding must be considered to have a possible ectopic pregnancy.
- Pelvic inflammatory disease causes inflammation to the reproductive system, including the uterus, fallopian tubes, and ovaries, and, if untreated, may cause infertility.
- CCTPs should be prepared to treat gynecologic emergencies such as toxic shock syndrome, ovarian cysts, ruptured ovarian cysts, pathologic cysts, and ovarian torsion.
- Ovarian torsion is often a cause of lower abdominal pain in females that initially presents similar to appendicitis or an ectopic pregnancy.
- Ovarian cysts are typically a result of follicular maturation during the normal female menstrual cycle and are often undetectable and self-resolving. A small percentage may continue to grow and may cause lower abdominal pain.
- Symptoms of a cyst include abdominal pain, nausea, vomiting, and frequent urination from bladder pressure.
- Ovarian cyst diagnosis is made through ultrasonography and Doppler flow studies that can monitor blood flow as well as cyst size and location.
- An ovarian cyst may rupture spontaneously or following trauma, resulting in hemorrhage. If hemorrhage is present, patients may present with increased lower abdominal and pelvic pain, vaginal bleeding, and hypovolemia leading to shock.
- Treatment for a patient with a ruptured ovarian cyst includes controlling any immediate life threats, including evaluation for hypovolemic shock and maintaining adequate blood pressure with isotonic fluids if the patient is in shock.
- Gynecologic trauma includes vulvular hematoma (straddle injury) and sexual assault. The scene of an assault should be treated as a living crime scene, with efforts made to preserve evidence and limit unnecessary treatments.
- Gynecologic emergencies do not require significantly different treatment during critical care transport but are important to treat properly and with sensitivity.

Vital Vocabulary

amniotic fluid embolism A rare condition that can occur antepartum and postpartum, in which fetal tissue crosses over the placental barrier into maternal circulation, thereby causing obstruction to the mother's organs with organ failure or respiratory and cardiovascular compromise.

breech A delivery presentation in which the buttocks emerge first.

complete breech A delivery presentation in which the buttocks present first and the legs are crossed inside the uterus, oriented transversely to the birth canal; in this case, the mother is unable to vaginally deliver.

dilation Opening of the cervix to a maximum of 10 cm, at which point it is considered complete.

dilation and curettage (D&C) A surgical procedure in which the cervix is opened and the uterus scraped of tissue.

eclampsia The condition that exists once a patient with preeclampsia develops seizures; warning signs of the transition include severe headache, scotomata, hyperreflexia, epigastric pain, and anxiety; the condition causes serious maternal complications.

ectopic pregnancy A pregnancy in which the ovum implants somewhere other than the uterine endometrium.

endometrium The inner mucous membrane of the uterus.

external fetal monitoring Electronic heart monitoring of the fetus while in utero, performed via electrodes on the pregnant woman's abdomen.

footling breech A delivery presentation in which both feet extend into the birth canal; this is the only malpresentation in which field delivery may be considered.

frank breech A delivery presentation in which the buttocks present first, both of the infant's hips are flexed, and the feet are near the fetus' head.

gestation Period of time elapsed from conception to birth. For humans, the full period is normally 40 weeks.

gravida The number of pregnancies a woman has had, including those not carried to term.

HELLP syndrome A hemolytic disorder that occurs during the latter stages of gestation, usually after the 20th week, and whose clinical findings include hemolytic anemia, elevated liver enzyme levels, and a low platelet count; patients will present with blurred vision, abdominal pain, headache, and edema.

hydroureteronephrosis Dilation and obstruction of a ureter.

hyperreflexia A condition of overactive reflexes that can involve excessive twitching or spasms.

incomplete breech A delivery presentation in which the buttocks present first and one foot extends into the birth canal.

long-term variability A pattern of changes in the baseline fetal heart rate occurring within 30-second intervals rather than from beat to beat; due to the parasympathetic-sympathetic interplay in the fetal heart rate.

mittelschmerz pelvic pain Abdominal pain occurring midway between menstrual periods, at the time of ovulation and from the ovulation site.

ovarian cyst A fluid buildup within an outcropping of tissue from the ovary. If such a cyst is ruptured, significant bleeding can occur.

ovarian torsion Twisting of an ovary about its ligaments, resulting in ischemia and possibly necrosis.

parity The number of pregnancies a woman has had that were carried to more than 28 weeks' gestation.

partial thromboplastin time (PTT) A value that represents the intrinsic coagulation pathway's clotting ability; also known as activated partial thromboplastin time (aPTT).

pathologic edema Systemic swelling, which may have several causes, including preeclampsia.

pelvic inflammatory disease (PID) An infection of the female upper organs of reproduction, specifically the uterus, ovaries, and fallopian tubes.

preeclampsia A condition of late pregnancy that involves gradual onset of hypertension, headache, visual changes, and swelling of the hands and feet; also called toxemia of pregnancy.

pregnancy-induced hypertension (PIH) The occurrence of hypertension in a pregnant woman, usually after 20 weeks' gestation, defined as a blood pressure of 140/90 mm Hg or greater in a woman with a previously normal blood pressure, or a rise of 30 mm Hg systolic and/or 15 mm Hg diastolic in a woman with baseline hypertension; can lead to preeclampsia if uncontrolled.

premature Underdeveloped; refers to infants born before 36 weeks from the first day of the last menstrual period.

preterm labor Labor occurring before 36 weeks' gestation, leading to early birth.

proteinuria Protein levels detected in the urine.

prothrombin time (PT) A value that represents the extrinsic coagulation pathway's clotting ability by taking into account various clotting factors, fibrinogen, the prothrombin ratio, and the international normalized ratio.

shoulder dystocia A condition in which the infant's shoulders are too large to travel through the birth canal without additional clinical maneuvering of the infant.

spontaneous abortion Expulsion of the fetus that occurs naturally; also called miscarriage.

supine hypotensive syndrome Low blood pressure resulting from compression of the inferior vena cava by the weight of the pregnant uterus when the mother is supine.

term Used to describe an infant delivered at 37 to 42 weeks of gestation.

thrombocytopenia Reduction in the number of platelets.

tocolytics A group of medications used to suppress preterm labor.

vasospastic disease Vascular constriction or spasm.

vertex A fetal position in which the head is the lowest part of the fetus, resulting in the head presenting first during delivery; this is the normal delivery presentation.

REGA 1414

Neonatal Emergencies

Authors

Patricia R. Chess, MD

Yogangi Malhotra, MD

Nirupama Laroia, MD

Objectives

1. Define the terms newborn, neonate, and term newborn (p 876).
2. Discuss the roles of the CCTP when caring for a neonate (p 876).
3. Recognize anatomy and physiology unique to a neonate, including differences in thermoregulation, respiratory structure and function, oxygen transport, cardiovascular function, renal function, fluid and electrolyte balance, central nervous system, and the skeletal system (p 877).
4. Understand how problems with transitional circulation can result in neonatal emergencies (p 877–879).
5. Describe developmental aspects of pain in the neonate (p 879).
6. Discuss anatomic and physiologic differences in the premature infant and how these relate to management (p 881).
7. Discuss medical complications for which late preterm infants are at risk (p 881).
8. Identify important antepartum and intrapartum factors that can affect labor, delivery, and the neonate, and understand the pathophysiology that is associated with these factors (p 880).
9. Identify when a CCTP would use the APGAR score in caring for a newborn (p 880).
10. Discuss neonatal assessment, stabilization, and management (p 880).
11. Discuss how to prepare for and provide neonatal resuscitation, and identify situations in which it should be performed (p 881).
12. Explain the initial steps in resuscitation of a neonate (p 881).
13. Describe methods that can be used to improve airway and breathing in a neonate with inadequate respiration (p 882).
14. Determine when vascular access is indicated for a neonate and appropriate fluid selection (p 888–889).
15. Describe appropriate assessment technique for examining a neonate (p 879).
16. Describe free-flow oxygen delivery and appropriate assisted ventilation for a neonate (p 882).
17. Describe appropriate endotracheal intubation technique for a neonate (p 885–886).
18. Determine when an orogastric tube should be inserted, and describe how to insert an orogastric tube in a neonate (p 886).
19. Describe appropriate chest compression and ventilation technique for a neonate (p 888).
20. Discuss indications for medications, dosage, and routes of administration for a neonate (p 890–891).
21. Discuss the use of ventilators during neonatal transports (p 889).

22. Distinguish between primary and secondary apnea, and list causes, assessment, and management (p 892).
23. Describe how to perform needle thoracentesis for pneumothorax decompression for a neonate (p 895).
24. Discuss the pathophysiology, assessment findings, management, and treatment plan of the following respiratory emergencies in a neonate: meconium aspiration, apnea, pneumonia, pneumothorax, respiratory distress, and respiratory failure (p 893–896).
25. Recognize congenital anomalies that may lead to compromise of the neonate (p 897).
26. Discuss the pathophysiology, assessment findings, and management of the following cardiovascular emergencies in a neonate: cyanosis, tachyarrhythmias, and bradyarrhythmias, bradycardia, cardiac arrest, persistent pulmonary hypertension, acidosis, shock, and anemia (p 896–902).
27. Describe how to perform umbilical vein catheterization in a neonate (p 900).
28. Discuss the pathophysiology, assessment findings, and management of the following gastrointestinal emergencies in a neonate: gastroschisis, omphalocele, gastrointestinal obstruction and vomiting, acute intestinal perforation, hematemesis and bleeding from the rectum, volvulus, intussusception, and diarrhea (p 902–907).
29. Discuss management of infectious diseases and sepsis in the neonate (p 907).
30. Discuss management of hyperthermia and hypothermia in the neonate (p 908).
31. Discuss management of toxic exposure in the neonate, including the appropriate treatment for the neonate with narcotic depression (p 908).
32. Discuss the pathophysiology, assessment findings, and management of the following trauma/birth injuries in the neonate: head and neck injuries, nerve injuries, bone injuries, and abuse/maltreatment (p 908–910).
33. Discuss the pathophysiology, assessment findings, and management of the following neurologic conditions in the neonate: seizures, hypoxic ischemic encephalopathy, and lethargy (p 910–911).
34. Discuss the pathophysiology, assessment findings, and management of the following metabolic conditions in the neonate: hypoglycemia, hypocalcemia, and inborn errors of metabolism (p 912–913).
35. Discuss the use of an incubator (p 913).
36. Recognize the emotional impact and the need for information, empathy, and compassion for the parent/guardian during a critical care transport (p 913–914).
37. Discuss risks associated with critical care transport, including factors unique to air transport of a neonate (p 914–915).

Introduction

The care of a newborn or neonate must be tailored to meet the unique needs of this population. A **newborn** refers to an infant within the first few hours after birth; a **neonate** refers to an infant within the first 28 days after birth **Table 22-1**. A **term newborn** is one delivered between 37 and 42 weeks' **gestation**. This chapter reviews challenges that the CCTP may face when transporting a neonate, including recognizing anatomic differences in a neonate, understanding the physiologic changes that occur in a newborn during transition from fetal circulation after birth, thermoregulation, and the special needs of

infants delivered prematurely or births complicated by other factors. The steps involved in neonatal resuscitation, patho-physiology of common congenital anomalies, medical emergencies encountered during the first month after birth, and how these factors affect the process of transporting a critically ill infant are also discussed.

Additional skilled care intervention (intubation, obtaining peripheral IV access, placement of umbilical venous and arterial lines, needle aspiration of the chest, and chest tube placement) is needed for approximately 6% of neonates, with the rate of complications increasing as the neonate's birth weight and gestational age decrease. In the United States, approximately 80% of the 30,000 babies born each year weighing less than 3 lb (1,500 g) require resuscitation. Because both short- and long-term outcomes in neonates have been linked to initial stabilization efforts, it is imperative that CCTPs anticipate problems with neonates, are knowledgeable about how to deal with them, have the appropriate resuscitation equipment readily available, and carefully consider the neonate's ultimate transport plan.

TABLE 22-1 Infant Age Terminology

Term	Age
Newborn	Within the first few hours after birth
Neonate	Within the first 28 days after birth
Infant	Age 1 month to 1 year
Term newborn	Delivered between 37 and 42 weeks' gestation
Preterm	Delivered before 37 weeks' gestation

Anatomy and Physiology of a Neonate

Neonates are not small children. Newborn infants have anatomic differences and undergo unique physiologic changes at birth, placing them at special risks.

Thermoregulation

Neonates become cold easily due to a variety of factors. The potential for heat loss is greater due to a high body surface area-to-body weight ratio and limited subcutaneous fat. Neonates also lose heat to the environment through the mechanisms of thermal conduction, convection, radiation, and increased evaporative heat loss through the skin. Heat production is limited due to low glycogen stores and brown fat, especially in premature infants (brown fat is used in older individuals as a heat energy source), and limited capacity to generate heat by shivering. Neonates have a narrow range of *neutral thermal environment*, the temperature at which maintenance of normal body temperature requires only minimal metabolic expenditure. The term newborn is able to increase heat production through brown fat metabolism (nonshivering thermogenesis); however, this is at the expense of increased oxygen consumption. Hypothermia is associated with hypoxia, prolonged coagulation time with reduced platelet function and increased risk of intraventricular hemorrhage, reduced drug metabolism, cerebral depression, myocardial depression, acidosis, decreased immunity, patient discomfort, and increased mortality. The preterm infant is particularly vulnerable because the immature skin is thin, allowing significant heat (and evaporative fluid) losses. To help maintain normothermia, CCTPs should use prewarmed blankets and equipment, including a prewarmed transport **incubator** Figure 22-1, place a cap on the infant's head, and minimize the infant's exposure to cold. It is also important to avoid

environmentally induced hyperthermia because this condition is associated with increased energy expenditure, morbidity, and mortality.

Respiratory Structure and Function

Lung development starts early in embryonic life, but the lungs are unable to sustain life *ex utero* until later in the canalicular stage of development, after approximately 23 weeks' gestation or 500 g. The neonatal lung is small relative to the body size, with little respiratory reserve. Surfactant is present by 23 weeks of gestation, but surfactant deficiency is common before 32 weeks; babies born prematurely may benefit from exogenous surfactant delivered endotracheally. The neonate has a respiratory rate of 30 to 60 breaths/min with a tidal volume of about 5 to 7 mL/kg. Their heads are large in relation to their bodies, resulting in neck flexion and obstruction in the supine position. Placing a rolled towel under the neonate's shoulders helps open up the airway. The infant's tongue occupies a larger intraoral volume and can lead to airway obstruction. Newborn infants are obligate nose breathers and may present with obstructive apnea when the nasal passages are blocked by a developmental defect (choanal atresia), edema of the nasal mucosa by vigorous suctioning, or secretions. Placing and maintaining an oral airway is often a sufficient intervention to stabilize a neonate with a fixed nasal obstruction during transport. Another important airway anatomic feature of neonates is a relatively more cephalad and anterior larynx, which needs to be considered when locating the vocal cords during intubation. When positive-pressure ventilation (PPV) is needed, attempts should be made to maintain physiologic tidal volume breaths because volutrauma, hypercapnia, and hypocapnia have been associated with bleeding in the brain (intraventricular hemorrhage), hearing loss, and chronic lung disease or bronchopulmonary dysplasia.

Figure 22-1 A transport incubator.

Oxygen Transport

Fetal hemoglobin (HbF) forms 70% to 80% of the total hemoglobin in the neonate. Fetal hemoglobin delivers oxygen to the tissues in the hypoxic condition *in utero*, but tends to hold on to oxygen in the normal conditions after birth (the oxygen dissociation curve is shifted to the left). Neonates have a high oxygen requirement (6 to 8 mL/kg/min vs 4 to 6 mL/kg/min in adults). Tissue oxygenation is achieved by a relatively high cardiac output (300 mL/kg/min vs 60 to 80 mL/kg/min in adults), high heart rate (120 to 160 beats/min), and high respiratory rate (30 to 40 breaths/min). Neonates do not tolerate interruption in oxygen delivery for any length of time and become hypoxic and bradycardic quickly.

Cardiovascular Function

The heart rate, normally 120 to 160 beats/min in neonates, is an important determinant of cardiac output because the cardiac muscle is immature. Neonates respond to careful volume loading (fluid bolus of 10 to

20 mL/kg) with an increase in cardiac output, but they do not tolerate fluid overload. The two most common inotropic agents used in neonates are dopamine, used when an infant has cardiac compromise and is peripherally vasodilated from septic shock, and dobutamine, which also improves cardiac function but can exacerbate hypotension due to peripheral vasodilation. **Table 22-2** summarizes newborn, neonate, and term newborn vital signs.

Transitional Circulation

In utero the pulmonary vasculature has a high resistance, so most of the blood returning to the right atrium from the placenta (oxygenated blood) passes to the left atrium via the foramen ovale **Figure 22-2**. The oxygenated blood enters the left atrium, mixes with the small pulmonary return, and is pumped via the left ventricle and the aorta to the coronary arteries and the brain. Deoxygenated blood returns from the lungs to the left atrium and mixes with the oxygenated blood in the left atrium. Of the ejected right ventricular output, most blood flows to the aorta via the ductus arteriosus, mixing with the left ventricular output. Blood carried by the descending aorta perfuses various organs and the lower body. Umbilical arteries, which branch from the internal iliac arteries, lead to the placenta where blood is oxygenated.

With the clamping of the umbilical cord at birth (removal of the low resistance placenta), there is a sudden rise in the systemic vascular resistance. Cardiorespiratory adaptation at birth results in an increase in pulmonary blood flow and physiologic closure of the fetal shunts that allowed the blood to bypass the lungs—the foramen ovale and ductus arteriosus.

TABLE 22-2 Normal Infant Vital Signs

Age	Respiratory Rate (breaths/min)	Pulse Rate (beats/min)	Minimal Systolic Blood Pressure (mm Hg)
Newborn	30-60	120-160	Varies (target mean blood pressure equals gestational age)
Neonate	30-40	120-160	> 60
Infant	25-50	70-160	> 70

With extrauterine breathing and expansion of the lungs, tissue oxygenation increases, the pulmonary vascular resistance decreases, and pulmonary blood flow increases. The increased pulmonary venous return to the left atrium raises the left atrial pressure above the right, closing the flap valve of the foramen ovale. With increasing left ventricular pressure and a fall in right ventricular pressures, there is a decrease or reversal of flow through the ductus arteriosus. Anatomic closure may occur as early as 6 hours after birth, but complete occlusion may take up to 6 weeks. Pulmonary vascular resistance may increase with hypoxia, acidosis, cold stress, primary pulmonary disease such as meconium aspiration or pneumonia, or hypercarbia, causing persistent pulmonary hypertension, the return of left-to-right shunting through the ductus arteriosus and/or foramen ovale, profound hypoxia and cardiovascular compromise, and sometimes death. This process is worsened if the patient has systemic hypotension. Optimizing a neonate's condition during transport, with special attention given to maintaining normothermia, optimal oxygenation, fluid status, and systemic blood pressure, and minimizing acidosis and noise decreases the risk of developing severe persistent pulmonary hypertension.

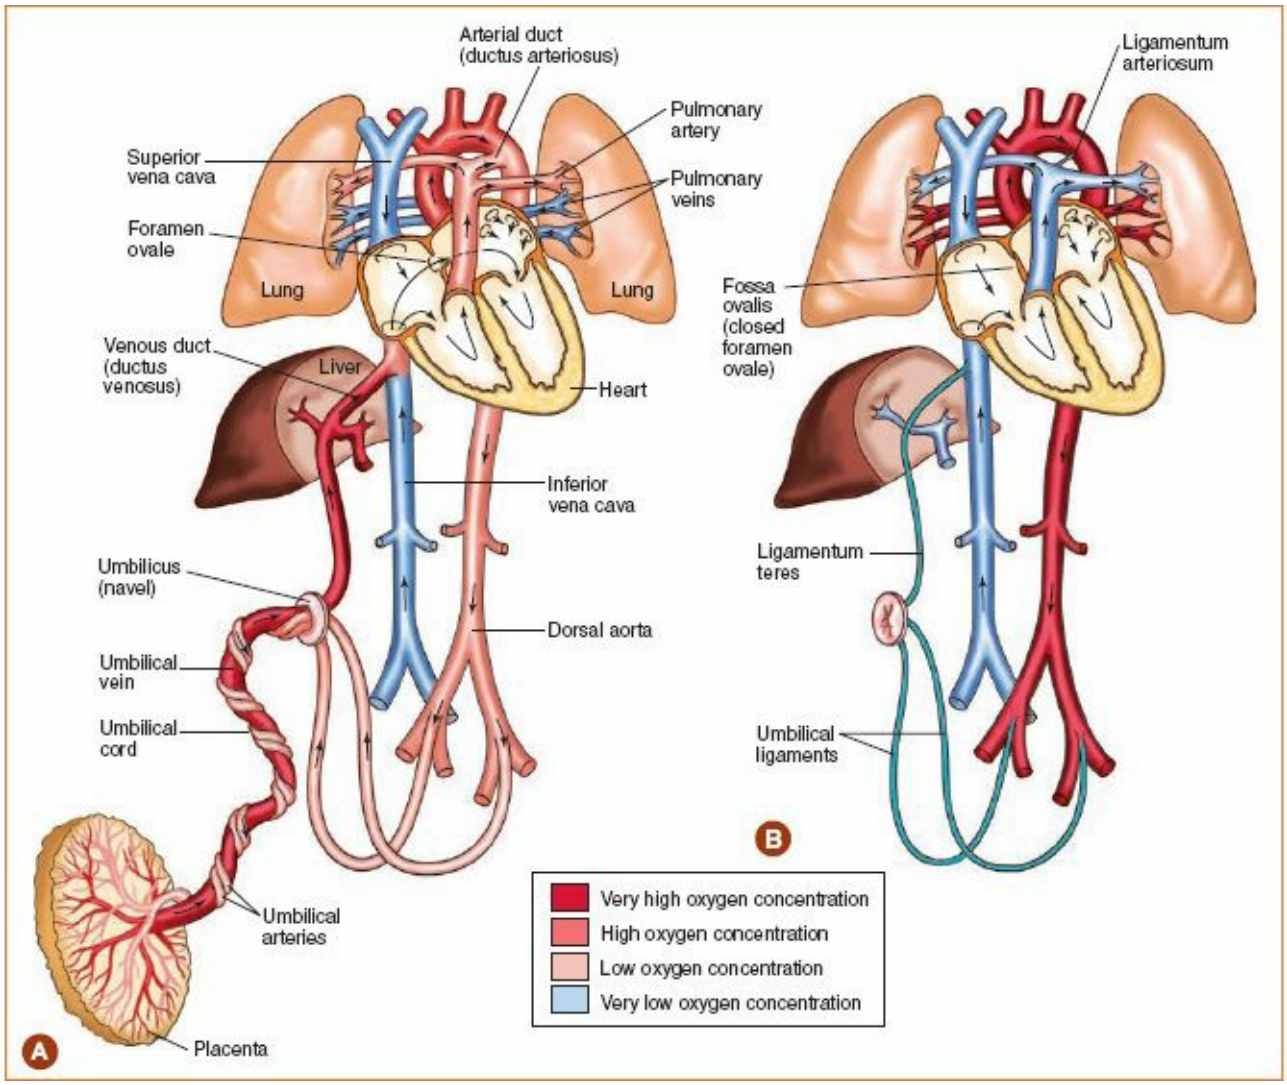

Figure 22-2 Fetal circulation. **A.** Oxygenated blood from the placenta reaches the fetus through the umbilical vein. Blood returns to the placenta via two umbilical arteries. Right-to-left shunts occur at the foramen ovale and the ductus arteriosus. **B.** Fetal circulation following transition.

Patent ductus arteriosus is seen in 50% of extremely premature infants (< 26 weeks' gestation) and is a risk factor for intraventricular hemorrhage and necrotizing enterocolitis. Whereas immediate treatment for a patent ductus arteriosus during critical care transport is not indicated, minimizing fluid overload during transport can decrease the risk of a persistent symptomatic patent ductus arteriosus.

Some cardiac abnormalities depend on a patent ductal flow, and circulatory collapse occurs with the closure of the ductus, often at 2 to 7 days of age. Maintenance of ductal patency with prostaglandins during transport can be lifesaving and will be discussed further in the section on cyanotic congenital heart disease.

Renal Function

Nephrogenesis is completed at 36 weeks' gestation and no further nephrons are produced. Additional increases in renal mass are the result of the growth of tubules. The glomerular filtration rate at term is low and reaches adult indexed values only at 2 years of age. The newborn's creatinine level at birth reflects the mother's creatinine level and falls to reflect renal function by 1 week of age. Tubular function matures over the first few months of life; infants usually produce urine that is isotonic to plasma, but if required, can concentrate their urine to achieve an osmolality of 500 to 700 mOsm/kg H_2O. Adult values (urinary osmolality, typically 1,200 to 1,400 mOsm/kg H_2O) are reached by 1 year of age. Infants tolerate fluid

restriction poorly and become dehydrated quickly.

Fluid and Electrolyte Balance

The extracellular fluid compartment is expanded in neonates, with total body water representing 85% of body weight in premature babies, and 75% of body weight in term babies, compared to 60% of body weight in adults. Contraction of the extracellular fluid compartment and weight loss in the first few days after birth is a normal physiologic process, due in part to diuresis induced by atrial natriuretic peptide secondary to increased pulmonary blood flow and stretching of the left atrial receptors. After this period of negative water and sodium balance, water and sodium requirements increase to match those of the growing infant. Therefore, fluids should be restricted until the postnatal weight loss has occurred. Liberal fluid regimens in the first few days of life have been shown to be associated with worse outcomes in premature infants (increased patent ductus arteriosus, necrotizing enterocolitis, and death). Fluid requirements increase incrementally from day 1 of life (60 to 100 mL/kg/d for term to extremely low birth weight infants, respectively) to 150 mL/kg/d at 1 week of life (up to 180 mL/kg/d by 1 week in a premature neonate with high evaporative losses). $D_{10}W$ is commonly used for IV fluid maintenance in a newborn for the first 24 hours. After 24 hours, once adequate urine output is established, 10% dextrose in 0.25 normal saline is used as a maintenance fluid in a neonatal transport; 10 mEq of potassium chloride in 500 mL may be added unless findings show abnormal electrolyte levels or renal function, necessitating adjustment. In general, a full-term infant needs 60 mL/kg/d, a very low birth weight infant (< 1,500 g) needs 80 mL/gk/d, and an extremely low birth weight infant (< 1,000 g) needs 100 mL/kg/d on day 1 of life, increasing by 10 mL/kg/d each day until reaching total fluids of 150 mL/kg/d.

Central Nervous System, Nociception, and the Stress Response

The lower limit for cerebral autoregulation in neonates is not known, but it is thought to be near a cerebral perfusion pressure of 30 mm Hg. In general, neonates are considered to have pressure passive cerebral circulation (as mean arterial pressure falls, cerebral blood flow falls, and vice versa). Appropriate mean arterial blood pressures for extreme premature neonates have not been determined but it is generally acknowledged that an acceptable mean arterial pressure equates to the gestational age of the newborn. It is also important to minimize stress and use appropriate sedation for procedures to minimize blood pressure peaks that can lead to intraventricular hemorrhage.

Developmental Aspects of Pain

Neonates, including premature neonates, show well-developed responses to painful stimuli. Pain in neonates should be treated using appropriate analgesic measures, such as bundling and a pacifier dipped in $D_{10}W$ for blood draws or IV placement, or local anesthetics or opiates for more invasive procedures.

Skeletal Development

Neonates have incomplete ossification of bones and tissues are more fragile than in older children and adults, making them more prone to soft-tissue and bony injuries. This should be considered when providing CPR because neonates are at higher risk of rib fractures and liver laceration during chest compressions. Optimal technique for chest compressions in neonates is reviewed later in the section on neonatal resuscitation.

Neonatal Assessment and Stabilization

Steps taken to assess, stabilize, and optimally transport an ill neonate can make a significant difference in

long-term outcome. For this reason, it is critical for CCTPs to recognize neonatal emergencies and know how to respond to them. Optimally, as soon as a transport need is identified, or at the latest on arrival at the referring institution, the CCTP should review relevant history, including prenatal issues, neonatal symptoms, vital signs (including blood pressure), physical exam findings, chest or abdominal radiographs, if obtained, and laboratory values (including blood glucose). Communication among all health care providers remains critical throughout the transport to optimize care. Specifics regarding assessment and stabilization are described below.

Common Risk Factors

The risk for complications in neonates increases as birth weight and gestational age decrease. Risk also increases in term infants when additional complications such as maternal infection, diabetes, hypertension, or meconium are present. Antepartum and intrapartum risk factors for complications are listed in **Table 22-3** and **Table 22-4**.

The APGAR Score

The **APGAR score** is a standardized numeric expression of a baby's condition after birth **Table 22-5**. Traditionally, 1- and 5-minute scores are recorded, although extended scores (every 5 minutes up to 20 minutes if the score is < 7) may need to be recorded if the infant's condition remains depressed. Each of the five signs is awarded a score of 0, 1, or 2, with a maximum score of 10.

Factors that affect the APGAR score include physical maturity (APGAR scores are often lower in premature infants), maternal medication intake or narcotic use, and neuromuscular or cardiorespiratory conditions. The score is a limited indicator of the severity of asphyxia. The correlation of the APGAR score with adverse neurologic outcome increases when the score remains 0 to 3 at 20 minutes.

Laboratory Assessment

Neonatal laboratory values assist in managing a variety of critical conditions. Critical neonatal laboratory values are listed in **Table 22-6**.

Stabilization and Management

Stabilization of the neonate is needed if there is acute airway obstruction, ineffective respiration, or insufficient cardiovascular circulation. The neonate must be evaluated for respiratory effort, heart rate, and color. The first steps in stabilizing a neonate are airway management and ventilation. To optimize adequate oxygenation and ventilation, suction the neonate's airway thoroughly.

Free-flow (blow-by) supplemental oxygen is required if peripheral cyanosis is present despite adequate respiratory effort and a pulse rate greater than 100 beats/min. Ventilations are required if respiratory effort is inadequate, ineffective, or absent, or if the pulse rate is less than 100 beats/min. Gasping respirations usually indicate a significant problem and require the same intervention as no respiratory effort or apnea. Ventilations are provided at a rate of 40 to 60 breaths/min, with a tidal volume sufficient to expand the neonate's chest, keeping in mind that a physiologic tidal volume for a neonate is 5 to 7 mL/kg. Intubation will be required if bag-mask ventilations are ineffective, tracheal suctioning is required, or prolonged PPV is necessary (see the section on neonatal resuscitation). Chest compressions are indicated if the neonate's pulse is less than 60 beats/min without improvement despite assisted ventilations with bag-mask ventilations (3 compressions followed by 1 breath, with 90 compressions and 30 breaths delivered each minute). Volume expansion may be necessary (10- to 20-mL/kg bolus of normal saline) as well as pharmacologic medications (epinephrine for persistent

bradycardia < 60 beats/min despite optimal respirations and chest compressions, dextrose [$D_{10}W$] for blood glucose levels < 40 mg/dL, or sodium bicarbonate for documented or suspected metabolic acidosis).

TABLE 22-3 Antepartum (Before Birth) Risk Factors
Multiple gestation
Pregnant woman's age < 16 y or > 35 y
Postterm (> 42 weeks') gestation
Toxemia, hypertension, diabetes
Polyhydramnios (excessive amount of amniotic fluid)
Premature rupture of the membrane and fetal malformation
Inadequate prenatal care
History of perinatal morbidity or mortality
Use of drugs/medications
Fetal anemia
Oligohydramnios (decreased volume of amniotic fluid during a pregnancy)

TABLE 22-4 Intrapartum (During Birth) Risk Factors
Premature labor
Rupture of membranes > 24 h before delivery
Abnormal presentation
Prolapsed cord
Chorioamnionitis
Meconium-stained amniotic fluid
Use of narcotics within 4 h of delivery
Prolonged labor or precipitous delivery
Bleeding
Placenta previa

TABLE 22-5 The APGAR Score

Sign	Score 0	1	2
Appearance (color)	Blue or pale	Body pink, extremities blue	Completely pink
Pulse (heart rate)	0	0-100	> 100
Grimace (irritability)	No response	Grimace	Cries
Activity (muscle tone)	Limp	Some flexion	Active movement
Respirations	Absent	Slow or irregular	Strong cry

TABLE 22-6 Critical Neonatal Lab Values

Name	Normal	Critically Low	Critically High
Blood Hematology and Coagulation Studies			
Hematocrit (% vol), neonate	44-64	< 33	> 70
Hemoglobin (g/dL), neonate	14.5-22	< 9.5	> 22
Chemistry			
Bilirubin (mg/dL), neonate	1-10	None	> 13
Glucose (mg/dL), neonate	40-65	< 40	> 200
Microbiology (Qualitative Results) and Serology			
Group B streptococcus antigen (delivery and nursery)	None	None	Positive
Urinalysis			
Note exceptions:	None	Urine glucose in patient < 2 y	Positive
	None	Urine ketones in patient < 2 y	Positive

Note: There is variance in unpublished lists—this is not an official list.

Special care needs to be taken when stabilizing and transporting a preterm neonate. Infants born before 34 weeks of gestation are at increased risk for bleeding into the brain (intraventricular hemorrhage). Avoiding rapid fluctuations in blood pressure, temperature, fluid volume, and pH status minimizes this risk. Preterm infants needing oxygen therapy and mechanical ventilation are also at risk of long-term lung damage, or bronchopulmonary dysplasia. Minimizing oxygen exposure and avoiding excessive pressures from assisted ventilation minimizes this risk. Even late preterm infants, those born at 34 to 36 weeks of gestation, are at increased risk of jaundice, dehydration, hypothermia, hypoglycemia, and sepsis.

It is important for the CCTP to communicate with the receiving facility as soon as possible. Important information includes relevant history, vital signs, physical exam findings, diagnostic studies done such as labs and radiographic results, relevant social issues, anticipated needs on arrival (ventilator, etc), and estimated time of arrival.

Provide psychological support and communicate with the neonate's parents. Encourage maternal bonding. Explain to the parents what is happening to their infant and what steps are being done to optimize the infant's outcome. Do not provide false hope and avoid discussing the neonate's chances of survival.

Determining the Need For and Providing Neonatal Resuscitation

The ABCs of neonatal resuscitation are the same as those applied to adults:

- Airway (position and clear)
- Breathing (stimulate to breathe)

- Circulation (assess pulse rate and color)

The most important and effective action in neonatal resuscitation is getting oxygen into the infant's lungs. In addition, maintenance of normal body temperature is important during neonatal resuscitation. The initial evaluation of the neonate begins with the evaluation of breathing, color, and pulse rate (counted for 6 seconds at the base of the cord or by auscultation and multiplied by 10).

In an infant who is cyanotic, first ensure patency of the airway by bulb suctioning the mouth and then the nose, and gently stimulating the infant. Stimulation is provided by flicking the soles of the feet and rubbing the back. It is important not to be too rough with the rubbing and to avoid slapping the infant because these actions may lead to traumatic injury.

In an emergency situation where it may not be possible to weigh the infant or child, CCTPs should be familiar with the length-based/color-coded resuscitation tape (for example, the Broselow tape) to help provide an estimate of body weight based on the child's crown-to-heel length **Figure 21-3**. This is helpful because most neonatal and pediatric (up to 40 kg) drug doses are based on body weight. It will also help determine the appropriate size of resuscitation supplies for the patient. The sizes for pediatric supplies are organized and listed according to the length-based/color-coded classification scheme.

Figure 22-3 Use of a length-based resuscitation tape is one way to estimate a child's weight and identify the correct size for pediatric equipment and appropriate medication doses. A child is shown here, but the tape also can be used on an infant.

Airway/Breathing Management

Free-Flow Oxygen

If an infant is cyanotic or pale, provide supplemental oxygen. Oxygen should be warmed and humidified if it needs to be provided for more than a few minutes. If PPV is not indicated (pulse rate > 100 beats/min and adequate respiratory effort), oxygen initially can be delivered through an oxygen mask held close to the infant's face. Alternatively, if a flow-inflating bag is set up, CCTPs can deliver oxygen by holding the mask close to the infant's face. If a self-inflating bag is connected to an oxygen source, the oxygen reservoir can be held close to the infant's face to provide oxygen, or CCTPs can disconnect the oxygen tubing from the self-inflating bag, and hold the tubing within a hand cupped loosely over the mouth and nose to facilitate delivery of supplemental oxygen. Holding the face mask over the neonate's face without squeezing the bag does not deliver oxygen from a self-inflating bag. The oxygen flow rate should be less than or equal to 5 L/min to minimize hypothermia. Remember that 5 g/dL of deoxygenated hemoglobin is needed before clinical cyanosis is observed. A severely anemic hypoxic neonate will be pale, but not cyanotic. Studies have demonstrated that even short exposure to supplemental oxygen may be associated with adverse oxidant stress in the neonate, both directly to the lungs and indirectly to premature neonates' eyes, and that resuscitation with room air may be an acceptable alternative. Oxygen, while life sustaining, can have negative side effects. Excessive oxygen in premature infants can lead to blindness. Oxygen toxicity, from a direct oxidant stress, can cause and exacerbate lung disease. For these reasons, once resuscitation has been achieved, an oxygen saturation monitor should be used to adjust the amount of

oxygen to the target range appropriate for each condition. In general, a premature infant's oxygen saturation should be maintained at 88% to 92%, and a term infant's oxygen saturation should be maintained at 95% to 98% saturation.

Oral Airways

Oral airways are rarely used for neonates, but can be lifesaving if airway obstruction leads to respiratory failure. Bilateral **choanal atresia** (a bony or membranous obstruction at the back of the nose preventing airflow) can be rapidly fatal, and usually responds to the placement of an oral airway (or a gloved finger until an adequate sized oral airway is located). The **Pierre Robin syndrome** is a series of developmental anomalies including a small chin and posteriorly positioned tongue that frequently leads to airway obstruction. Positioning the patient prone (chest down) may relieve the obstruction. If not, an oral airway should be placed.

Bag-Mask Ventilation

Signs of respiratory distress that suggest a possible need for bag-mask ventilation include gasping or periodic breathing, intercostal retractions (sucking in between the ribs), nasal flaring, and grunting on expiration. Respiratory distress occurs in approximately 8/1,000 live births and accounts for approximately 15% of neonatal deaths. Bag-mask ventilation is indicated when an infant is apneic, has inadequate respiratory effort, or has a pulse rate of less than 100 beats/min (this constitutes bradycardia in a newborn) after clearing the airway of secretions, relieving obstruction from the tongue, and stimulation. Bag-mask ventilation is also required when there is persistent **central cyanosis** despite breathing 100% oxygen.

Figure 22-4 Bag-mask ventilation of the newborn. Hold the mask securely to the face with your thumb and index finger. Apply countertraction under the bony part of the chin with your middle finger.

Figure 22-5 The sniffing position.

Adequate bag-mask ventilation with 100% oxygen necessitates the use of appropriately sized

equipment with techniques modified for the unique needs of the neonate. The face mask needs to provide an airtight seal, fitting over the infant's mouth and nose, extending down to the chin but not over the eyes **Figure 22-4**. The infant needs to have a patent airway, cleared of secretions, with the neck slightly extended in the sniffing position **Figure 22-5**. The first few breaths of a neonate after birth frequently require higher pressures (sometimes as high as 30 cm H_2O pressure or higher for brief periods of time) because the lung is not yet expanded and is still filled with fluid. To deliver these initial breaths, the pop-off valve (usually set by the manufacturer at 30 to 40 cm H_2O) on the bag may need to be disabled. Subsequent breaths should be delivered with sufficient pressure to result in visible but not excessive chest rise. The neonate should appear to be taking an easy breath, with a pressure of about 15 to 20 cm H_2O for normal lungs.

Three devices are used to deliver bag-mask ventilation to a neonate. The first device is a self-inflating bag with an oxygen reservoir **Figure 22-6A**. For this method, an oxygen source is not necessary to provide PPV but is necessary to provide supplemental oxygen. The second device is a flow-inflating bag that needs a gas source to provide PPV **Figure 22-6B**. The third device is a T-piece resuscitator that minimizes the risk of excessive pressures, pneumothorax, and lung injury in the neonate, and is becoming more widely available **Figure 22-6C**.

CCTPs should be familiar with available equipment in advance and ensure that the equipment is in working order. CCTPs will most likely be using a self-inflating bag. It is important to use the infant size (240 mL) if available. Since the tidal volume of a neonate is only 5 to 7 mL/kg, even when using a 240-mL bag, only one tenth the volume is used for each breath. If a neonatal bag is not available and the infant has severe respiratory distress, apnea, or bradycardia, a bag designed for adults or older children (750 mL or greater volume) may be used if the delivered breath size is kept appropriately small. In this situation, it is even more critical to monitor chest rise to avoid an excessive volume of delivered breaths. The algorithm for managing a distressed newborn is shown in **Figure 22-7**.

The most common reasons for ineffective bag-mask ventilation are inadequate mask seal and incorrect head position. Other causes such as mucous plug, pneumothorax, or equipment malfunction need to be considered. The correct timing is 40 to 60 breaths/min in a neonate. It is easy to deliver breaths at a much higher rate, which can increase risks such as hypocapnia, air trapping, and pneumothorax. Counting "breathe-two-three-breathe-two-three" as you ventilate (give a breath on "breathe," release while you say "two-three") can help with timing. PPV is continued as long as the pulse rate remains less than 100 beats/min or respiratory effort is ineffective. If prolonged PPV is needed, using a pressure manometer is important to help with monitoring and minimizing excessive pressures (usually less than 25 cm H_2O pressure in term infants, less in preterm infants).

Whereas newborn resuscitation with 100% oxygen is standard in the United States and is currently recommended by the American Academy of Pediatrics, a growing number of studies suggest that newborn resuscitation with room air is a safe alternative, including a recent meta-analysis published that showed increased survival in newborns initially resuscitated with room air compared to those resuscitated with 100% oxygen. Regardless, if oxygen is not readily available, bag-mask ventilation can be initiated with room air while an oxygen source is established. Remember to continuously monitor the effectiveness of ventilation and keep the infant warm throughout his or her care. Ventilation of the lungs is the single most important and effective step in cardiopulmonary resuscitation of the compromised neonate. Signs of effective ventilation include rapid rise in heart rate, improvement in color and tone, audible breath sounds by auscultation, and visible chest rise.

Table 22-7 lists equipment and medications needed for preparation for neonatal resuscitation.

Intubation

Most neonatal resuscitations can be successfully completed with bag-mask ventilation. However, intubation is indicated if:

- Meconium-stained fluid is present at birth and the infant is significantly depressed. (Intubation should occur prior to stimulating the infant, for the purpose of suctioning the trachea before the infant takes his or her first breath.)
- Congenital **diaphragmatic hernia** (congenital defect where abdominal organs herniate through an opening in the diaphragm into the chest cavity) is suspected and respiratory support is indicated.
- The infant is not responding to bag-mask ventilation and chest compressions leading to the need for epinephrine administration in a neonate when IV access is being obtained.
- Prolonged PPV is needed.

Figure 22-6 One of three devices can be used to deliver bag-mask ventilation to a neonate. **A.** A self-inflating bag. **B.** A flow-inflating bag. **C.** A T-piece resuscitator.

TABLE 22-8 Neonatal Endotracheal Tube Sizes

Size	Recommended Age, weeks
2.5	< 28
3.0	28-34
3.5	34-38

4.0	> 38

Before beginning to intubate the neonate, ensure the appropriate equipment is at hand. Use the straight blade #1 for a term infant and #0 for a preterm infant. Endotracheal (ET) tubes for neonates are available in size 2.5 to 4.0 mm **Table 22-8**. Again, a length-based/color-coded resuscitation tape or Broselow tape can be used to estimate ET tube size. A stylet may be used to provide rigidity to the ET tube. If a stylet is used, it is imperative that it is secured in its position (bending it over at the top of the ET tube so it can't advance) and not extended beyond the ET tube, or tracheal perforation may occur.

Skill Drill 22-1 shows intubation of the neonate, which is discussed in the following steps.

1. Ensure the neonate is preoxygenated by bag-mask ventilation with 100% oxygen prior to an intubation attempt **Step 1**.
2. Suction the oropharynx to ensure removal of secretions **Step 2**. This is a vagal stimulus, so pay close attention to pulse rate; bag-mask ventilation may again be needed prior to the intubation attempt if bradycardia results.
3. Place the laryngoscope blade in the oropharynx and then visualize the vocal cords, keeping in mind the vocal cords are more cephalad and anterior relative to adults **Step 3**. Take care to avoid applying torque to the blade, which increases the risk of trauma. Place the ET tube between the vocal cords until the black line on the tube is at the level of the cords. A general rule of thumb is that for term babies, the ET tube usually is advanced until it is at 9 cm at the lip. ET tube depth of insertion for premature infants is generally determined using this formula:

   Weight in kg + 6

   An extremely low birth weight baby (< 1,000 g) may only need to have the ET tube advanced to 6½ to 7 cm at the lip. Intubation attempts should be limited to 20 seconds, followed by bag-mask ventilation if unsuccessful or if significant bradycardia develops.
4. Confirm placement **Step 4** by observing chest rise when applying positive pressure through the ET tube, auscultating laterally and high on the chest, noting the absence of significant air sounds over the stomach, noting mist in the ET tube (will be seen when patient exhales through the tube from condensation of humidified air leaving the lungs), and clinical improvement of the patient. A CO_2 detector should be used if available.
5. Tape the ET tube in place on the face to minimize the risk of the tube dislodging **Step 5**. Once you place an ET tube, the infant needs to be monitored closely for complications such as tube dislodgement, tube occlusion by mucous plug, or pneumothorax.

Complications of ET tube placement include oropharyngeal or tracheal perforation, esophageal intubation with subsequent persistent hypoxia, and right mainstem intubation that can lead to atelectasis, persistent hypoxia, and pneumothorax. These risks can be minimized by optimal placement of the laryngoscope blade and carefully noting how far the ET tube is being advanced. Premedication is often not needed in depressed neonates. Consider atropine to avoid vagal-induced bradycardia. Administer sedation if agitation is present. Avoid paralytics since neonatal airways are very small, and may be difficult to maintain once the neonate is paralyzed.

Gastric Decompression

Gastric decompression using an orogastric tube is indicated for prolonged bag-mask ventilation (more than 5 to 10 minutes), if abdominal distention is impeding ventilation, or in the presence of a known or suspected diaphragmatic hernia. Many diaphragmatic hernias are diagnosed prenatally by routine ultrasound. They are suspected clinically if the following are noted: decreased breath sounds (90% of diaphragmatic hernias are on the left), a scaphoid or concave abdomen because many of the abdominal contents are in the chest, and increased work of breathing.

Skill Drill 22-2 shows neonatal orogastric tube placement, which is discussed here:

1. To determine the length of tube to insert, use an 8F feeding tube and measure the length from the bottom of the earlobe to the tip of the nose to halfway between the xiphoid process (lower tip of sternum) and the umbilicus **Step 1**.
2. Insert the tube through the mouth to this distance **Step 2**.
3. Attach a 20-gauge syringe and suction the stomach contents **Step 3**. Tape the tube to the neonate's cheek. Remove the syringe from the feeding tube to allow venting of air from the stomach, and intermittently suction the feeding tube.

Circulation

If the heart rate remains below 60 beats/min despite positioning, clearing the airway, drying and stimulation, and 30 seconds of effective PPV, chest compressions are indicated. Two techniques are used to perform chest compressions: the thumb technique and the two-finger technique. In the thumb technique, two thumbs are placed side by side over the sternum between the nipples and the hands encircle the torso. In the two-finger technique, the tips of two fingers are placed over the sternum between the nipples, and the sternum is compressed between the fingers **Figure 22-8**.

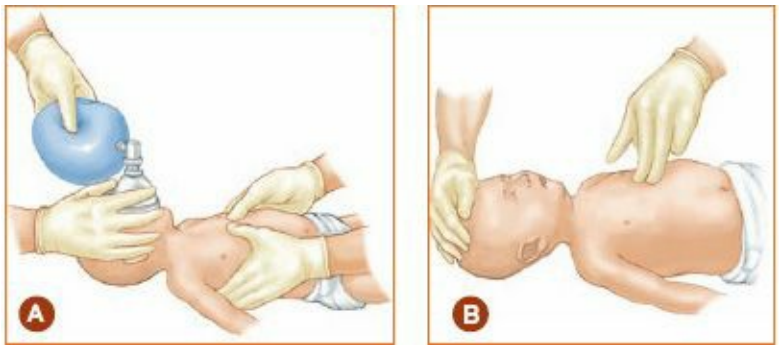

Figure 22-8 Chest compressions in the neonate. **A.** When there are two providers, use your thumbs side by side, placed just below an imaginary line drawn between the two nipples. **B.** When working alone, or when the infant is large, use two fingers to depress the sternum.

Skill Drill 22-1

Intubation of a Neonate

1 Preoxygenate the infant by bag-mask ventilation with 100% supplemental oxygen.

2 Suction the oropharynx. Provide bag-mask ventilation if bradycardia results.

3 Place the laryngoscope blade in the oropharynx. Visualize the vocal cords. Place the ET tube between the vocal cords until the black line on the tube is at the level of the cords.

4 Confirm placement. Observe chest rise, auscultate laterally and high on the chest, note the absence of significant air sounds over the stomach, note mist in the ET tube, and use a CO_2 detector.

5 Tape the ET tube in place. Monitor the neonate closely for complications.

Skill Drill 22-3 reviews the steps for resuscitating a neonate, which are listed here:

1. Lay the neonate flat (Trendelenburg position can cause intracranial hemorrhage especially in preterm infants) **Step 1**.
2. Suction the mouth and nose with a bulb syringe (if available) after delivery of the shoulders. Drying and suctioning are usually enough stimulation to induce breathing. If these do not suffice, gently flick your fingers against the soles of the neonate's feet and/or rub the neonate's back **Step 2**. Rough handling is not needed. *Do not shake the baby*.
3. If the neonate is still not breathing effectively, begin bag-mask ventilation **Step 3**. If the neonate begins breathing on his/her own, support and assist respirations and recheck the airway to be sure it remains clear.
4. If the neonate is still not breathing, continue bag-mask ventilation and check for an umbilical, femoral, or brachial pulse **Step 4**.
5. If you cannot feel a pulse or if the heart rate is less than 60 beats/min, begin closed-chest cardiac compressions **Step 5**.

Skill Drill 22-2

Inserting an Orogastric Tube in the Neonate

1 Measure for correct depth—from the bottom of the earlobe to the tip of the nose to halfway

between the xiphoid process (lower tip of sternum) and the umbilicus.

2 Insert the tube to the appropriate depth.

3 Remove the gastric contents with a 20-mL syringe. Tape the tube to the neonate's cheek. Remove the syringe from the feeding tube to allow air to vent from the stomach.

The depth of compression is one third of the anterior-posterior diameter of the chest. The fingers should remain in contact with the chest at all times to minimize risk of trauma. Time the compressions in synchrony with artificial ventilation, which continues during chest compressions. (In neonates, even if respirations are being supported by bag-mask ventilation, the ventilation is still timed with the chest compressions.) The person delivering the chest compression counts aloud, "one and two and three and breath and." Downward strokes of chest compressions should be delivered while saying "one, two, three." Release of the strokes should occur while saying "and." The person ventilating delivers a breath during "breath-and." This results in 90 compressions and 30 breaths/min. Note that this rate applies to one-rescuer infant CPR and it is best to use two rescuers for a faster compression rate. Heart rate is assessed at 30-second intervals and chest compressions stopped when the heart rate is greater than 60 beats/min. Liver laceration and rib fractures are possible risks of delivering chest compressions.

If the neonate is not responding to resuscitation, other causes must be considered. Generally, the difficulties relate to the following: technical/mechanical/equipment problems, unrecognized pulmonary complications, severe metabolic derangements, congenital abnormalities of organs systems, or severe anemia.

Pharmacologic Interventions

Medications are rarely needed in neonatal resuscitation because most infants can be resuscitated with

effective venti-latory support. Epinephrine is indicated when the heart rate remains below 60 beats/min despite PPV and chest compressions. Normal saline bolus, lactated Ringer's, or blood may be indicated for hypovolemia, blood loss, or for suspected metabolic acidosis while awaiting blood gas results. Sodium bicarbonate is only indicated when the degree of metabolic acidosis is known from a blood gas. Naloxone is generally not used during resuscitation but may be used if the infant continues to have depressed respirations and there is a history of narcotic use in labor. It is contraindicated if the mother is a chronic narcotics user. Medications in neonates are based on weight, so you may need to estimate the infant's weight for dosing. A term infant usually weighs 3 to 4 kg (approximately 6½ to 8½ lb). An infant born at 28 weeks of gestation averages 1 kg (2.2 lb), and an infant born at 34 weeks of gestation averages 2 kg (4½ lb). Medications that may be used are listed in **Table 22-9**.

Epinephrine

If the infant has a pulse rate of less than 60 beats/min after 30 seconds of effective ventilation and 30 seconds of chest compressions, administration of epinephrine is indicated. The recommended concentration for neonates is 1:10,000. The recommended dose is 0.1 to 0.3 mL/kg of 1:10,000 epinephrine IV, equal to 0.01 to 0.03 mg/kg, administered rapidly, and followed by a 0.5- to 1-mL normal saline flush to clear the line. While IV is the optimal route to deliver epinephrine, if IV access is not yet established, consider starting with the higher dose of 0.3 to 1.0 mL/kg of 1:10,000 epinephrine via the endotracheal tube. Epinephrine dosing may be repeated every 3 to 5 minutes for persistent bradycardia.

Skill Drill 22-3

Resuscitating a Neonate

1 Lay the neonate flat. Suction the mouth and nose with a bulb syringe.

2 If drying and suctioning do not induce breathing, gently snap your fingers on the soles of the neonate's feet.

3 Begin bag-mask ventilation if the neo-nate is not breathing effectively.

4 If the neonate is still not breathing, continue bag-mask ventilation and check for an umbilical, femoral, or brachial pulse. The brachial location is shown here.

5 If you cannot feel a pulse or if the heart rate is less than 60 beats/min, begin chest compressions.

Volume Replacement

If the infant's intravascular volume is significantly depleted from conditions such as placental abruption or septic shock, fluid resuscitation may be needed. In a newborn, a low umbilical venous catheter can be placed in the large vein in the umbilical cord, advancing the line just far enough to allow blood return, but not far enough to enter the liver. In an infant older than a few days, a peripheral IV or intraosseous (IO) line will need to be placed. It is important to note that while the technique for an IO line is similar to that for older children or adults, a smaller needle needs to be used to avoid exiting the far side of the bone. A fluid bolus in an infant is 10 to 20 mL/kg of normal saline IV over 5 to 10 minutes. More than one bolus may be needed if the patient is still clinically hypovolemic. Signs of hypovolemia include pallor, delayed capillary refill, and weak pulses despite a good heart rate or high-quality chest compressions (defined as compressions delivered at a depth of approximately one third of the anterior-posterior diameter of the chest that allow for full chest recoil at a rate of 90 compressions per minute with minimal interruptions. Note that in the neonate, the specific depth is important since the size of the neonate is variable; compressing too little leads to ineffective compressions, while compressing too deeply leads to trauma).

Ventilation During Transport

Neonatal transport incubators are typically fitted with a ventilator that provides synchronized intermittent mandatory ventilation. Settings are adjusted relative to the patient's condition. Peak inspiratory pressure is adjusted to provide a comfortable breath (typically 14 to 20 mm Hg, lower range for more premature infants, higher for term infants with decreased lung compliance such as seen in pneumonia). Peak end expiratory pressure is typically 3 to 4 mm Hg, rate 20 to 60 breaths/min, inspiratory time 0.4 seconds. If volume ventilation is used, a tidal volume of 6 to 8 mL/kg is targeted. Ventilator tubing can affect the measured tidal volume on some ventilator circuits, so close observation of chest rise and peak inspiratory pressure is critical, especially when first placing a neonate on tidal volume ventilation. For patients with very severe lung disease, a standard ventilator may not provide adequate support. High-frequency ventilation, a respiratory frequency of 400 to 800 breaths/min and optimal PEEP (usually higher than that used with conventional ventilation), relies primarily on convection and molecular diffusion of gas rather than tidal volume ventilation to exchange oxygen and carbon dioxide. Some transport incubators can be fitted with a high-frequency ventilator, in which case comparable ventilator settings can be used for transport. Frequently only a conventional ventilator is available for transfer. When switching a neonate from high-frequency ventilation back to a conventional ventilator, the neonate usually tolerates the fastest rate that the conventional ventilator can deliver; inspiratory pressures need to be kept relatively low and expiratory times long (I:E at least 1:2) to minimize the risk of air trapping. If the neonate is critically ill and oxygen saturations cannot be maintained on a conventional transport ventilator, hand bagging may provide acceptable ventilation and oxygenation until arrival at a tertiary care center. In the case of term infants with respiratory failure, some centers can initiate inhaled nitric oxide to optimize pulmonary vasodilation or extracorporeal membrane oxygenation in the field and transport on an inhaled nitric oxide or extracorporeal membrane oxygenation circuit. It is important to have discussions with the regional referral center in advance to know the technology that is available in the area.

TABLE 22-9 Medications for Neonates

Drug Name	Dose/Route	Concentration	Indications/Comments	Side Effects
Ampicillin	50 mg/kg IV over 5–10 min	Reconstitute with sterile water	1st line antibiotic for sepsis workup Use with gentamicin Use 100 mg/kg if meningitis suspected	None
Atropine	0.01–0.03 mg/kg IV/IM; may repeat every 5 min × 3 PO: 2–3 × IV dose; minimum dose of 0.1 mg in infants > 5 kg		Preintubation medication to minimize vagal-induced bradycardia Standard dose of 0.02 mg/kg used PALS	Tachycardia, arrhythmia Fever, rash, urinary retention
Cefotaxime	50 mg/kg q 6–12h IV depending on weight/age	In D_5W, $D_{10}W$, NS; infuse over 30 min	Broad spectrum antibiotic used for suspected/documented gram negative sepsis	Potential increased risk of fungal infection due to broad spectrum of coverage.
Ceftriaxone	50 mg/kg/dose q 24h IV/IM	In D_5W, $D_{10}W$, NS; IV infusion given over 30–60 min	Can be used to complete antibiotic course at home Do not use in a newborn nor a neonate with total bilirubin > 5 mg/dL since it displaces bilirubin from albumin and can lead to kernicterus	Cases of fatal reactions with calcium-ceftriaxone precipitates in lung and kidneys in both term and premature neonates have been described.
Dextrose	2 mL/kg IV bolus over 5–10 min	$D_{10}W$; if $D_{25}W$, dilute to < 12.5% to give via peripheral IV	Symptomatic hypoglycemia (blood glucose level < 40 mg/dL) May use for hydration May repeat bolus or follow with 5 mg/kg/min Incompatible with blood products	None
Dobutamine	3–5 μg/kg/min IV; increase 3–10 μg/kg/min to max 40 μg/kg/min	12.5 μg/mL; reconsitute in D_5W/$D_{10}W$/NS	Cardiogenic shock, hypotension, increased myocardial contractility, cardiac failure Try volume first Incompatibile with sodium bicarbonate	Hypoxemia, tachycardia, arrhythmia
Dopamine	5 μg/kg/min IV; increase 2–3 μg/kg/min to max 40 μg/kg/min for effect	40 μg/mL; reconstitute in D_5W/$D_{10}W$/NS	Nonhypovolemic shock, increased cardiac output Try volume first	Hypoxemia, tachycardia, arrhythmia
Epinephrine	0.01–0.03 mg/kg or 0.1–0.3 mL/kg ET or IV q 3–5 min; may titrate IV dose up to max 1 μg/kg/min for effect	1:10,000 (0.1 mg/mL); dilute 1:1 for ET administration	Resuscitation medication for asystole and bradycardia Bronchodilator Standard dose used in PALS and recommended by the AAP is 0.01 mg/kg IV	Arrhythmia Hypertension, IVH Renal failure Hypokalemia
Gentamicin	4 mg/kg IV/IM (IV preferred) over 30 min	Compatible w/TPN, NS, D_5W, $D_{10}W$	Part of sepsis workup Obtain cultures before administering Do not give with cephalosporin	None

Inhaled nitric oxide	20 ppm starting dose		Selective decrease in pulmonary vascular resistance Used for PPHN Started with oxygenation index > 25 Needs specific delivery device	Methemoglobinemia Need daily methemoglobinemia levels
Morphine sulfate	0.05–0.1 mg/kg IM/IV over 15–20 min (may push over 4–5 min if needed), then q 4 h or 10–15 μg/kg/h infusion	Compatible with D_5W, $D_{10}W$, NS	Analgesia and sedation Do not stop suddenly. Do not use in shock and increased intracranial pressure. Use naloxone as antidote for respiratory depression.	Respiratory depression, hypotension, bradycardia
Naloxone hydrochloride	0.1 mg/kg IV push/IM; may repeat in 3–5 min	1.0 mg/mL or 0.4 mg/mL; compatible with D_5W and NS	Narcotic-induced respiratory depression Avoid in newborns with narcotic use in mother.	Hypertension, arrhythmia, Pulmonary edema Vomiting
Normal saline-volume expander	10 mL/kg IV; may repeat × 1 if needed	Alternatives include whole blood or lactated Ringer's, 10 mL/kg	First line for volume resuscitation, shock, hypotension, hemorrhage	None
Phenobarbital	10–20 mg/kg IV, infuse over 10–15 min; may repeat for continued seizures	Compatible with $D_5W/D_{10}W/NS$	Anticonvulsant First line for seizures	Hypotension, repiratory depression Stevens-Johnson syndrome
Prostaglandin E_1	0.05 μg/kg/min infusion; may titrate down when stable, with good effect	Compatible with D_5W/NS; 1 ampule (500 μg) + 500 mL IV fluids = 1 μg/mL PGE solution; not compatible with other solutions or medications	Keeps ducts arteriosus patent Recommend intubating patient for long transports and obtain second IV access prior to infusion.	Apnea, hyperthermia, hypotension, bradycardia, hypoglycemia, seizures, hypocalcemia
Sodium bicarbonate	2 mEq/kg IV push over 2 min for resuscitation; repeat as needed	0.5 mEq/mL (4.2% solution); also available in 1 mEq/mL; compatible with $D_5W/D_{10}W/NS$	Resuscitation Metabolic acidosis Dose in mEq = base deficit on blood gas × 0.3 × weight in kg, over 15 min When the patient has a high serum sodium level, tromeThamine (Tham) may be used at a comparable dose to treat metabolic acidosis.	Rapid infusion may cause IVH

Abbreviations: AAP, American Academy of Pediatrics; D_5W, 5% dextrose in water; $D_{10}W$, 10% dextrose in water; $D_{25}W$, 25% dextrose in water; ET, endotracheal(ly); IM, intramuscularly; IVH, intraventricular hemorrhage; MI, myocardial infarction; NS, normal saline; PALS, pediatric advanced life support; PGE, prostaglandin E; PO, orally; PPHN, persistent pulmonary hypertension.

Additional Transport Considerations

While PPV and chest compressions can be performed in a moving emergency vehicle, it is key to ensure a secure airway before beginning the transport. The neonate is best stabilized at the referral center. Evaluation during air transport is difficult because of vibration, noise, and poor lighting. CCTPs must rely on cardiorespiratory equipment to determine the stability of vital signs. Procedures such as intubation or needle aspiration of the chest can be particularly challenging in flight because of limited available space and inability to maintain a stable environment for needle aspiration. An airway must be secured prior to a helicopter flight.

If additional interventions such as intubation or needle aspiration are needed during ambulance transport, it is recommended that the CCTP consider pulling the ambulance to the side of the road while performing the procedure. If in flight, the CCTP needs to rely more on nonauditory assessments (visual, tactile, electronic monitoring) to provide care and perform necessary procedures. If necessary, bag-mask ventilation can be performed during air transport if the ET tube becomes dislodged and is unable to be replaced readily.

Respiratory Conditions

Clearing the airway and providing stimulation establish adequate cardiorespiratory function in most neonates. However, a small subset of neonates need assisted ventilation, as discussed earlier. Conditions leading to respiratory compromise in the neonate include anatomic anomalies leading to obstruction, such as choanal atresia and Pierre Robin syndrome. Both of these conditions respond to placement of an oral airway. The next sections discuss specific conditions, their causes, and management.

Apnea

Apnea is defined as a pause in respirations of more than 20 seconds. It is often associated with cyanosis, pallor, **hypotonia**, or bradycardia.

There are two types of apnea: primary and secondary apnea. **Primary apnea** is present at birth. This is the initial response to asphyxia at birth. It responds well to stimulation and oxygen supply. If asphyxia continues beyond the primary apnea period, **secondary apnea** sets in after a few deep gasping breaths. It only responds to assisted ventilation and supplemental oxygen. Though these two types of apnea seem clinically indistinguishable, it is critically important to recognize the difference between them to provide appropriate management.

In the neonate, there are multiple causes of apnea. Respiratory causes include fixed anatomic obstruction, obstruction from position (head on chin obstructing airway), secretions, or reflux with aspiration. Metabolic causes include hypoglycemia, inborn errors of metabolism that cause high ammonia levels, and hypocalcemia. Cardiovascular causes include poor tissue oxygenation from arrhythmia, congenital heart disease, shock, anemia/hemorrhage, patent ductus arteriosus, and hypotension. Infectious etiologies include necrotizing enterocolitis, pneumonia, sepsis, respiratory syncytial virus, *Chlamydia*, and pertussis. Neurologic causes include seizures, encephalopathy, intraventricular hemorrhage, congenital hypoventilation, increased intracranial pressure, and apnea of prematurity. Hypothermia or hyperthermia, trauma, child abuse, and illicit drugs vs delivered or prescribed medications need to be considered as well.

Signs and Symptoms

Apnea

- Cyanosis
- Pallor
- Hypotonia
- Bradycardia

Differential Diagnosis

Apnea

- Fixed anatomic obstruction
- Obstruction from position, secretions, or reflux with aspiration
- Hypoglycemia
- Inborn errors of metabolism
- Arrhythmia

- Congenital heart disease
- Shock
- Anemia/hemorrhage
- Patent ductus arteriosus (PDA)
- Hypotension
- Necrotizing enterocolitis
- Pneumonia
- Sepsis
- Respiratory syncytial virus
- *Chlamydia*
- Pertussis
- Seizures
- Encephalopathy
- Intraventricular hemorrhage
- Congenital hypoventilation
- Increased intracranial pressure
- Apnea of prematurity
- Hypothermia
- Hyperthermia
- Trauma
- Child abuse

Transport Management

Apnea

- Manage the ABCs.
- Keep the patient warm.

Management of apnea includes managing the ABCs as needed. Administer free-flow oxygen at 2 L/min for cyanosis and then assisted ventilation if needed. Next, obtain the neonate's history and examine the neonate: Check the fontanelle for a bulge that may indicate increased intracranial pressure. Check the nose and oropharynx for obstruction. During the cardiac exam, listen for murmurs; listen for crackles on pulmonary auscultation. Check capillary refill to assess perfusion. Obtain a set of vital signs. Check the blood glucose level immediately. Then ensure that a complete blood count (CBC), cultures, chest radiograph, a blood gas analysis, and electrolyte levels are obtained if possible. Administer 2 mL/kg of 10% dextrose bolus if the glucose level is less than 40 mg/dL. Keep the patient warm. Ensure that a sepsis workup, including a CBC and appropriate cultures (urine, blood, cerebrospinal fluid), is performed. Administer antibiotics (eg, ampicillin, gentamicin) if these haven't been started. (The sepsis workup is often started at the sending facility and antibiotics chosen by the sending physician.) Administer naloxone if there is positive acute (not chronic) exposure to narcotics. Treatment of apnea often resolves associated symptoms such as cyanosis, bradycardia, and hypotonia. If apnea persists, intubate the patient prior to transport.

Causes of Respiratory Distress in a Neonate

Meconium-Stained Amniotic Fluid

Meconium is the first stool of an infant, and is usually expelled after birth. However, it may be expelled *in utero* in term infants during fetal stress. Post-term infants are at even higher risk for meconium-stained amniotic fluid due to relatively impaired placental function. Meconium-stained amniotic fluid is present in 10% to 15% of deliveries. Meconium aspiration occurs when infants inhale the meconium into their lungs before or during the delivery, when hypoxia or acidosis causes the infant to take a gasping breath. If they inhale the meconium-stained amniotic fluid either *in utero* or at delivery, plugging of the airways and hypoxia can follow. The respiratory distress caused by meconium aspiration is termed meconium aspiration syndrome. It can lead to atelectasis in the lungs, persistent pulmonary hypertension (delayed transition from fetal to neonatal circulation), pneumonitis, and pneumothorax. The differential diagnosis for meconium aspiration syndrome includes respiratory distress syndrome, **transient tachypnea of the newborn** (transient respiratory distress lasting a few hours and which is secondary to retained fetal lung fluid), sepsis, pneumonia, and congenital respiratory or cardiac malformation. Patchy/fluffy infiltrates may be seen on the chest radiograph **Figure 22-9**.

If meconium is present in the amniotic fluid of a depressed newborn at birth, tracheal intubation and aspiration with a meconium aspirator is performed before other interventions. Even when tracheal suctioning is performed, meconium aspiration syndrome may occur. When transporting an infant who has been exposed to meconium-stained amniotic fluid and has respiratory symptoms after delivery, it is important to monitor for the development of complications from meconium aspiration syndrome such as worsening lung compliance and pneumothorax and intervene as symptoms indicate. Consider PPV on transport if progressive hypoxia develops. Short inspiratory time and long expiratory time is commonly used to provide adequate ventilation and minimize air trapping in the neonate. High positive end expiratory pressure values may also be used. A needle set-up should be available in the event the infant develops a significant pneumothorax en route. If a significant pneumothorax develops, as suspected by acute cyanosis, increased work of breathing, and decreased breath sounds, clean the area just over the nipple on the affected side, insert a small (22-gauge) butterfly needle in the second intercostal space, midclavicular line, over the rib, while pulling back on a syringe to evacuate the extrapleural air and relieve the intra-thoracic pressure. This is discussed further in the section on pneumothorax and shown in **Figure 22-11**.

Figure 22-9 A chest radiograph with patchy/fluffy infiltrates, indicating meconium aspiration syndrome.

Signs and Symptoms

Meconium Aspiration Syndrome

- Respiratory distress
- Hypoxia

Differential Diagnosis

Meconium Aspiration Syndrome

- RDS
- Transient tachypnea of the newborn (TTN)
- Sepsis
- Pneumonia
- Congenital respiratory malformation
- Congenital cardiac malformation

Transport Management

Meconium Aspiration Syndrome

- Monitor for development of complications.
- Intervene as necessary.
- Consider PPV if progressive hypoxia develops.
- Perform needle thoracentesis if a significant pneumothorax develops.

Pneumonia

Neonates have an impaired immune response and as a result are at increased risk of pneumonia. Signs and symptoms of pneumonia include tachypnea (respiratory rate > 60 breaths/min), increased work of breathing, and hypothermia. Initial assessment should include a chest radiograph, blood gas measurements in infants with significant respiratory symptoms, CBC, and blood culture. Management includes antibiotics (eg, ampicillin and gentamicin), maintaining the infant with nothing given by mouth until respiratory symptoms resolve (because of the increased risk of aspiration), and administration of IV fluids to maintain hydration and blood glucose levels. Respiratory support such as supplemental oxygen and PPV needs to be provided based on the infant's clinical condition and oxygen saturations.

Signs and Symptoms

Pneumonia

- Tachypnea
- Increased work of breathing
- Hypothermia

Differential Diagnosis

Pneumonia

- Airway foreign body
- Asthma
- Bronchiectasis
- Bronchitis
- Heart failure
- Cystic fibrosis
- Empyema
- Gastroesophageal reflux
- Human immunodeficiency virus infection
- Pertussis
- Pneumococcal infections

Transport Management

Pneumonia

- Maintain the infant with nothing given by mouth (NPO).
- Provide IV fluids.
- Provide respiratory support.

Respiratory Distress Syndrome

Infants delivered prematurely, especially at less than 32 weeks of gestation, have a high risk of respiratory distress syndrome (RDS) as the result of insufficient **surfactant**, a surface-active agent naturally occurring in the lungs that minimizes surface tension in the lung. Within a few hours of birth, neonates with RDS present with grunting, retractions, nasal flaring, tachypnea, and, often, cyanosis. Male infants and infants of diabetic mothers are at increased risk of RDS. Surfactant inactivation can also occur due to interactions with abnormal alveolar proteins such as meconium or blood or in the case of pneumonia, albumin. Both surfactant deficiency and dysfunction may respond to exogenous surfactant, administered in a controlled clinical setting by providers experienced in its delivery. When transporting an infant after surfactant administration, the CCTP needs to recognize improving compliance and the potential need to decrease respiratory support (eg, wean oxygen as saturations improve, decrease peak pressure as chest excursion improves). Peak pressures and oxygen concentration should be minimized as appropriate throughout transport to minimize the risk of pneumothorax or chronic lung disease. An oxygen saturation of 85% to 92% should be targeted during transport of premature infants with RDS to minimize oxygen toxicity. Continuous positive airway pressure can be helpful in mild RDS to minimize alveolar collapse during transport. Ensure that a sepsis workup has been performed prior to transport, since pneumonia in the newborn is indistinguishable from RDS. Prevent cold stress by keeping the neonate warm and bundled.

Signs and Symptoms

Respiratory Distress Syndrome

- Grunting
- Retractions
- Nasal flaring
- Tachypnea
- Cyanosis

Differential Diagnosis

Respiratory Distress Syndrome

- Sepsis
- Pneumonia
- Wet lung
- Lung malformations

Transport Management

Respiratory Distress Syndrome

- Monitor for improving compliance and need to decrease respiratory support.
- Minimize peak pressures and oxygen concentration.
- Target oxygen saturation of 85% to 92% to minimize oxygen toxicity.
- Provide continuous positive airway pressure (CPAP).
- Keep the neonate warm and bundled.

Pneumothorax

Simple pneumothorax is a collection of gas in the pleural space, causing lung collapse. Tension pneumothorax involves air in the pleural space under pressure and is a life-threatening condition. Causes of pneumothorax include meconium aspiration, pneumonia, neonatal resuscitation, trauma, and aggressive assisted ventilation. A pneumothorax may present with increased oxygen requirements, tachypnea, increased work of breathing, agitation, bradycardia if mild/moderate, tachycardia if a large pneumothorax is causing tamponade, cyanosis, and hypotension if the pneumothorax is large. Management of pneumothorax includes transillumination, thoracentesis, and possible intubation, recognizing that PPV may cause an enlargement of the pneumothorax. With transillumination, increased transmission of light on one side of the chest suggests pneumothorax. A chest radiograph will confirm the diagnosis. Findings include an ipsilateral edge of the lung parallel to the chest wall, lucency, and a deep sulcus sign (deep lateral costophrenic angle). Mediastinal shift to the contralateral side is seen in cases of tension pneumothorax. If a symptomatic pneumothorax is suspected, a needle thoracentesis can be lifesaving. On the side of the suspected pneumothorax, clean the area around the second intercostal space, midclavicular line (usually just above the nipple), with alcohol **Figure 22-10**. Prepare the equipment needed: a 22-gauge butterfly

needle attached to extension tubing, a three-way stopcock, and a 20-mL syringe. Insert the needle above the third rib (in the second intercostal space) as a second provider pulls back on the syringe (which is open to the patient). The nerves and blood vessels run below the ribs, so avoid piercing this area **Figure 22-11**. Continue to slowly advance the needle until air is recovered. The butterfly needle is rigid, so be gentle to avoid further tearing the lung. If the 20-mL syringe becomes filled with air, turn the stopcock off to the neonate, push out the air from the syringe, open the stopcock to the neonate, and continue withdrawing air. When no more air can be withdrawn, remove the needle. If there is a symptomatic ongoing air leak, a 22-gauge angiocatheter can be inserted in a similar location, the introducer needle removed, and the angiocatheter attached to the extension tubing. Note that the angiocatheter may further tear the lung during its initial placement and it is more likely to kink than the butterfly needle. Remove as much air as possible with the syringe. At this point, the tubing may be briefly occluded while you place the end of the tubing that had been attached to the syringe in a small bottle of sterile water and release the tubing occlusion. This relieves the pressure buildup from the pneumothorax until the patient can be transferred to a facility skilled in placement of a chest tube in a neonate. Intubate the infant if respiratory distress continues.

Signs and Symptoms

Pneumothorax

- Increased oxygen requirement
- Tachypnea
- Increased work of breathing
- Agitation
- Bradycardia
- Tachycardia
- Cyanosis
- Hypotension

Transport Management

Pneumothorax

- Perform needle thoracentesis if necessary.

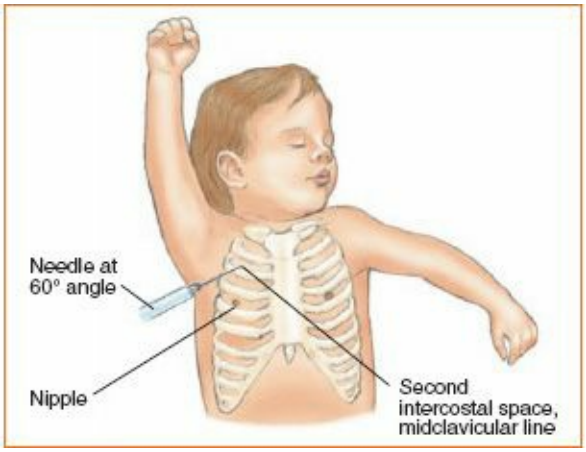

Figure 22-10 For needle thoracentesis to treat a tension pneumothorax or a symptomatic pneumothorax, position the child and identify the entry site.

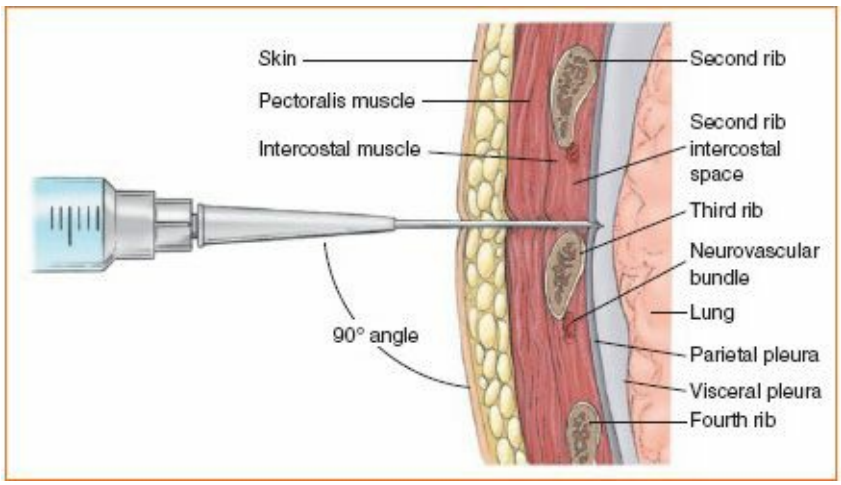

Figure 22-11 Insert the needle over the top of the rib margin in the second intercostal space at the midclavicular line. Nerves and blood vessels run below the ribs, so avoid piercing this area.

Resuscitation in a Neonate Beyond the Newborn Period

The neonate must be assessed using a systematic approach. Begin a rapid visual assessment of the child's overall appearance, work of breathing, and circulation. This can generally be completed within the first few seconds of the patient encounter.

- A rapid assessment to evaluate cardiopulmonary and neurologic function includes assessment of vital signs and pulse oximetry.
- Obtain a focused medical history and a thorough head-to-toe physical exam. Categorize the clinical condition by type and severity (respiratory to include upper/lower airway obstruction, lung disease, or disorder of control of breathing) and cardiovascular to include hypovolemia or cardiogenic shock.

The following is a modification of the pediatric advanced life support as applicable to the newborn and neonate.

A general assessment includes assessment of appearance (muscle tone, interaction, consolability, gaze, cry), work of breathing (nasal flaring, reduced or absent respiratory effort), and abnormal breath sounds (wheezing, grunting, stridor). Evaluation of circulation includes abnormal skin color (pallor, mottling) or bleeding. Determine if the condition is life threatening.

Primary Assessment Includes Airway, Breathing, and Circulation

Assessment of the airway is essential to determine if it is patent. Look for movement of the chest or abdomen. Listen for breath sounds and feel the movement of air at the nose and mouth. Increased inspiratory effort with retractions, snoring or high-pitched stridor, and periods where no breath sounds are heard suggest upper airway obstruction. Attempt to open and maintain the airway by use of the head tilt-chin lift or jaw-thrust maneuver. Suction the nose and pharynx. Attempt foreign body removal by back slaps and chest thrusts in a child younger than 1 year. Intubation may be required if these measures do not work. A respiratory rate of greater than 60 breaths/min is abnormal at any age in a child. A decreasing or irregular respiratory rate may suggest worsening of the clinical condition, especially if associated with a worsening level of consciousness. A decreased respiratory rate or an irregular respiratory rate in an acutely ill child is an ominous clinical sign because it often signals impending cardiopulmonary arrest.

Assessment of circulation includes both cardiovascular function and end-organ function.

Cardiovascular function is assessed by skin color, temperature, heart rate, rhythm, blood pressure, peripheral and central pulses, and capillary refill time. End-organ function is assessed by evaluation of mental status (brain perfusion), skin perfusion, and renal output. A systolic blood pressure of less than 60 mm Hg in a term infant up to 1 month of age and less than 70 mm Hg up to 6 months of age is an ominous sign. Hypotension represents a state of shock in which physiologic compensatory mechanisms (tachycardia, vasoconstriction) have failed. Hypotension with hemorrhage is consistent with about a 20% to 25% loss in circulating volume, whereas hypotension in septic shock represents inappropriate vasodilation rather than loss of circulating volume. Aggressive fluid resuscitation along with management of airway and breathing are needed to prevent cardiac arrest.

TABLE 22-10 Management of Respiratory Distress and Failure

Assessment Parameter	Action as Indicated
Airway	Support the airway. Clear the airway (suction the nose and mouth as needed). Insert an oropharyngeal airway if indicated.
Breathing	Assist ventilation (bag-mask ventilation or intubation). Provide oxygen (humidified if available). Begin with 100% and wean as needed based on oximetry. Continuously monitor oxygen saturation by pulse oximetry. Prepare for intubation as indicated.
Circulation	Monitor heart rate and rhythm. Establish vascular access for fluid therapy and medications.

Alteration in neurologic signs may be caused by conditions other than cerebral hypoxia. Some drugs and metabolic conditions such as rising ammonia from an inborn error of metabolism or increased intracranial pressure may cause neurologic signs. Careful evaluation of pallor, mottling, and cyanosis may indicate inadequate oxygen delivery to the tissues. Acrocyanosis (bluish discoloration of hands and feet) is often seen in healthy newborns, and unlike central cyanosis, is not associated with hypoxia.

Management of Respiratory Distress and Failure

Respiratory problems are a major cause of cardiac arrest in newborns and infants. Clinical deterioration in respiratory function may progress rapidly; therefore, prompt recognition and effective management are fundamental to pediatric life support. The primary goal is to restore adequate oxygenation and ventilation. **Table 22-10** lists measures for ensuring airway, breathing, and circulation.

Cardiovascular Conditions

Cyanosis

Cyanosis (blue coloration of gums and face) is caused by decreased arterial oxygenation. **Acrocyanosis**, or cyanosis of the extremities, with pink color centrally is a benign, common condition that presents as bluish coloration of the hands and feet and is often seen in newborns secondary to cold stress and

peripheral vasoconstriction.

Cyanosis often presents in association with poor perfusion and congestive heart failure. It may also present with shock or the result of either a pulmonary or cardiac process. Cardiac causes of cyanosis include cyanotic congenital heart disease, arrhythmia, cardiomyopathy, patent ductus arteriosus, and myocarditis. Noncardiac causes of cyanosis include persistent pulmonary hypertension (PPHN), sepsis/pneumonia, RDS, aspiration pneumonitis (meconium/blood), severe anemia, and arteriovenous malformation.

Signs and Symptoms

Cyanosis

- Blue coloration of gums and face

Differential Diagnosis

Cyanosis

- Congestive heart failure
- Shock
- Cyanotic congenital heart disease
- Arrhythmia
- Cardiomyopathy
- PDA
- Myocarditis
- Pulmonary hypertension (PPHN)
- Sepsis/pneumonia
- RDS
- Aspiration pneumonitis (meconium/blood)
- Severe anemia
- Arteriovenous malformation

Transport Management

Cyanosis

- Provide oxygen.
- Ventilate with bag-mask device as needed.
- Consider transfusion as needed.

Cyanotic Congenital Heart Disease

Cyanotic congenital heart disease (CHD) is caused by developmental anomalies of the heart or major vessels leading to abnormal blood flow. Deoxygenated blood from the right side of the heart is shunted to the left side, causing cyanosis. The cyanotic heart lesions, known as “The 5 Ts” are truncus arteriosus,

transposition of the great vessels, tetralogy of Fallot, tricuspid atresia, and total anomalous pulmonary venous return. A hypoplastic left heart also leads to cyanosis.

Management of cyanosis in a neonate suspected of CHD includes assessment of the ABCs, monitoring blood pressure and oxygen saturation (preferably upper and lower saturations to follow for PPHN), optimizing oxygenation to prevent acidosis, and supporting cardiovascular function. Administer oxygen to the infant, using a nonrebreathing mask if needed, to keep the oxygen saturation level > 70%. Hyperoxygenation can be harmful because it reduces pulmonary vascular resistance and diverts blood from systemic circulation to pulmonary circulation. For the same reason, hyperventilation can be harmful to the infant as well. Consider intubation if respiratory distress is severe. Obtain IV access as soon as possible. Obtain a CBC with platelet count and differential count, and perform electrolyte and blood gas determinations. Measuring arterial blood gas helps determine the degree of oxygenation/perfusion and ventilation. Ensuring that laboratory tests for lactate and hemoglobin with blood gases have been obtained is a quick way of determining the extent of acidosis and anemia. Simultaneous determinations of blood gases from a preductal and postductal extremity, ie, right arm (preductal) and left leg (postductal), are also useful. A difference in Pa_{O_2} (preductal–postductal) of greater than 15 mm Hg indicates a diagnosis of PPHN. Sodium bicarbonate may be needed if poor perfusion has caused significant metabolic acidosis (check base excess on the blood gas). Obtain four limb blood pressures to help determine the level of stenosis/obstruction to blood flow. If possible, perform a hyperoxia test because it is a very important test to distinguish cardiac from noncardiac (lung disease) causes of cyanosis. This test is performed by placing the infant in an **oxygen hood** with 100% oxygen for 20 minutes. Obtain a blood gas measurement. A Pa_{O_2} measurement greater than 150 mm Hg on blood gas analysis essentially rules out cardiac causes of cyanosis because deoxygenated blood bypasses the lungs and is shunted to the left side of heart in the case of CHD. The exception to this rule is total anomalous pulmonary venous return, in which oxygenated blood returns to the right side of the heart, leading to progressive pulmonary edema. Because results from a blood gas analysis may not be readily available, upper and lower oxygen saturations can be obtained. A preductal (right upper extremity) upper saturation more than 10 points higher than a postductal (lower extremity) saturation suggests pulmonary hypertension. Hyperoxia with hyperventilation supports PPHN as the cause of cyanosis. Correct any other metabolic abnormalities that may be found on lab analysis. Consider prostaglandin administration in discussions with the supervising physician. In the case of ductal-dependent congenital heart lesions (transposition of the great arteries, left ventricular outflow obstruction), timely infusion of prostaglandin E_1 is crucial. It keeps the ductus arteriosus open. Prostaglandin is not indicated in nonductal-dependent lesions. An echocardiogram is used to assess the type of CHD and determine the presence of pulmonary hypertension; however, this is often not available when transferring a neonate from a community hospital to a higher level facility. If the diagnosis of CHD is suspected but uncertain during transport and the patient is severely acidotic, hypoxic, hypotensive, or poorly perfused, discuss a trial of prostaglandins with the supervising physician. The infant may need to be intubated for the infusion since prostaglandins can cause apneas. Other side effects of prostaglandins are seizures, bradycardia, hyperthermia, and hypotension. Follow vital signs closely throughout the transport. The infant may have congestive heart failure and low blood pressure/delayed capillary refill in addition to cyanosis. Management of hypotension includes a normal saline bolus as a first line of therapy. After ensuring adequate volume expansion, consider inotropes or pressors. Dobutamine and dopamine are agents for supporting blood pressure. The dose is 5 to 20 μg/kg/min. Administer sodium bicarbonate for severe acidosis.

Signs and Symptoms

Cyanotic Congenital Heart Disease

- Cyanosis
- Respiratory distress

Differential Diagnosis

Cyanotic Congenital Heart Disease

- Truncus arteriosus
- Transposition of great vessels
- Tetralogy of Fallot
- Tricuspid atresia
- Total anomalous pulmonary venous return
- Hypoplastic left heart

Transport Management

Cyanotic Congenital Heart Disease

- Discuss a trial of prostaglandins with the supervising physician if the infant is severely acidotic, hypoxic, hypotensive, or poorly perfused.
- Follow vital signs closely.
- Manage hypotension, if present.
- Manage acidosis.

Recognition and Management of Tachyarrhythmias and Bradyarrhythmias

Sinus tachycardia is defined as a heart rate faster than normal for the child's age. Heart rate generally varies with activity and other factors influencing oxygen demand (ie, the infant's temperature). Common pathologic causes for tachycardia include tissue hypoxia, hypovolemia, fever, metabolic stress, pain, anxiety, drugs, and anemia.

Supraventricular tachycardia (SVT) is an abnormally fast rhythm originating above the ventricles. It is the most common cause of tachyarrhythmia producing cardiovascular compromise in infancy. It is commonly caused by a reentry mechanism that involves an accessory pathway, atrioventricular nodal reentry, or ectopic atrial focus. Wolff-Parkinson-White syndrome, in which ventricular preexcitation produces a delta wave on electrocardiogram, is an example of a condition that produces SVT via an accessory pathway. SVT is often tolerated well in infants. They often present with symptoms of congestive cardiac failure, poor feeding, rapid breathing, irritability, pale or blue color, and vomiting. Initial management includes determination of pulse and signs of adequate perfusion, supporting the ABCs and oxygenation as needed, obtaining an electrocardiogram to determine the rhythm, and obtaining vascular access and establishing monitoring by a cardiopulmonary monitor and/or pulse oximeter. Specific emergency intervention is dictated by the condition of the infant and varies depending on the width of the observed QRS complex on the electrocardiogram. Vagal maneuvers, cardioversion, and pharmacologic interventions are among the options available, but should be performed under the

supervision of a credentialed provider of such care. Children with tachyarrhythmias need to be evaluated by a pediatric cardiologist, but this should not delay appropriate emergency treatment.

Signs and Symptoms

Supraventricular Tachycardia

- Symptoms of congestive heart failure
- Poor feeding
- Rapid breathing
- Irritability
- Pale or blue color
- Vomiting

Differential Diagnosis

Supraventricular Tachycardia

- Wolf-Parkinson-White syndrome
- Sinus tachycardia

Transport Management

Supraventricular Tachycardia

- Support ABCs and oxygenation as needed.
- Monitor by cardiopulmonary monitor and/or pulse oximeter.
- Perform vagal maneuvers, cardioversion, and pharmacologic interventions based on protocol.

Bradycardia in a neonate is usually a result of tissue hypoxia and resolves when tissue oxygenation is restored. The most common neonatal bradyarrhythmia is due to maternal lupus, resulting in heart block. If the resting fetal heart rate is low enough, hydrops (edema) develops. Postdelivery cardiac pacing may need to be initiated, but it is usually nonurgent.

Recognition and Management of Cardiac Arrest

In contrast to cardiac arrest in adults, sudden cardiac arrest in children is uncommon. Cardiac arrest is more often caused by progression of respiratory distress, respiratory failure, or shock, typically associated with hypoxemia and acidosis, than from cardiac arrhythmias. Sudden infant death syndrome has decreased significantly in recent years with the “back to sleep” campaign, which instructs parents to place the infant on its back to sleep. Trauma is an important cause of cardiopulmonary collapse in infants older than 6 months. Details of infant resuscitation, including the importance of adequate ventilation, have already been discussed.

Persistent Pulmonary Hypertension

Persistent pulmonary hypertension (PPHN) is persistence of elevated pressures in pulmonary vasculature after birth. It is associated with failure to transition from fetal circulation to postpartum or normal newborn circulation. The elevated pulmonary blood pressure causes ineffective pulmonary perfusion, hypoxemia, and right-to-left shunting of blood via the patent foramen ovale and/or patent ductus arteriosus. PPHN presents mostly in term or post-term neonates, within the first few hours of life. PPHN frequently presents with a combination of cyanosis, tachypnea, hypoxemia (often labile/fluctuating, respiratory distress, and differential oxygen saturations [upper > lower]).

The exact cause of PPHN is not understood. However, several factors contribute to the failure of normal circulatory transition at birth. Pulmonary vasoconstriction often occurs secondary to perinatal events. The most potent vasoconstrictors of the pulmonary artery are hypoxia and acidosis. Meconium aspiration is the most common cause of PPHN, often causing perinatal distress. Additional conditions and risk factors associated with PPHN are RDS, asphyxia, pneumonia, hypothermia, hypoglycemia, and sepsis.

Abnormal development of the pulmonary vasculature is more frequently seen if the mother has taken NSAIDs during pregnancy and in infants of diabetic mothers. It is also common in chronic fetal distress/hypoxia resulting in hypertrophy of the vascular muscles of the pulmonary artery (characterized by idiopathic or black lung PPHN, because there is no parenchymal disease seen on a chest radiograph), aspiration, hypoxic ischemic encephalopathy, and congenital diaphragmatic hernia.

It is important to have a low threshold of suspicion for PPHN. Care should be taken to optimize oxygenation, minimize stress, maintain a normal blood pressure, and avoid or correct acidosis. Obtain a CBC, differential count, platelet count, blood gas analysis for hyperoxia, and follow upper and lower oxygen saturations while treating the underlying cause of the PPHN.

Signs and Symptoms

Persistent Pulmonary Hypertension

- Cyanosis
- Tachypnea
- Hypoxemia (often labile/fluctuating)
- Respiratory distress
- Differential oxygen saturations

Differential Diagnosis

Persistent Pulmonary Hypertension

- Meconium aspiration
- RDS
- Asphyxia
- Pneumonia
- Hypothermia
- Hypoglycemia
- Sepsis

Transport Management

Persistent Pulmonary Hypertension

- Optimize oxygenation.
- Minimize stress.
- Maintain normal blood pressure.
- Avoid or correct acidosis.

Acidosis

Respiratory acidosis may be caused by maternal drug use that results in respiratory depression in the neonate or a primary pulmonary or neurologic cause for suboptimal gas exchange. Respiratory acidosis frequently presents with visually obvious hypoventilation or increased work of breathing, and often responds to assisted ventilation. Metabolic acidosis results when cations, frequently lactic acid from poor tissue perfusion or toxic byproducts in inborn errors of metabolism, build up in the bloodstream. Causes of metabolic acidosis include asphyxia, congenital heart disease, sepsis, inborn errors of metabolism, hypovolemia, seizures, bradycardia, or hypotension. The presentation of metabolic acidosis may include compensatory tachypnea, mottled/gray skin with delayed capillary refill (normally < 3 seconds) apnea, lethargy, hypertonia or hypotonia, feeding intolerance, seizures, or emesis. Management of metabolic acidosis includes managing the ABCs, providing adequate oxygenation, ventilation, and hydration, and treating the underlying cause. If adequate ventilation and fluid resuscitation fail to clear the metabolic acidosis, sodium bicarbonate can be given at a dose of 0.3 × the base deficit on the blood gas analysis × the neonate's weight in kilograms. If the exact deficit is not known, a dose of 2 mEq/kg can be given. In premature neonates, the dose should be given over at least 30 minutes to minimize the risk of intraventricular hemorrhage. If inborn error of metabolism is suspected, enteral feeding should be stopped, and IV dextrose should be initiated to minimize production of toxic byproducts. Critically ill neo-nates often have a mixed metabolic and respiratory acidosis.

Signs and Symptoms

Metabolic Acidosis

- Compensatory tachypnea
- Mottled/gray skin with delayed capillary refill
- Apnea
- Lethargy
- Hypertonia/hypotonia
- Feeding intolerance
- Seizures
- Emesis

Differential Diagnosis

Metabolic Acidosis

- Asphyxia
- Congenital heart disease
- Sepsis
- Inborn errors of metabolism
- Hypovolemia
- Seizures
- Bradycardia
- Hypotension

Transport Management

Metabolic Acidosis

- Manage the ABCs.
- Provide adequate oxygenation, ventilation, and hydration.
- Treat the underlying cause.

Shock

Shock is a serious condition where perfusion is inadequate to meet tissue demands. All organ systems can be affected by shock. Both lung ventilation and tissue perfusion are needed to maintain oxygen delivery to the tissues. Hypovolemia is a common cause of shock in a neonate. Causes include hypovolemia from acute blood loss or fluid losses from decreased intake, polyuric renal failure, or diarrhea. Cardiogenic shock can follow congenital heart disease, arrhythmias, myocardial ischemia from asphyxia, cardiac tamponade, pneumothorax, or high intrathoracic pressure from PPV with secondary decreased venous return. Distributive shock includes sepsis, cardiac depression, and vasodilation.

Mean blood pressure is often used in a neonate, especially in the preterm population, where the lowest acceptable mean blood pressure is equal to the gestation age of the neonate (for example, a mean arterial pressure of 28 mm Hg in a neonate at 28 weeks' gestation and a mean arterial pressure of 38 mm Hg in a neonate at 38 weeks' gestation).

Shock presents with some, if not all, of the following: hypotension, tachycardia (or bradycardia in cases of asphyxia), poor perfusion, tachypnea, oliguria/anuria, hypothermia, acidemia, and weak pulses. Hepatomegaly, cardiomegaly, and peripheral edema are seen in cardiogenic shock. Absence of a heart murmur does not rule out cardiogenic shock. Disseminated intravascular coagulopathy may be a late presentation.

The management of shock includes managing the ABCs, checking blood glucose levels, obtaining vascular access, providing fluid resuscitation, and treating the underlying cause. If it is necessary to provide fluids to support circulation or deliver resuscitation medications intravenously to a neonate, emergent access must be obtained. It is usually difficult to establish peripheral access in an infant who needs volume or resuscitation medications. The umbilical vein can be catheterized using an umbilical vein catheter in a newborn using the following steps:

1. Clean the cord with alcohol or another antiseptic.
2. Place a sterile tie firmly but not too tightly around the base of the cord for control of bleeding. If available, place a sterile drape over the site. While the line needs to be placed quickly in a code situation, maintain sterile technique as much as possible.

3. Prefill a sterile 3.5F to 5F umbilical vein line catheter (a comparable sized sterile feeding tube can be used in an emergency) with normal saline using a 3-mL syringe.
4. Using sterile technique and after a tie is wrapped around the base of the cord to control bleeding, cut the cord with a scalpel below the clamp placed on the cord at birth about 1 to 2 cm from the skin (between the clamp and the cord tie).

Signs and Symptoms

Shock

- Hypotension
- Tachycardia (or bradycardia in cases of asphyxia)
- Poor perfusion
- Tachypnea
- Oliguria/anuria
- Hypothermia
- Academia
- Weak pulses
- Hepatomegaly, cardiomegaly, and peripheral edema in cardiogenic shock
- Disseminated intravascular coagulopathy

Differential Diagnosis

Shock

- Hypovolemia from acute blood loss or fluid loss
- Polyuric renal failure
- Diarrhea
- Congenital heart disease
- Arrhythmias
- Myocardial ischemia from asphyxia
- Cardiac tamponade
- Pneumothorax
- High intrathoracic pressure from PPV with secondary decreased venous return
- Sepsis
- Cardiac depression
- Vasodilation
- Profound anemia

Transport Management

Shock

- Manage the ABCs.

- Check blood glucose levels.
- Treat the underlying cause.

5. The umbilical vein is a large thin-walled vessel usually at the 12 o'clock position, as compared to the two thick-walled umbilical arteries usually found at 4 and 8 o'clock **Figure 22-12**. Insert the catheter 2 to 4 cm (less in preterm infants) until blood can be aspirated. If the catheter is advanced too far, infusing hypertonic solutions directly into the liver may lead to irreversible damage **Figure 22-13**. If the catheter is advanced into the heart, arrhythmias may develop.
6. Once access is established, flush with 0.5-mL normal saline and tape in place.

For an older neonate (after the first week), emergent IV access is needed but if peripheral IV access cannot be obtained, an intraosseous line can be placed similar to an older child. Care must be used to choose a small size line and to avoid traversing the bone.

Anemia

Anemia is defined as a hematocrit value of less than 38% in preterm neonates and less than 42% in term neonates. A neonate with anemia may be asymptomatic or present with any of the following signs or symptoms, depending on the cause: tachycardia, pallor, petechiae/purpura, jaundice, hepatosplenomegaly, respiratory distress, hydrops, heart failure, visible bleeding/hematoma, cyanosis, shock, or acidosis.

Causes of anemia in a neonate can be categorized by increased destruction, decreased production, or loss of red blood cells. Causes of increased destruction include hemolysis from red blood cell defects (hereditary spherocytosis, glucose 6-phosphate dehydrogenase or pyruvate kinase deficiency, or thalassemia) or immune processes (Rh incompatibility, ABO incompatibility, maternal lupus, maternal penicillin use). Disseminated intravascular coagulopathy, hemangiomas, vitamin E deficiency, or arterial stenosis can also lead to hemolysis. Decreased production can be seen in infections such as parvovirus, rubella, or cytomegalovirus; congenital leukemia; Diamond-Blackfan syndrome; or trisomy 21 (Down syndrome). Hemorrhage can occur *in utero*, with fetal-maternal hemorrhage or twin-twin transfusion, in the perinatal or neonatal period with abruptio placentae, placenta previa, velamentous insertion of the cord on the placenta, cord rupture, fetomaternal bleeding, cephalohematoma, subgaleal/intracranial hemorrhage, splenic hemorrhage, intracranial hemorrhage, necrotizing enterocolitis, or traumatic injury.

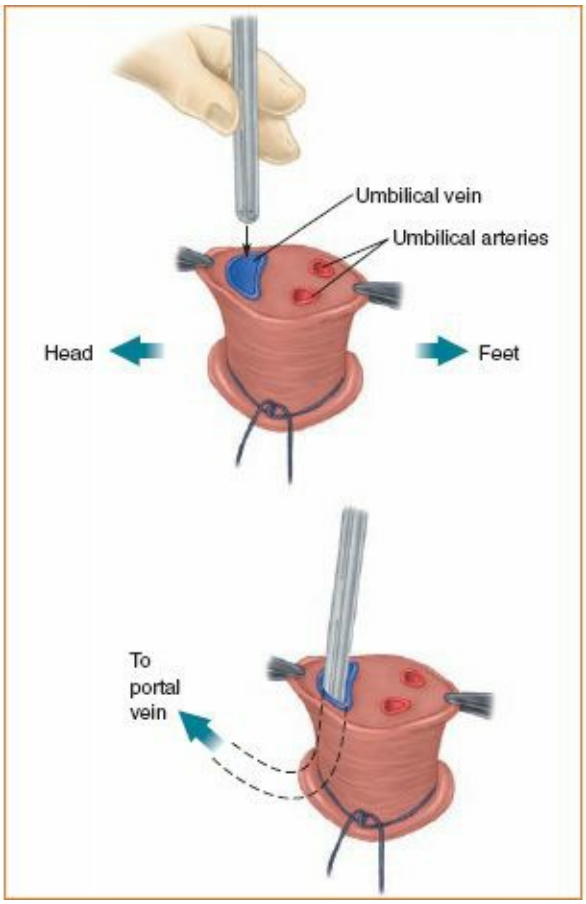

Figure 22-12 Location of the umbilical vein.

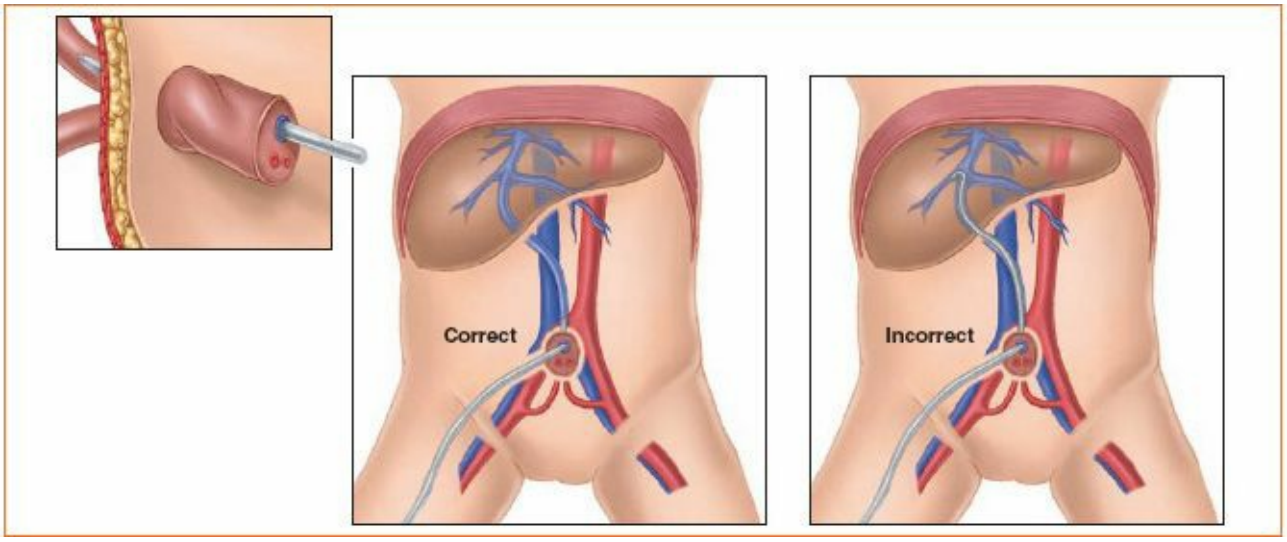

Figure 22-13 Umbilical vein catheterization. Note that if the catheter is advanced too far, infusing hypertonic solutions directly into the liver may lead to irreversible damage.

Rh incompatibility is a serious situation that can have dire consequences. If a pregnant woman's blood type is Rh negative and the fetus's blood type is Rh positive, the woman can be sensitized to the Rh-positive blood, making antibodies against it, when small amounts of fetal blood get into her circulation. Rhogam is routinely given to Rh-negative mothers during and immediately after delivery to minimize this risk, but sensitization still occurs, such as after unrecognized spontaneous early miscarriages. In subsequent pregnancies, if the fetus is Rh positive, maternal antibodies can cross the placental barrier and destroy the Rh-positive fetal red blood cells, leading to severe anemia and ultimately heart failure and hydrops.

Signs and Symptoms

Anemia

- Tachycardia
- Pallor
- Petechiae/purpura
- Jaundice
- Hepatosplenomegaly
- Respiratory distress
- Hydrops
- Heart failure
- Visible bleeding/hematoma
- Cyanosis
- Shock
- Acidosis

Differential Diagnosis

Anemia

- Hereditary spherocytosis
- Glucose-6-phosphate dehydrogenase or pyruvate kinase deficiency
- Thalassemia
- Rh incompatibility
- ABO incompatibility
- Maternal lupus
- Maternal penicillin use
- Disseminated intravascular coagulopathy
- Hemangiomas
- Vitamin E deficiency
- Arterial stenosis
- Parvovirus
- Rubella
- Cytomegalovirus
- Congenital leukemia
- Diamond-Blackfan syndrome
- Trisomy 21
- Hemorrhage *in utero* or in the perinatal or neonatal period

Transport Management

Anemia

- Manage the ABCs.
- Transfuse as ordered/indicated.

Management of anemia includes managing the ABCs and obtaining IV access (optimally two sites). Initially the following lab values should be obtained in consultation with a physician: a blood type and crossmatch, CBC, **peripheral blood smear** (allows the lab to microscopically examine the structure of the blood cells), reticulocyte count, **Coombs' test**, bilirubin level, liver function tests, a **TORCH screen** (a blood test that checks for several infections in a newborn, such as toxoplasmosis, rubella, cytomegalovirus, and herpes simplex), cultures of scrapings from any vesicular lesions, electrolyte levels, and coagulation factors. (TORCH is a set of infections pregnant women are susceptible to that result in fetal deformities.) The neonate may be in shock. Volume resuscitation with a 20-mL/kg bolus of normal saline followed by the administration of blood is crucial. If the anemia is chronic, the infant is at risk of volume overload after transfusion. The supervising physician may need to perform an exchange transfusion to avoid cardiac collapse. If coagulopathy is suspected, use packed red blood cells and fresh-frozen plasma.

Gastrointestinal Conditions

Any part of the gastrointestinal tract may have congenital anomalies. The most common lesions are **atresias** (complete absence of lumen), stenosis (narrowing), duplications of loops of bowel, and functional obstructions.

Presenting features may include increased salivation; choking with feeding; cyanosis; vomiting, especially if bile stained; abdominal distention; blood in stool or failure to stool; lethargy; or irritability. Physical findings may include a distended, discolored (erythematous), tender abdomen; absent bowel sounds; or lethargy and poor perfusion. Important principles include the knowledge that bilious (green or yellow) vomiting is considered an indication of an obstruction until proven otherwise, passage of meconium does not rule out an obstructed bowel, and an obstructed bowel can lead to perforation and peritonitis.

Abdominal Wall Defects

Gastroschisis and **omphalocele** are abdominal wall defects that can be distinguished by their presentation **Table 22-11**. Gastroschisis is a full-thickness defect of the abdominal wall, usually to the right and adjacent to the intact umbilical cord. Variable amounts of edematous intestine, stomach, and fallopian tube extrude from the defect. The liver and spleen are normally situated in the abdomen. The extruded intestine does not have a protective covering. Omphalocele is a herniation of the abdominal contents into the umbilical cord. A protective membrane covers the herniated contents (unless ruptured during the birth process). Gastroschisis is usually an isolated defect, whereas omphalocele has an association with congenital defects, such as a congenital diaphragmatic hernia, and other anomalies.

Ideally, these infants should be delivered at a regional perinatal center that has immediate access to a neonatal intensive care unit and pediatric surgery. However, occasionally these infants deliver at remote locations even when the condition may have been diagnosed prenatally. Under those circumstances, newborn transport should be expedited, and care coordinated between obstetricians, pediatricians, and surgeons. Immediate care includes initial resuscitation, then placing the infant in a clear sterile bag to cover and protect the exposed abdominal contents to limit fluid and protein loss and prevent hypothermia. Handling of the bowel should be minimized to decrease vascular compromise. In a large defect, the infant may be placed right side down to minimize stretching of the mesenteric vessels. The intestines should be

visualized throughout the transport, and if they begin to look dusky, they should be repositioned to optimize blood flow. A nasogastric or orogastric tube should be maintained at low intermittent suction. A wide-bore double-lumen **repogle** tube, if available, is ideal **Figure 22-14**. A repogle tube is a double-lumen tube used for gastric decompression in infants with gastrointestinal issues; for an infant, usually an 8F is used and is connected to low intermittent wall suction to collect gastric secretions. Vascular access should be maintained. Generous IV fluids of $D_{10}W$ are initiated at approximately 120 to 150 mL/kg/d because of increased fluid loss and third space deficits. Provide necessary hemodynamic support with fluids and pressors, if necessary. Broad-spectrum antibiotics should be used before initiating the transport given the increased risk of infection in these infants.

TABLE 22-11 Comparison of Gastroschisis and Omphalocele

	Gastroschisis	Omphalocele
Definition	Centrally located, full-thickness abdominal wall defect	Herniation of abdominal contents into base of cord
Features	2- to 4-cm defect Right side of cord Intact umbilical cord Uncovered intestine, thick, edematous, matted Liver, spleen in normal position	Different sizes Protective membrane covers abdominal contents Elements of umbilical cord course over the sac and come together at the top to form a normal umbilical cord. Large omphalocele may contain the liver and/or spleen.
Associated abnormalities	Isolated defect	25% to 40% of infants have associated chromosomal, cardiac, neurologic, genitourinary, skeletal, or other gastrointestinal defects.

An intact omphalocele is a less urgent surgical problem than a gastroschisis or ruptured omphalocele because the intact membrane conserves heat and protects the intestine. The sac should be carefully protected. Surgical consultation should be obtained as soon as possible, initially by telephone, so that a surgical plan can be developed. Provide urgent transport to an appropriate pediatric surgical facility.

Gastrointestinal Obstruction and Vomiting

The causes of vomiting can be differentiated by the presence or absence of bile, which turns the vomitus green. Presence of bile must be treated as a surgical emergency until obstruction, especially **malrotation**, has been ruled out. Bile-stained vomiting may occasionally be seen without intestinal obstruction, such as with a septic ileus. In these situations, it is often present without abdominal distention and does not continue to recur.

The differential diagnosis of bilious vomiting includes malrotation with volvulus, intestinal atresia, or annular pancreas. The differential diagnosis of nonbilious vomiting includes esophageal atresia, gastroesophageal reflux, overfeeding (excessive volume of feed), milk or formula intolerance, sepsis, or obstructive lesions above the ampulla of Vater such as pyloric stenosis or partial intestinal obstruction.

Congenital gastrointestinal obstruction should be considered when polyhydramnios (extra amniotic fluid) is present. **Esophageal atresia** is suspected when the infant presents with increased salivation and

chokes on feeding. Vomitus with esophageal atresia is never bile stained, and the infant often develops respiratory distress from aspiration. Examine the infant for other abnormalities such as anal atresia (an abnormal or absent anal opening). The diagnosis is further substantiated by inability to pass a nasogastric tube to the stomach because the tube coils in the esophageal pouch. Stomach contents may be obtained when suctioning the ET tube of an intubated baby with esophageal atresia with a tracheoesophageal fistula. When trying to document an esophageal atresia, use as large a tube that will pass through the nares. Atresia can be confirmed by obtaining a chest radiograph that includes the neck and upper abdomen if available. Note the presence or absence of air in the stomach (no air in the stomach suggests that there is an esophageal atresia without a communication between the trachea and the lower esophagus, whereas the presence of air in the stomach suggests the presence of such a connection). Note the presence of other vertebral and/or rib anomalies suggesting Vater syndrome. Diagnosis requires a high index of suspicion. During transport, position the neonate with the head elevated at a 30° angle, place a suction catheter in the upper pouch, and provide intermittent suction. Neonates often do not need to be intubated if the airway is kept clear of secretions, which necessitates frequent oral suctioning.

Figure 22-14 A repogle tube.

Signs and Symptoms

Esophageal Atresia

- Increased salivation
- Choking on feeding
- Nonbilious vomit
- Respiratory distress
- Inability to pass a nasogastric tube to the stomach

Transport Management

Esophageal Atresia

- Position the infant with the head elevated at a 30° angle.
- Place a suction catheter in the upper pouch and provide intermittent suction.
- Keep the airway clear of secretions.

Proximal intestinal obstruction is an obstruction at or above the level of the jejunum. Duodenal

obstruction may be complete (duodenal atresia) or partial (annular pancreas, duodenal atresia, malrotation, and midgut volvulus). The clinical presentation may include bilious vomiting, minimal dilation of the abdomen, or evidence of intestinal ischemia (bloody mucoid stools). There is an increased incidence of duodenal atresia in trisomy 21, where a prenatal ultrasound or abdominal radiograph shows the classic "double-bubble," in which two large collections of gas are present, one in the stomach and the other in the dilated part of the duodenum **Figure 22-15**. The rest of the abdomen is generally gasless in complete obstruction. The exact cause of obstruction may not be evident until laparotomy. Malrotation should be considered, as midgut **volvulus** (twisting of the entire midgut on the superior mesenteric artery pedicle) constitutes a surgical emergency. The ensuing ischemia may result in a nonviable bowel and death, resulting in the phrase known to most pediatricians, "Never let the sun set on bilious emesis." Management includes establishing IV access, fluid resuscitation, broad-spectrum antibiotics, and urgent laparotomy. When volvulus is suspected, surgery should be consulted by telephone before leaving the referring institution to expedite a surgical plan.

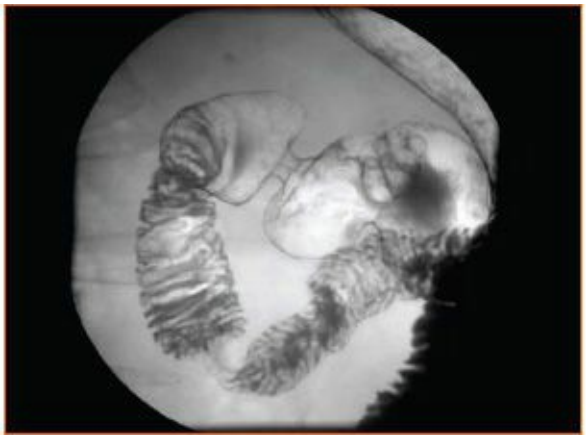

Figure 22-15 An abdominal radiograph showing a collection of gas in the stomach and in the duodenum.

Signs and Symptoms

Proximal Intestinal Obstruction

- Bilious vomiting
- Minimal dilatation of the abdomen
- Evidence of intestinal ischemia (bloody mucoid stools)

Differential Diagnosis

Proximal Intestinal Obstruction

- Duodenal atresia
- Annular pancreas
- Malrotation
- Midgut volvulus

Transport Management

Proximal Intestinal Obstruction

- Maintain thermoregulation.
- Closely monitor vital signs, including oxygen saturation, heart rate, respiratory rate, and blood pressure.
- Ensure strict intake/output.

Distal intestinal obstruction refers to partial or complete obstruction of the distal small bowel (ileum) or large intestine. The differential diagnosis includes ileal atresia, meconium ileus (obstruction of the terminal ileum by inspissated meconium), meconium plug or hypoplastic left colon, colonic atresia, or Hirschsprung's disease (congenital aganglionic colon). The clinical presentation often includes a distended abdomen, failure to pass meconium in the first 24 to 48 hours, and bilious or nonbilious vomiting. An abdominal radiograph often shows multiple dilated loops of bowel **Figure 22-16**. Management considerations include ensuring IV access, hydration, and placement of a nasogastric tube or repogle if available to suction air and avoid further abdominal dilation during transport. Transfer the infant to a pediatric surgical center for specific diagnosis and management.

Figure 22-16 An abdominal radiograph after a barium enema showing multiple dilated loops of bowel.

Signs and Symptoms

Distal Intestinal Obstruction

- Distended abdomen
- Failure to pass meconium in the first 24 to 48 hours
- Bilious or nonbilious vomiting

Differential Diagnosis

Distal Intestinal Obstruction

- Ileal atresia
- Meconium ileus
- Meconium plug or hypoplastic left colon
- Colonic atresia

- Hirschsprung's disease

Transport Management

Distal Intestinal Obstruction

- Maintain thermoregulation.
- Closely monitor vital signs, including oxygen saturation, heart rate, respiratory rate, and blood pressure.
- Ensure strict intake/output.

Imperforate anus is a congenital condition where the anal opening is either absent or displaced. Diagnosis is made by inspection of the anal opening and should be made in the delivery room. If the condition is diagnosed shortly after birth, the infant is usually asymptomatic, but a delay in diagnosis can lead to progressive abdominal distention and perforation. On diagnosis, maintain NPO status, establish IV access, administer maintenance IV fluids, and place a nasogastric tube or repogle and provide low intermittent suction to minimize abdominal distention; transfer to a surgical center for evaluation and management should be arranged. These infants have a higher rate of CHD and other anomalies that may further complicate the transport.

In each of these transports, thermoregulation of the neonate should be maintained and close monitoring of vital signs including oxygen saturation, heart rate, respiratory rate, blood pressure, and strict intake/output should occur.

Hirschsprung's disease is a congenital anomaly in which a portion of the intestine lacks ganglion nerve cells. As a result, normal peristalsis does not occur, and stool backs up. If undiagnosed, this can lead to toxic megacolon. Signs include decreased stooling, abdominal distention, and in later stages, shock. Fluid resuscitation and transport to a referral center with pediatric surgery capability can be life saving.

Signs and Symptoms

Hirschsprung's Disease

- Decreased stooling
- Abdominal distention
- Shock

Transport Management

Hirschsprung's Disease

- Fluid resuscitation
- Transport to a referral center with pediatric surgery capability.

Acute Intestinal Perforation

Perforation of the bowel can be caused by an obstructed bowel; necrotizing enterocolitis (NEC)—a disorder seen predominantly in premature infants; iatrogenic perforation (may be caused by suprapubic bladder aspiration or paracentesis); or it may occur spontaneously. It is sometimes seen in preterm infants in association with indomethacin use, especially when combined with hydrocortisone or dexamethasone treatment.

Signs and Symptoms

Acute Intestinal Perforation

- Progressive abdominal distention
- Respiratory distress
- Hypotension
- Acidosis (mixed metabolic and respiratory)
- Feeding intolerance
- Grossly bloody stools

Differential Diagnosis

Acute Intestinal Perforation

- Obstructed bowel
- NEC
- Iatrogenic perforation

Transport Management

Acute Intestinal Perforation

- Maintain NPO status.
- Monitor for development of apnea.
- Intubate the infant if recurrent apnea develops during transport.

The clinical presentation includes progressive abdominal distention, respiratory distress, hypotension, and acidosis (mixed metabolic and respiratory). NEC presents with abdominal distention, feeding intolerance, and grossly bloody stools. The infant often appears septic. The diagnosis is confirmed by an abdominal radiograph of pneumatosis intestinalis (air in the bowel wall), and may be suspected when an abnormal gas pattern, ileus, and a fixed sentinel loop are seen on radiographs. Other features include intra-hepatic portal venous gas. The physical examination and laboratory tests are helpful in making the diagnosis of intestinal perforation. Radiographic studies will show free air in the abdomen that can be confirmed by a cross-table lateral or left lateral decubitus view (right side up). For transport, maintain NPO status. A nasogastric or repogle tube should be placed and low intermittent suction provided to assist decompression of the bowel. These infants are at high risk of shock and severe metabolic acidosis secondary to inflammation and vascular leak. Establish vascular access and provide

10-mL/kg normal saline boluses as needed to support perfusion and blood pressure, in addition to maintenance fluids. Blood cultures and CBC should be drawn and broad-spectrum antibiotics initiated prior to leaving the referring facility. These neonates often develop apnea. A low threshold for intubation before beginning the transport should be maintained. If the infant develops recurrent apnea en route, intubate the infant quickly to avoid further abdominal distention from bag-mask ventilation. Provide transport to an appropriate pediatric surgical facility for further evaluation and surgical intervention. If intestinal perforation is confirmed, notify surgery before leaving the referring institution so a surgical plan can be expedited.

Hematemesis and Bleeding from the Rectum

Bleeding from the upper gastrointestinal tract may be seen in a nasogastric tube aspirate or be associated with vomiting. Blood is generally bright red, though brownish blood may be seen if the bleeding is slow or starts high in the intestines. The differential diagnosis includes idiopathic (no clear cause, generally resolves within a few days), swallowed maternal blood (accounts for about 10% of cases; the infant may swallow blood during a cesarean section, occasionally during a vaginal delivery), nasogastric trauma from a nasogastric tube, a stress ulcer (often seen in sick neonates), coagulopathy (hemorrhagic disease of the newborn [vitamin K deficiency] or disseminated intravascular coagulation), bleeding Meckel's diverticulum, necrotizing entrocolitis, intestinal fissure, formula intolerance (usually cow's milk protein allergy), maternal bleeding nipples in breast-fed infants, or volvulus. Volvulus is the abnormal twisting of the intestine. Volvulus can lead to gangrene and death of the segment of intestine, intestinal obstruction, perforation peritonitis, and death of the patient. Midgut volvulus occurs in infants with malrotation of the bowel during fetal development. Segmental volvulus occurs at any age and can be caused by abnormal intestinal contents (meconium ileus); sigmoid volvulus is usually the result of a dilated rectosigmoid on a narrow pedicle. Volvulus often has a sudden onset. The symptoms and signs may include abdominal pain, nausea, vomiting, and blood in the stool. Intestinal volvulus is a surgical emergency (release of the abnormal twisting and ensuring normal blood supply). If suspected, keep the patient at NPO status, establish IV access, begin maintenance fluids, decompress the intestines with a nasogastric tube or repogle, provide low intermittent suction, and expedite transfer to a center with pediatric surgical services.

Signs and Symptoms

Volvulus

- Abdominal pain
- Nausea
- Vomiting
- Blood in the stool

Differential Diagnosis

Volvulus

- Malrotation of the bowel during fetal development
- Abnormal intestinal contents (meconium ileus)
- Dilated rectosigmoid on a narrow pedicle

Transport Management

Volvulus

- Maintain NPO status.
- Provide maintenance fluids.
- Decompress the intestines with a nasogastric tube or repogle.
- Provide low intermittent suction.

Intussusception

Intussusception is the telescoping of one segment of intestine into another adjacent distal segment of the intestine. Intussusception is the most common cause of intestinal obstruction in children between 3 months and 6 years of age. It is extremely rare in children younger than 3 months of age or in older children and adults, and can present with passage of bloody stool, often described as currant jelly stool due to its resemblance to that food. When suspected, keep the patient at NPO status, establish IV access, begin maintenance fluids, decompress the intestines with a nasogastric tube or repogle, provide low intermittent suction, and expedite transfer to a center with pediatric radiology and surgical services, because the intussusception may be reduced by enema, but frequently needs open reduction.

Signs and Symptoms

Intussusception

- Bloody stools, often described as currant jelly stool

Transport Management

Intussusception

- Maintain NPO status.
- Provide maintenance fluids.
- Decompress the intestines with a nasogastric tube or repogle.
- Provide low intermittent suction.

Diarrhea

Diarrhea in a neonate is unusual because the infant still has maternal immunoglobulins that help aid in minimizing the risk of contracting diarrheal illness in the first few weeks of life. When transferring a neonate with diarrhea, the infant should be maintained at NPO status, IV access established, and fluid resuscitation provided as clinically indicated. Maintenance fluids should be continued en route to minimize further dehydration and hypoglycemia. Vital signs should be monitored throughout, and attention paid to maintaining normothermia.

Transport Management

Diarrhea

- Maintain NPO status.
- Provide maintenance fluids.
- Monitor vital signs.
- Maintain normothermia.

Infectious Diseases/Sepsis

Neonates are particularly prone to becoming compromised by serious infectious disease because their immune system is not fully developed. Signs of infection in a neonate include decreased activity (lethargy), hypothermia, hypoglycemia, poor perfusion, low blood pressure, and apnea. Neonates are at higher risk of infection with group B *Streptococcus* and gram-negative bacteria, which frequently respond to ampicillin and gentamicin. Primary assessment includes a blood culture, urine culture, and lumbar puncture followed by broad-spectrum antibiotics. A chest radiograph is taken if respiratory symptoms are present. Viral illness can also lead to dire illness in a neonate. Regardless of the causative organism, it is important to support the infant's cardiorespiratory state and aggressively fluid resuscitate if signs of shock are present. Monitor vital signs and maintain normothermia while transferring to a center that can manage a critically ill neonate because the infant's condition can rapidly deteriorate.

Signs and Symptoms

Infectious Diseases/Sepsis

- Decreased activity (lethargy)
- Hypothermia
- Poor perfusion
- Low blood pressure
- Apnea

Transport Management

Infectious Diseases/Sepsis

- Monitor vital signs.
- Maintain normothermia.

Hyperthermia/Hypothermia

Hyperthermia (temperature > 99.5°F [37.5°C]) in a neonate is usually caused by overbundling or exposure to excessive heat. It can also be seen with herpes simplex infection. Hypothermia in the neonate, a drop in body temperature to less than 97.5°F (36.4°C), occurs in all climates, but is more common during the winter months. It can also be an early sign of sepsis.

Neonates have increased surface area-to-volume ratio, making them extremely sensitive to environmental conditions, especially when wet after delivery. An increase in metabolic function in an attempt to overcome the heat loss can cause hypoglycemia, metabolic acidosis, pulmonary hypertension, and hypoxemia. Infection should be considered as an etiology in any hypothermic neonate.

Hypothermic neonates are cool to the touch, initially in the extremities; as their temperature drops, however, the skin becomes cool all over. The infant may also be pale and have acrocyanosis. The hypothermic neonate may present with apnea, bradycardia, cyanosis, irritability, and a weak cry. As a neonate's temperature drops, he or she may become lethargic and obtunded. In severely hypothermic babies, the face and extremities may appear bright red. Sclerema—hardening of the skin associated with reddening and edema—may be seen on the back, limbs, or all over the body. Thermal shock, disseminated intravascular coagulopathy, and death may occur in more serious cases.

Preventive measures include warming your hands before touching the baby, using prewarmed blankets and equipment, and placing a cap on the neonate's head since the head is the largest source of heat loss. The critically ill neonate, once stabilized, should be placed in a prewarmed incubator or, if none is available, covered with warm blankets for transport. Recent studies in neonates with hypoxic-ischemic injury indicate improved outcomes when the infant is provided mild therapeutic hypothermia within 6 hours of birth. This approach is not recommended in the field, although it is prudent to prevent hyperthermia. Maintain the infant at the lower margin of normal temperature (axillary temperature no higher than 97.5°F [36.4°C]).

Signs and Symptoms

Hypothermia

- Temperature below 97.5°F (36.4°C)
- Skin that is cool to the touch
- Apnea
- Bradycardia
- Cyanosis
- Irritability
- Weak cry
- Lethargy
- Sclerema
- Thermal shock
- Disseminated intravascular coagulopathy

Transport Management

Hypothermia

- Maintain the infant at the lower margin of normal temperature (axillary temperature no higher than 97.5°F [36.4°C]).

Toxic Exposure

Most toxic exposures in neonates are from transplacental exposure (eg, maternal alcohol or narcotic use), or purposeful administration by another individual such as a well-meaning younger child. The most important principle of managing toxic exposure/ingestion is stabilization of the neonate. Manage the patient's ABCs. Obtain IV access as indicated based on history and physical exam. Be sure to obtain the history from the sending facility. In the case of respiratory suppression from narcotics, which is much more likely to be from chronic maternal exposure, respiratory support should be provided until the infant is transferred to a tertiary hospital. If respiratory depression is suspected to be from acute narcotic exposure, such as when an infant delivers shortly after a dose of maternal narcotic for labor pain control, naloxone, 0.1 mg/kg may be administered to reverse the narcotic effect. While the IV route is preferred, IM administration may be used. If there is a chronic maternal (and therefore newborn) exposure to narcotics, administering naloxone may precipitate seizures in the infant, potentially causing death, and therefore is not recommended.

For additional exposures, including topical exposures, contact your local poison control center where experts will be able to guide you regarding a response to a myriad of exposures.

Signs and Symptoms

Toxic Exposure

- Stabilize the infant.
- Manage the ABCs.

Trauma/Birth Injuries

Injuries to the infant that result from mechanical forces (ie, compression, traction) during the birth process are categorized as birth trauma. Significant birth injury accounts for fewer than 2% of neonatal deaths and stillbirths in the United States. It still occurs occasionally and unavoidably, with an average of 6 to 8 injuries per 1,000 live births. Hypoxic injury may coexist with mechanical injury. Most birth traumas are self-limiting and have a favorable outcome.

Causes/risk factors for birth injuries include macrosomia, prolonged labor, precipitous delivery, breech presentation, instrumentation (forceps/vacuum-assisted delivery), extreme prematurity, and oligohydramnios.

Head and Neck Injuries

Most birth injuries self-resolve with time and are not fatal. Birth injuries to the head and neck include the benign head and neck injuries: **vacuum caput**, which is accumulation of fluid at the site of the vacuum extractor that usually resolves within hours, and **caput succedaneum**, a subcutaneous collection of fluid with poorly defined margins in the scalp, resulting from pressure on the infant's head during delivery, that usually resolves within a few days. Serious head and neck injuries include a subgaleal hematoma, which can spread slowly and result in shock. A subgaleal bleed can present as an ill-defined mass in the dependant part of the head (usually the occipital region). It does not follow suture lines. Significant blood loss may occur and the infant may present with shock and acute renal failure if the condition is not promptly identified and treated. **Cephalohematoma** is a subperiosteal collection of blood and may be accompanied by a linear skull fracture. It is most commonly seen in the parietal region and is limited by suture lines. It resolves within a few months with resulting calcification. A skull fracture may present with a slight depression in the skull; however, this may not be obvious secondary to an overlying hematoma.

In addition to the skull findings, these injuries may present with anemia and jaundice. If the hemorrhage progresses, it may cause hypotension and shock. The hematoma may also become infected. Management of head and neck injuries is based on presentation. Blood transfusion may be needed for hemorrhage and anemia. Phototherapy (light therapy to reduce bilirubin) is needed for jaundice based on the bilirubin level. If the neonate is in hypovolemic shock from excessive blood loss, manage the ABCs and treat for shock, focusing on volume resuscitation.

Signs and Symptoms

Head and Neck Injuries

- Skull fracture
- Anemia
- Jaundice
- Hypotension
- Shock
- Acute renal failure

Transport Management

Head and Neck Injuries

- Manage the ABCs.
- Treat for shock, focusing on volume resuscitation.

Nerve Injuries

Nerve injuries often occur because of hyperextension or overstretching during delivery, especially with breech presentation. The nerve injuries incurred during the birth process can range from peripheral nerve branch injury to major spinal cord injury. Most nerve injuries do not require any immediate intervention or admission to a neonatal intensive care unit (NICU). Nerve injuries that need immediate attention and possible transfer to a facility that can provide a higher level of care include recurrent laryngeal nerve injury, which causes paralysis of the vocal cords, unilaterally or bilaterally. This injury presents with respiratory distress, stridor, or desaturations. It may be associated with intracranial bleeding. Visualize the vocal cords by direct laryngoscopy. Intubate in the event of bilateral vocal cord paralysis. Do not feed the neonate to avoid the risk of aspiration during transport. Vaginal breech delivery is the greatest risk factor for spinal cord injury. It frequently presents with a loud "snap" sound at the delivery. It may be associated with epidural hemorrhage, loss of motor function distal to the injury, temperature instability, and loss of bladder and bowel function. Immobilize the head and restrain the neonate. If the nerve injury impairs spontaneous respiration, intubate and provide PPV until the infant can be transferred to an appropriate health care facility.

Signs and Symptoms

Nerve Injuries

- Respiratory distress
- Stridor
- Desaturations
- Paralysis of vocal cords, unilaterally or bilaterally

Spinal Cord Injury

- Epidural hemorrhage
- Loss of motor function distal to the injury
- Temperature instability
- Loss of bladder and bowel function

Transport Management

Nerve Injuries

- Maintain NPO status.
- Provide PPV if spontaneous respiration is impaired.

Bone and Other Injuries

The clavicle is the most common fracture seen in a newborn, and may be accompanied by a pneumothorax. Risk factors include a large infant, shoulder dystocia, and instrumentation during delivery (especially forceps). A fractured clavicle itself does not need any urgent intervention as it heals with limited motion of the arm within 7 to 10 days. However, a rare complication of a fractured clavicle is a pneumothorax. If the neonate presents with tachypnea or increased work of breathing, consider a pneumothorax. See the section on pneumothorax for management.

Transport Management

Bone and Other Injuries

- Monitor for pneumothorax; treat if present.
- Treat for shock.

Fractures of the humerus or femur are uncommon. Manage these by splinting the arm or leg and transferring to a pediatric orthopaedic center.

Intra-abdominal injuries are rare but often present as shock and bluish discoloration of the abdominal wall. Treat the patient for shock, ensure that a hematocrit, type and cross, and if possible, an abdominal ultrasound have been performed at the referring facility before transferring to a hospital with pediatric surgical support.

Finally, soft-tissue injuries include abrasions, lacerations, and ecchymosis; these injuries mostly need routine care.

Abuse/Maltreatment

Shaken baby syndrome is the most common cause of death in cases of child abuse. Shaking of a baby may cause tearing of bridging veins in the brain, a subdural hematoma, or hypoxic injury. Most often, there are no significant findings on physical exam to indicate this condition. It should be suspected in a previously well infant who presents with nonspecific signs such as feeding intolerance, irritability, and vomiting. Severe cases may even present with seizures or apnea secondary to intracranial hemorrhage. Other maltreatment includes blunt trauma to the abdomen, burns, bruising, and skeletal injuries. The management for these is again based on presentation as follows. Obvious extremity fractures should be stabilized, with attention given to maintaining circulation to the affected extremity. Fluid resuscitation may be needed if hemorrhaging has occurred. Respiratory support may be needed if intracranial hemorrhage or trauma to the upper airway has occurred. With severe burns, the affected areas should be protected with sterile material and IV fluids initiated due to increased insensible water loss through the burned skin. The CCTP's goal is to stabilize the neonate and transport safely to a health care facility where further workup and treatment may be done.

Signs and Symptoms

Shaken Baby Syndrome

- Feeding intolerance
- Irritability
- Vomiting
- Seizures
- Apnea secondary to intracranial hemorrhage

Transport Management

Shaken Baby Syndrome and Other Maltreatment

- Stabilize the neonate.

Neurologic Conditions

Seizures

Seizures represent the most distinctive sign of neurologic disease in the neonatal period. Seizures may be identified by direct observation. A seizure is defined as a paroxysmal alteration in neurologic function, ie, behavioral and/or autonomic function. Apnea is also a common manifestation of seizures in a neonate. It is important to distinguish other motor phenomenon (eg, jitteriness, myoclonic activity) that could be confused with seizures. Seizures represent a relative medical emergency because they are usually a sign of a serious underlying abnormality. It is critical to recognize neonatal seizures and to determine their cause because they may interfere with cardiopulmonary function, feeding, affect metabolic function, and if prolonged, may cause brain injury.

Jitteriness is often confused with a seizure **Table 22-12**. Jitteriness is characteristically a disorder of the newborn and is rarely seen at a later age. Jitteriness is most commonly seen with hypoxic-ischemic encephalopathy, hypocalcemia, hypoglycemia, and drug withdrawal. It is important to recognize that newborns exhibit normal motor activity that could be mistaken for seizures. These myoclonic,

dysconjugate eye movements, or sucking movements are often seen when the infant is drowsy or asleep.

Simple classification of seizure types suggests that four essential types can be recognized: subtle, tonic, clonic, and myoclonic. Subtle seizures are characterized by apnea, eye deviation, blinking, sucking, and pedaling movements of the legs. Tonic seizures are characterized by tonic extension of the limbs. Less commonly, with this type of seizure, flexion of the arms and extension of the legs may also occur. Tonic seizures are more common in premature infants, especially in those with intraventricular hemorrhage. Seizures characterized by clonic localized jerking are classified as focal clonic seizures; these types of seizures can occur in both term and premature infants. Lastly, myoclonic seizures are characterized by flexion jerks of the upper or lower extremities, singly or in a series of repetitive jerks.

Causes of neonatal seizures include hypoxic ischemic encephalopathy, intracranial hemorrhage, intracranial infections (meningitis), development defects, hypoglycemia, hypocalcemia, and other metabolic disturbances, frequently the result of inborn errors of metabolism. You may observe a quiet, often hypotonic infant. The infant may be lethargic and/or apneic. Hypoglycemia must be recognized quickly and treated promptly, within a few minutes, to minimize the risk of brain damage. $D_{10}W$ may be given as an IV bolus (2 mL/kg) if the blood glucose level is less than 40 mg/dL. A blood glucose measurement and administration of dextrose if hypoglycemia is present may be lifesaving. The blood glucose level should be rechecked every 30 minutes after treatment for hypoglycemia, until the blood glucose level is documented to be stable. An IV bolus of dextrose should be followed by an infusion of $D_{10}W$ to maintain normoglycemia during transport. The neonate's vital signs and oxygen saturation should be monitored throughout transport. Apnea, a common symptom of neonatal seizures, may require intubation and ventilatory support during transport. Phenobarbital (Luminal) and phenytoin (Dilantin) are the two commonly used anticonvulsants in neonates. Both drugs may interfere with respiratory and cardiac function and should only be used in consultation with the supervising physician. Because seizures may be a sign of meningitis, the referring facility should have performed a septic workup and begun antibiotics before the transfer.

TABLE 22-12 Jitteriness vs Seizures

Characteristics	Jitteriness	Seizures
Ocular phenomenon (deviation or fixation of the eyes)	Not seen	Commonly associated
Stimulus sensitive (may be triggered by a stimulus)	Yes	No
Dominant movement	Tremor	Clonic jerking
Application of gentle pressure to limb	Stops jitteriness	Does not stop seizures
Autonomic phenomenon	Not associated	Common association

Signs and Symptoms

Seizures

- Apnea
- Eye deviation
- Blinking
- Sucking

- Pedaling movements of the legs
- Tonic extension of the limbs
- Flexion of the arms and extension of the legs
- Clonic localized jerking
- Flexion jerks of the upper or lower extremities

Differential Diagnosis

Seizures

- Jitteriness
- Hypoxic ischemic encephalopathy
- Intracranial hemorrhage
- Intracranial infections (meningitis)
- Development defects
- Hypoglycemia
- Hypocalcemia
- Inborn errors of metabolism

Transport Management

Seizures

- Monitor vital signs and oxygen saturations.
- Intubate and provide ventilatory support if necessary to treat apnea.

Hypoxic Ischemic Encephalopathy

Hypoxic ischemic encephalopathy (HIE) is the neuronal injury caused by oxygen deprivation (hypoxia) or decreased perfusion (ischemia) to the brain. Redistribution of blood occurs during prolonged asphyxia, with more of the cardiac output being delivered to the vital organs (eg, brain, heart, adrenal glands) at the expense of less vital organs (eg, lungs, gut, kidneys, skin). Multiple organ dysfunction is common after HIE and may influence the eventual outcome for the infant. HIE is the single most common cause of seizures in both term and preterm infants. The time of onset for organ dysfunction from HIE, hypoglycemia, and other metabolic disturbances is from birth to 3 days. As compared to HIE, the time of onset for all the other listed causes of seizures can be from birth to longer than 3 days. Infants with HIE often present with decreased tone, poor perfusion, and in more severe situations, hypotension and recurrent apnea.

Management of neonatal HIE includes maintaining adequate ventilation, perfusion, and blood pressure; maintaining adequate blood glucose levels; carefully monitoring fluid intake and output; and adjusting treatment based on renal output, oxygen saturation, and ventilation status. The infant's temperature should be maintained in the low normal range (97.5°F [36.4°C]) to avoid hyperthermia, which is associated with a worse outcome in HIE. If a newborn with HIE arrives at the tertiary care center within 6 hours of birth, more aggressive therapeutic hypothermia may be offered as a treatment modality under controlled conditions. It is therefore critical to expedite transport of these infants to a

center that can provide appropriate therapy.

Transport Management

Hypoxic Ischemic Encephalopathy (HIE)

- Maintain adequate ventilation, perfusion, and blood pressure.
- Maintain adequate blood glucose.
- Monitor fluid intake and output and adjust based on renal output.
- Monitor saturations and maintain oxygen levels in the normal range.
- Maintain the infant's temperature in the low normal range.

Lethargy

In infants, lethargy (a decreased level of consciousness during which you are unable to arouse the infant) can be caused by many conditions, but it almost always implies a serious, frequently life-threatening underlying condition. Some common causes of lethargy include sepsis, severe hypoxia, severe hypoglycemia, intracranial hemorrhage, and hypoxic ischemic encephalopathy.

Management includes attention to the ABCs, obtaining IV access, ensuring normoglycemia, providing oxygen as needed, initiating antibiotics in conjunction with the supervising physician, and expediting transfer to a tertiary center skilled in dealing with critically ill neonates.

Differential Diagnosis

Lethargy

- Sepsis
- Severe hypoxia
- Severe hypoglycemia
- Intracranial hemorrhage
- Hypoxic ischemic encephalopathy

Transport Management

Lethargy

- Monitor the ABCs.
- Ensure normoglycemia.
- Provide oxygen as needed.

Metabolic Conditions

Hypoglycemia

Hypoglycemia, or a blood glucose level of less than 40 mg/dL, is a medical emergency; in severe cases, it can lead to brain damage and even death. Hypoglycemia is more common in infants who are small or

large for gestational age, infants of diabetic mothers, and infants who are stressed. Signs of hypoglycemia include decreased activity, jitteriness, and seizures.

If you suspect hypoglycemia, a heel stick should be performed immediately to determine the blood glucose level. If hypoglycemia is present, IV dextrose (2 mL/kg $D_{10}W$) should be given, followed by an infusion of glucose. First administer 60 mL/kg/d $D_{10}W$ to maintain the neonate's blood glucose level as you contact the regional perinatal center for guidance on the rate and type of IV solution; this can vary based on gestational and chronological age. An inborn error of metabolism is another metabolic condition that is initially treated with a glucose infusion. Fortunately, these are relatively rare, but if a neonate is lethargic and experiences tachypnea (suggesting a metabolic acidosis), an infusion of glucose should be started, even if the neonate is normoglycemic. This infusion will help decrease the buildup of toxic byproducts the body produced when the neonate was unable to metabolize nutrients normally.

Signs and Symptoms

Hypoglycemia

- Decreased activity
- Jitteriness
- Seizures

Transport Management

Hypoglycemia

- Maintain the infant's blood glucose level.

Hypocalcemia

Hypocalcemia is most commonly seen in low birth weight infants and can occur after significant stress, as well as in infants of diabetic mothers. Significant hypocalcemia can lead to cardiac arrhythmias, seizures, and tetany. In general, calcium infusion is not indicated unless hypocalcemia is documented. There are two common timeframes when hypocalcemia occurs in the neonate. The first is at age 2 to 3 days. The second (late-onset hypocalcemia) is unusual in the United States but may be seen in infants who consume cow's milk or synthetic formulas that are high in phosphorus. In an infant with documented hypocalcemia and who is younger than 24 hours, administer an IV infusion of 2 to 3 mEq/kg/d of calcium in $D_{10}W$ during transport. If an infant has documented hypocalcemia, is older than 24 hours, and has normal renal function, administer 10% dextrose in 0.25 normal saline with 10 mEq/kg of potassium chloride in 500 mL during transport.

Signs and Symptoms

Hypocalcemia

- Cardiac arrhythmias
- Seizures

- Tetany

Transport Management

Hypocalcemia

- Administer an IV infusion of 2 to 3 mEq/kg/d of calcium in $D_{10}W$ during transport to an infant with documented hypocalcemia and who is younger than 24 hours.
- Administer 10% dextrose in 0.25 normal saline with 10 mEq/kg of potassium chloride to an infant who has documented hypocalcemia, is older than 24 hours, and has normal renal function.

Inborn Errors of Metabolism

An **inborn error of metabolism** is a class of genetic diseases mostly due to defects of single genes that code for enzymes that facilitate conversion of various substances into others leading to accumulation of substances which are toxic or interfere with normal function. There are many different inborn errors of metabolism, and they are relatively rare, so a complete review would be outside the scope of this chapter. Common presenting features include lethargy, acidosis, poor perfusion, and hypoglycemia. If an inborn error of metabolism is suspected, enteral feeding should be stopped and an IV glucose infusion begun before transfer by the critical care transport team.

Signs and Symptoms

Inborn Errors of Metabolism

- Lethargy
- Acidosis
- Poor perfusion
- Hypoglycemia

Congenital Adrenal Hyperplasia

- Dehydration
- Shock

Transport Management

Inborn Errors of Metabolism

- If suspected, stop enteral feeding and begin an IV glucose infusion before transfer.

Congenital Adrenal Hyperplasia

- Normalize electrolytes and fluid balance.
- Consider initiating hydrocortisone replacement; consult with supervising physician.

Congenital adrenal hyperplasia results from a defect in the synthesis of cortisol. An infant may have virilizing features and problems with salt loss, depending on which enzyme is deficient. If the infant experiences salt loss, he or she can present with dehydration and shock. Acute treatment includes normalizing electrolytes and fluid balance, and initiating hydrocortisone replacement after consultation with the supervising physician.

The Transfer Process for a Neonate

In the well-organized regional referral system, transport of a high-risk neonate proceeds through the following steps:

1. A physician at the referring hospital initiates a request for transport. A physician in the regional control center decides which facility can accommodate the patient and gives the referring physician advice on management of the neonate until the transport team arrives.
2. A mode of transportation is chosen—ground transportation, helicopter, or fixed-wing aircraft, depending on the patient's status, distance, availability of services, and weather conditions.
3. The transport team is mobilized, including communication with the CCTP regarding any relevant information known about the neonate to be transferred, and equipment is assembled. Optimally the team consists of a health care provider with special training in caring for critically ill neonates, a respiratory therapist with similar special training, and a paramedic who has spent a period of apprenticeship or received additional training in transporting an ill neonate. For particularly critical patients, a physician may also accompany the team. The equipment used by the CCTP is highly specialized, requiring appropriately designed ventilation and oxygenation units and an incubator meeting stringent criteria.
4. On arriving at the referring hospital, the transport team helps with further stabilization of the infant if needed, before embarking on transport. Conditions such as hypoxemia, acidosis, hypoglycemia, pneumothorax, shock, and hypovolemia must be treated before leaving the referring hospital. If the infant is suspected of having an infectious disease, appropriate cultures should be obtained prior to transport and early antibiotic therapy initiated. If a contagious disease is suspected, transport personnel should take adequate safety precautions.
5. While stabilizing the infant, the team collects information and materials, including a copy of the mother's and infant's medical records and any radiographs, labs, and medications for the infant. Often transport teams operate on the basis of implied consent, meaning that transport is considered a part of treatment of the life-threatening emergency. Some areas require signed consent before transport is initiated. Awareness of local and state guidelines is important.

Once the infant's condition is stabilized as much as possible at the referring hospital, transport the patient to the nearest facility that can provide the appropriate level of care. Ideally, someone will contact this facility to discuss the situation and obtain advice regarding care and disposition throughout the process. Complications can arise en route, such as a dislodged breathing tube, or development of a pneumothorax. It is critically important to keep vigilant to recognize changes in the status of the infant, such as desaturation or change in color. Quick intervention will help ensure an optimal outcome.

Using an Incubator

An incubator is a box with clear walls, a heat source, and portal access in which a neonate can be placed to maintain normothermia and minimize noise stress. An incubator is indicated for transport of infants

who weigh less than 10 lb or are younger than 30 days. When preparing to use an incubator, also ensure that the oxygen tank attached to the incubator is full, and that there are blankets and a bulb syringe inside the incubator.

Skill Drill 22-4 shows the steps for using an incubator, which are described below:

1. Plug in the AC power cord **Step 1**.
2. Set the main AC power switch **Step 2**. The charging indicator will be a constant light if internal batteries need charging. The light will flicker or go off when fully charged. Battery life is approximately 2 hours.
3. Depress the "controller" switch **Step 3**. The power failure alarm and AC/DC power mode should light up. The high temperature sensor, heater temperature, and low DC alarm should flash. A short beep will be heard at the end of the test. The set point indicator should light and the centigrade reading should indicate 91.4°F (33°C) ± 0.1 for 15 seconds.
4. Check and adjust the set point temperature to 100.4°F (38°C) **Step 4**. The maximum temperature is 104°F (40°C). It takes approximately 30 minutes to warm up.
5. Do not block or cover the end portions of the incubator.
6. Check the oxygen and air tanks **Step 5**. All tanks should read 2,000 psi.

Family Communication and Support

Throughout the process of transporting an ill neonate, ongoing communication with the family regarding what is being done for the infant and what care is planned will help allay fears. Do not be specific about the infant's chances of survival. Many factors play into morbidity and mortality and you do not want to be misleading. If family members have questions you cannot answer, be straightforward. Tell them that you do not have a definite answer, but you will help put them in touch with the people who do (most likely individuals at the center to which the infant is being transferred). Often, just explaining what you are doing and giving the family a realistic time frame in which they should be able to speak to someone at the receiving institution is very helpful. Families usually appreciate knowing the name of the receiving physician, if this is known at the time of transfer.

Skill Drill 22-4

Using an Incubator

1 Plug in the AC power cord.

2 Set the main AC power switch. The charging indicator will be a constant light if internal batteries need charging. The light will flicker or go off when fully charged.

3 Depress the "controller" switch. Check that the power failure alarm and AC/DC power mode light up; and that the high temperature sensor, heater temperature, and low DC alarm flash. A short beep will be heard at the end of the test. The set point indicator should light and the centigrade reading should indicate 91.4°F (33°C) ± 0.1 for 15 seconds.

4 Check and adjust the set point tempera-I ture to 100.4°F (38°C). Do not block or cover the end portions of the incubator.

5 Check the oxygen and air tanks. All tanks should read 2,000 psi.

Flight Considerations

Air transport, either fixed wing or helicopter, presents a new set of challenges and should be managed appropriately. Some of these are listed here:

- **Airway:** It is critical to establish a secure airway before takeoff, because it is extremely difficult to intubate and assess breath sounds during flight. If this step is necessary while in flight, special attention to signs of adequate ventilation and endotracheal tube position need to be considered, such as condensation on the ET tube, chest rise, and change in color of the $ETCO_2$ indicator.
- **Circulation:** It can also be difficult to hear a heartbeat while in the air, so alternative methods of assessment, such as palpating pulsation on a freshly clamped umbilical cord, or feeling the cardiac movement at the point of maximal intensity, can be helpful.
- **Oxygenation:** There is decreased partial pressure of oxygen at higher altitudes; additional oxygen may be needed to maintain oxygen saturation.
- **Temperature regulation:** Extra care should be taken to avoid hypothermia.

Finally, minimize the neonate's exposure to fuel vapor and noise.

Helicopter transport may be used for medium distance transfers of up to 150 miles. This mode may not be appropriate for transporting the neonate because of limited space and the relative inability to carry the necessary equipment such as an incubator with additional personnel. There is restricted patient access during flight and patient evaluation may be compromised because of noise and vibrations. The cabin is not pressurized, which may lead to further hypoxic and hypothermic stress.

Fixed-wing (airplane) transport is generally reserved for long distances (> 150 miles). As compared to helicopter transport, the space allocated for patient care is generally adequate. Transport will involve ambulance transportation to the airport, subsequent air transport, and further ambulance transportation to the hospital. It is important to not only arrange the helicopter or airplane, but also the ambulance to and from the airports and the respective hospitals.

Summary

Neonates have a unique anatomy, physiology, and pathology, making transfer of such patients challenging but rewarding. The CCTP must be familiar with the special needs of this age group to provide optimal care during transfer to reduce morbidity and improve survival.

Case Study

YOU AND YOUR NEW PARTNER HAVE STOPPED for a slice of pizza after a routine transport. While ordering, you receive a call to respond to a local emergency room for a 3-week-old with a fever. You and your partner understand that young children do not fare well in febrile states. The pizza will have to wait.

On arrival at the emergency room, you are met by the charge nurse and attending physician. They report to you that a 20-day-old African-American female was brought in by the mother, who said that the infant was sleepy, refusing to eat, and felt warm to the touch. Triage noted that the patient was not responding to external stimuli and presented with a weak cry and delayed capillary refill. The patient was delivered at the same hospital and records showed a normal, cephalic delivery with no complications. In addition, the mother had received prenatal care and only had a history of asthma.

Physical exam of the patient reveals diffuse congestion with mild substernal and intercostal

retractions, peripheral cyanosis and mottling, a capillary refill time of 4 seconds, and a rectal temperature of 102°F (38.8°C). The child is nonresponsive to verbal stimulation and grimaces when you perform tactile stimulation. Vital signs show a pulse of 180 beats/min, with atrial tachycardia on the monitor, a blood pressure of 100/40 mm Hg, and an oxygen saturation of 90%. An IV of normal saline 9% has been established in the left antecubital vein with a 24-gauge catheter, and it appears patent. You estimate the infant's weight to be 8 kg. A CBC was drawn with a WBC count of 26,000/mm^3. The serum blood glucose level was 80 mg/dL. All other blood values were normal. No arterial blood gas analysis, chest radiograph, or lumbar puncture has been performed. The attending physician advises you that he has been in contact with the neonatal intensive care unit (NICU) at University Hospital and he has the receiving physician's information.

1. What is your presumptive diagnosis?
2. What are some potential causes of this patient's altered mental status?
3. What are your primary concerns in managing this patient?

You note that the patient is receiving oxygen by a nonrebreathing mask at a flow rate of 8 L/min. You ask your partner to switch to bag-mask ventilation at a rate of 20 breaths/min as you prepare to contact the receiving facility.

Your partner advises you that the bag-mask ventilation is compliant and there is good chest rise. The patient's oxygen saturation has increased to 95% with other vital signs remaining unchanged. You contact University Hospital and speak with the receiving physician. After confirming the bed assignment, you confer your findings. It is agreed that bag-mask ventilation, while effective in the emergency department, may become a challenge to maintain during the 45-minute transport. You receive an order to perform rapid sequence intubation. Your protocol for intubation includes premedication with atropine, fentanyl, and succinylcholine. The patient is intubated. You are unable to obtain cultures, but due to the high suspicion of serious infection, the referring physician instructs you to administer ampicillin and gentamicin at weight-appropriate doses per the *Harriet Lane Handbook*, by RE Rau, JW Custer, and CK Lee, a pediatric reference tool.

After administration of 160 mL of normal saline, you note that the infant's blood pressure is 110/70 mm Hg, the pulse is 170 beats/min, and capillary refill is 2 seconds. During transport, your patient's oxygen saturation increases to 98%, the $_{ETCO2}$ is 43 mm Hg, and her color has improved. However, lung sounds are still diffusely congested. You arrive at the NICU and transfer your patient.

Analysis

Although you are somewhat convinced the infant has sepsis, your concern is about the patient's impending respiratory failure due to acute respiratory distress syndrome. In addition, the $\dot{V}/\dot{Q}$ mismatch is causing acidosis by failing to allow release of carbon dioxide.

In addition to hypoxia, you must also be aware of the other potential causes of neonatal altered mental status, namely hypoglycemia and seizures. Once the airway is secured, CCTPs must assess the infant's blood glucose level.

Overall, the most critical aspect of managing this difficult patient is the ability to secure the airway, control oxygenation, and stabilize hemodynamics.

Two weeks later, you and your partner follow up on this case during a QA meeting. On admission, the patient received a spinal tap, which was negative, but a blood culture revealed *Streptococcus pneumoniae*, a very common bacterium that causes illnesses ranging from ear infections to meningitis. The patient received 7 days of IV ampicillin and gentamicin and successfully fought off the infection,

remaining on a ventilator for 3 days and being discharged after 7 days. Credit was given to the community hospital for prompt recognition that this patient was in need of more specialized care and to the transport unit that made the decision to aggressively manage the patient's airway.

Prep Kit

Ready for Review

- A newborn refers to an infant within the first few months of life; a neonate refers to an infant within the first 28 days of life; term newborns are delivered between 37 and 42 weeks of gestation.
- Because short-term and long-term outcomes in infants have been linked to initial stabilization efforts, CCTPs must be knowledgeable about problems that may occur with neonates and how to treat them, they must have the appropriate equipment available to treat neonates, and they must carefully consider the neonate's transport plan.
- Newborns differ anatomically and physiologically from young children. CCTPs must be aware of those differences.
- Neonates become cold easily due to a variety of factors ranging from a high body surface area to body weight ratio to increased evaporative heat loss through skin. To avoid hypothermia, use prewarmed blankets and equipment, including a prewarmed transport incubator, place a cap on the infant's head, and minimize exposure to cold. While avoiding hypothermia, be careful to also avoid environmentally induced hyperthermia.
- The lungs of neonates are small relative to their body size, with little respiratory reserve. Their heads are large in relation to their bodies, resulting in neck flexion and obstruction in the supine position. Placing a rolled towel under a neonate's shoulders helps open up the airway.
- Neonates are obligate nose breathers and may require an oral airway during transport if they present with obstructive apnea. When positive-pressure ventilation in needed, attempts should be made to maintain physiologic tidal volume breaths.
- Neonates have a high oxygen requirement; they do not tolerate interruptions in oxygen delivery for any length of time, and they become hypoxic and bradycardic quickly.
- The neonate's heart rate is an important determinant of cardiac output. Neonates respond to careful volume loading with an increase in cardiac output, but they do not tolerate fluid overload. Changes in cardiovascular circulation that take place after the umbilical cord is clamped at birth include a sudden rise in the systemic vascular resistance, increased pulmonary blood flow, and physiologic closure of the fetal shunts. With extrauterine breathing and expansion of the lungs, tissue oxygenation increases, pulmonary vascular resistance decreases, and pulmonary blood flow increases.
- Pulmonary vascular resistance may increase in the neonate, causing persistent pulmonary hypertension. During transport, give special attention to maintaining normothermia, optimal oxygenation, fluid status, and systemic blood pressure, and minimize acidosis and noise to reduce the risk of the neonate developing severe persistent pulmonary hypertension.
- Patent ductus arteriosus (PDA) is seen in 50% of extremely premature infants. Minimizing fluid overload during transport can decrease the risk of persistent symptomatic PDA.
- Nephrogenesis is complete at 36 weeks' gestation. The glomerular filtration rate at term is low; creatinine levels at birth reflect the mother's level and falls to reflect the infant's renal function by 1 week of age. Infants tolerate fluid restriction poorly and become dehydrated quickly.

- Total body water represents 85% of body weight in premature infants, 75% of body weight in term infants, and 60% of body weight in adults. Contraction of the extracellular compartment and weight loss in the first few days after birth are normal. Fluids should be restricted until after the postnatal weight loss occurs.
- Liberal fluid regimens in the first few days of life have been associated with worse outcomes in premature infants. $D_{10}W$ is usually used for IV fluid maintenance during the new-born's first 24 hours. After 24 hours and the establishment of adequate urine output, 10% dextrose in 0.25 normal **I** saline is used. Neonates are considered to have pressure-passive cerebral circulation. An acceptable mean arterial pressure generally equates to the gestational age of the newborn. It is important to minimize stress and use appropriate sedation for procedures to minimize blood pressure peaks that can lead to intraventricular hemorrhage.
- Neonates, including premature neonates, show well-developed responses to painful stimuli. Use appropriate analgesic measures to treat neonates for pain.
- Neonates are prone to soft-tissue and bony injuries, such as rib fractures, due to incomplete ossification of bones and fragile tissues. The CCTP should be aware of this when administering CPR.
- The risks for complications in neonates increase as birth weight and gestational age decrease. Additional complications such as maternal infection, diabetes, premature labor, and the presence of meconium also increase risk. The CCTP should be familiar with antepartum and intrapartum risk factors.
- The APGAR score is a numeric expression of an infant's condition after birth. It measures the infant's appearance, pulse, grimace, activity, and respiration. The score is affected by the infant's physical maturity, maternal medication intake or narcotic use, and neuromuscular or cardiorespiratory conditions.
- The first steps in stabilizing a neonate with acute airway obstruction, ineffective respiration, or insufficient cardiovascular circulation are airway management and ventilation. To optimize oxygenation and ventilation, thoroughly suction the neonate's airway. Free-flow supplemental oxygen, ventilations, intubation, chest compressions, or volume expansion may be necessary. The CCTP should communicate information such as relevant history, vital signs, and physical exam to the accepting facility as soon as possible.
- The ABCs of neonatal resuscitation are the same as those applied to adults—airway, breathing, circulation. The most important and effective action in neonatal resuscitation is getting oxygen into the baby's lungs. Maintenance of normal body temperature is also important.
- Familiarity with the length-based, color-coded resuscitation tape allows the CCTP to estimate body weight based on the child's crown-heel length. Most neonatal drug doses are based on body weight, and pediatric supplies are organized according to the color-coded, length-based classification scheme.
- Free-flow oxygen, oral airways, bag-mask ventilation, or intubation may be required to assist ventilation in a neonate. The CCTP should be familiar with the equipment and procedures associated with each of these interventions.
- Chest compressions and resuscitation may be necessary if the infant's heart rate remains below 60 beats/min despite other interventions. Chest compressions can be performed using the thumb technique or the two-finger technique with one or two rescuers. Medications are rarely used to resuscitate neonates, but the CCTP should be familiar with medications that may be used, and should be able to estimate the infant's weight because medication doses for neonates are based on weight.
- Fluid resuscitation may be required if the infant is hypovolemic. A low umbilical vein is used in a

newborn; a peripheral IV or intraosseous line is placed in an infant more than a few days old.

- Neonatal transport incubators are typically fitted with a ventilator that provides synchronized intermittent mandatory ventilation. In some areas high-frequency ventilators are available, as well as the ability to initiate and transport infants on a nitric oxide or extracorporeal membrane oxygenation circuit. CCTPs should be familiar with the technology available in their area.
- There are two types of apnea: primary and secondary. Primary apnea responds to stimulation and oxygen supply; secondary apnea responds to ventilation and supplemental oxygen.
- If the infant inhales meconium-stained amniotic fluid *in utero* or at delivery, the airways can become plugged and hypoxia can follow. Meconium aspiration syndrome (MAS) is the respiratory distress caused by meconium aspiration.
- Tracheal intubation and aspiration with a meconium aspirator are performed before other interventions when meconium is present in the amniotic fluid of a depressed newborn at birth. MAS may occur despite tracheal suctioning. During transport, the CCTP should monitor the infant for complications of MAS and should be prepared to perform a needle thoracentesis for pneumothorax decompression if necessary.
- Neonates are at increased risk for pneumonia. Premature infants, especially those less than 32 weeks' gestation, are at high risk for development of respiratory distress syndrome (RDS). Male infants and infants of diabetic mothers are at increased risk of RDS. A sepsis workup should be performed prior to transport because pneumonia is indistinguishable from RDS in a newborn.
- Exogenous surfactant may be administered to the infant with RDS in a controlled clinical setting by providers experienced in its delivery. During transport following administration of exogenous surfactant, the CCTP needs to monitor the infant for improving compliance and the potential need to decrease respiratory support.
- In mild RDS, continuous positive airway pressure can be helpful to minimize alveolar collapse during transport.
- Simple pneumothorax causes lung collapse; tension pneumothorax is a life-threatening condition. Management of pneumothorax includes transillumination, thoracentesis, and possible intubation. If a symptomatic pneumothorax is suspected, a needle thoracentesis can be life saving.
- General assessment of the neonate includes assessment of appearance, work of breathing, or abnormal breath sounds. Evaluation of circulation includes abnormal skin color or bleeding. Determine if the condition is life threatening.
- Primary assessment includes airway, breathing, and circulation. Assess the airway to determine if it is patent. Assess cardiovascular and end organ function. Respiratory problems are a major cause of cardiac arrest in newborns and infants. Prompt recognition and effective management are fundamental to pediatric life support.
- Cyanosis is caused by decreased arterial oxygenation. Cyanosis has cardiac and noncardiac causes. Acrocyanosis is a benign, common condition.
- Cyanotic congenital heart disease (CHD) is caused by developmental anomalies of the heart or major vessels leading to abnormal blood flow. The CCTP may perform tests ranging from a CBC to a hyperoxia test to monitor the infant's condition and determine the appropriate course of action.
- Sinus tachycardia is a heart rate faster than the normal for the child's age. Common pathologic causes for tachycardia include tissue hypoxia, hypovolemia, fever, metabolic stress, pain, anxiety, drugs, and anemia.

- Supraventricular tachycardia is an abnormally fast cardiac rhythm. Emergency interventions such as vagal maneuvers, cardioversion, and pharmacologic interventions should be performed under appropriate supervision.
- Bradycardia in a neonate is usually a result of tissue hypoxia and resolves when tissue oxygenation is restored. After delivery, cardiac pacing may need to be initiated, but is usually nonurgent.
- Cardiac arrest is uncommon in children. It is more often caused by progression of respiratory distress, respiratory failure, or shock typically associated with hypoxemia and acidosis, than by cardiac arrhythmias.
- Persistent pulmonary hypertension (PPHN) is persistence of elevated pressures in pulmonary vasculature after birth. Meconium aspiration is the most common cause of PPHN.
- Care for an infant with PPHN includes optimizing oxygenation, minimizing stress, maintaining a normal blood pressure, and avoiding or correcting acidosis. Critically ill neonates often have a mix of metabolic and respiratory acidosis. Respiratory acidosis often responds to assisted ventilation. Management of metabolic acidosis includes managing ABCs, providing adequate oxygenation, ventilation, hydration, and treating the underlying cause. Treatment may include administering bicarbonate or IV dextrose.
- Shock is a serious condition that can affect all organ systems If emergent access is necessary to provide fluids, an umbilical vein line can be placed in a newborn, or an intraosseous line can be placed in an older infant (older than 1 week).
- Anemia is a hematocrit value of less than 38% in preterm neonates and less than 42% in term neonates. A neonate with anemia may be asymptomatic or present with signs and symptoms, including, but not limited to, tachycardia, jaundice, heart failure, and shock.
- Management of anemia includes managing the ABCs and obtaining IV access (optimally two sites). Treatment may include volume resuscitation with normal saline bolus, followed by blood if the infant is in shock, or packed red blood cells and fresh-frozen plasma if coagulopathy is suspected.
- Any part of the gastrointestinal tract may have congenital anomalies. Bilious vomiting is considered obstruction until proven otherwise; passage of meconium does not rule out an obstructed bowel. An obstructed bowel can lead to perforation and peritonitis.
- Gastroschisis is a centrally located, full-thickness abdominal wall defect. Omphalocele is a herniation of abdominal contents into the umbilical cord. Gastroschisis is usually an isolated defect; omphalocele is often associated with congenital defects, CHD, and other anomalies.
- If an infant with gastroschisis or omphalocele is born at a remote facility, transport must be expedited to a facility with a neonatal intensive care unit and pediatric surgery. Precautions must be taken to cover and protect the exposed abdominal contents and to prevent infection.
- The presence of bile in vomit must be treated as a surgical emergency until obstruction, especially malrotation, has been ruled out. The CCTP should know the signs and symptoms of esophageal atresia, proximal intestinal obstruction, distal intestinal obstruction, imperforate anus, and Hirschsprung's disease. During transport of neonates with any of these conditions, thermoregulation of the neonate should be maintained and vital signs should be monitored closely.
- Obstructed bowel, necrotizing enterocolitis, and iatrogenic perforation can cause perforation of the bowel. Infants with acute intestinal perforation are at high risk of shock and severe metabolic acidosis secondary to inflammation and vascular leak. Hematemesis can occur with several conditions, including volvulus, which can be fatal. Intestinal volvulus is a surgical emergency.

- Intussusception is the most common cause of intestinal obstruction in children between 3 months and 6 years of age. Intussusception may be reduced by enema, but frequently needs open reduction.
- Diarrhea in a neonate is unusual. Maintain fluids during transport, monitor vital signs, and maintain normothermia.
- Neonates are prone to becoming compromised by serious infectious diseases because their immune systems are not fully developed. The infant's condition can deteriorate rapidly; monitor vital signs and maintain normothermia while transferring to a center that can manage a critically ill neonate.
- Hyperthermia is usually caused by overbundling or exposure to excessive heat. It is also seen with herpes simplex infection.
- Hypothermia is more common during the winter months. It can lead to thermal shock, disseminated intravascular coagulopathy, and death in serious cases. Once stabilized, the infant should be placed in a prewarmed incubator or covered with warm blankets for transport.
- The most important principle of managing toxic exposure/ingestion is stabilization of the neonate. Be sure to obtain a history from the sending facility. Contact the local poison control center for expert guidance in managing exposure to toxins.
- Most birth traumas are self-limiting and have a favorable outcome. Birth injuries can be caused by prolonged labor, breech presentation, and extreme prematurity among other causes and risk factors.
- Head and neck injuries include vacuum caput and caput succedaneum, which are benign, and serious head injuries such as subgaleal hematoma and cephalohematoma. Nerve injuries often occur because of hyperextension or overstretching during delivery, especially with breech presentation. Recurrent laryngeal nerve injury requires immediate attention and transfer to a facility that can provide a high level of care.
- Vaginal breech delivery is the greatest risk factor for spinal cord injury.
- The clavicle is the most common fracture seen in newborns. A fractured clavicle will heal itself within 7 to 10 days with limited motion of the arm. Pneumothorax is a rare complication of fractured clavicle. Soft-tissue injuries mostly need routine care.
- Shaken baby syndrome is the most common cause of death in cases of child abuse. Other maltreatment includes blunt trauma to the abdomen, burns, bruising, and skeletal injuries. It is important to be able to distinguish between seizures and jitteriness in the neonate. Seizures are usually a sign of a serious underlying abnormality; jitteriness is characteristically a disorder of the newborn and is rarely seen at a later age.
- Hypoxic ischemic encephalopathy (HIE), caused by oxygen deprivation or decreased perfusion to the brain, is the most common cause of seizures in term and preterm infants. Multiple organ dysfunction is common after HIE and may affect the outcome for the infant. Hyperthermia has been associated with a worse outcome for the infant with HIE.
- Lethargy is almost always a sign of a serious, frequently life-threatening underlying condition. Hypoglycemia is a medical emergency that can lead to brain damage and even death in severe cases. Signs of hypoglycemia include decreased activity, jitteriness, and seizures.
- Hypocalcemia is most commonly seen in low birth weight infants and can occur after significant stress, as well as in infants of diabetic mothers. Significant hypocalcemia can lead to cardiac arrhythmias, seizures, and tetany.
- An infant with congenital adrenal hyperplasia may present with dehydration and shock. Acute treatment includes normalizing electrolytes and fluid balance, and hydrocortisone replacement after consultation

with the supervising physician.

- Transport of a high-risk neonate proceeds through a series of well-organized, established steps. Awareness of local and state guidelines is important, as is communication among the members of the transport team, the referring facility, and the receiving facility. Communicating with family members regarding what is being done for the infant and a time frame in which they can expect to speak to someone at the receiving facility is helpful in allaying their fears.
- The CCTP must be prepared to manage the challenges presented by different modes of air transport. Airway, circulation, oxygenation, and temperature regulation are among those challenges.

Vital Vocabulary

acrocyanosis A decrease in the amount of oxygen delivered to the extremities. The hands and feet turn blue because of the lack of oxygen.

APGAR score A scoring system for assessing the status of a newborn that assigns a number value to each of five areas of assessment (the total possible score is 0 to 10).

apnea Respiratory pause greater than or equal to 20 seconds.

atresia Complete absence of lumen.

caput succedaneum In the newborn, a subcutaneous collection of fluid with poorly defined margins within the scalp, resulting from pressure on the head during delivery.

central cyanosis Bluish coloration of the skin due to the presence of deoxygenated hemoglobin in blood vessels near the skin surface.

cephalohematoma A subperiosteal collection of blood; may be accompanied by a linear skull fracture.

choanal atresia A congenital narrowing or blockage of the nasal airway by membranous or bony tissue.

congenital adrenal hyperplasia A disease group in which the adrenal glands do not function properly, and as a result do not produce a sufficient amount of the hormone cortisol.

Coombs' test A test used to identify antibodies that may bind to the red blood cells and cause hemolysis.

diaphragmatic hernia Passage of loops of bowel with or without other abdominal organs, through the diaphragm muscle; occurs as the bowel from the abdomen "herniates" upward through the diaphragm into the chest (thoracic) cavity.

distal intestinal obstruction Partial or complete obstruction of the distal small bowel (ileum) or large intestine.

esophageal atresia A congenital defect in which the esophagus ends in a blind pouch, often associated with other anomalies such as tracheoesophageal fistula.

gastroschisis A centrally located, full-thickness abdominal wall defect.

gestation Period of time from conception to birth. For humans the full period is normally 9 months (or 40 weeks).

Hirschsprung's disease A congenital lack of ganglion nerve cells in a portion of the distal intestines leading to poor intestinal peristalsis, constipation, and, if not diagnosed and treated, potentially death.

hypotonia Low or poor (floppy) muscle tone.

hypoxic ischemic encephalopathy (HIE) Damage to cells in the central nervous system (the brain and spinal cord) from inadequate oxygen.

imperforate anus A congenital condition where the anal opening is either absent or displaced.

inborn error of metabolism A class of genetic diseases mostly due to defects of single genes that code for enzymes that facilitate conversion of various substances into others leading to accumulation of substances which are toxic or interfere with normal function.

incubator An enclosed, clear plastic, heated bed that keeps the infant warm.

intussusception An event where one part of the intestine folds into another part of the intestines, leading to a blockage.

malrotation A congenital anomaly of rotation of the midgut, in which the small bowel is found predominantly on the right side of the abdomen.

meconium A dark green fecal material that accumulates in the fetal intestines and is discharged around the time of birth.

neonate An infant during the first 28 days after birth.

newborn An infant within the first few hours after birth.

oligohydramnios Decreased volume of amniotic fluid during a pregnancy; a risk factor associated with abnormalities of the urinary tract, postmaturity (birth after a prolonged pregnancy), and intrauterine growth retardation.

omphalocele Herniation of abdominal contents into the base of the umbilical cord.

oxygen hood A tent placed over the head of an infant for the purpose of delivering supplemental oxygen.

patent ductus arteriosus A situation in which the ductus arteriosus, which assists in fetal circulation, does not transition as it should after birth to become the ligamentum arteriosum; the result is that the connection between the pulmonary artery and the aorta remains, allowing some oxygenated blood to move back into the heart rather than all of it moving out of the aorta and into the systemic circulation.

peripheral blood smear A glass slide containing a drop of blood; analysis allows the lab to microscopically examine the structure of the blood cells.

persistent pulmonary hypertension (PPHN) The persistence of elevated pressures in pulmonary vasculature after birth, associated with failure to transition from fetal circulation to postpartum or normal newborn circulation.

Pierre Robin syndrome A condition present at birth marked by a very small lower jaw (micrognathia). The tongue tends to fall back and downward (glossoptosis) and there is a cleft soft palate.

polyhydramnios An excessive amount of amniotic fluid. May cause preterm labor.

primary apnea The initial response to asphyxia at birth, characterized by increased respiratory rate and a slight decrease in heart rate with increased blood pressure; responds to stimulation and oxygen therapy.

proximal intestinal obstruction Obstruction at or above the level of the jejunum.

repogle A double-lumen tube used for gastric decompression in infants with gastrointestinal issues; for an infant, usually an 8F size is used and is connected to low intermittent wall suction to collect gastric secretions.

secondary apnea The response if asphyxia at birth continues, characterized by a period of gasping respirations, falling heart rate, and falling blood pressure; does not respond to stimulation unless resuscitation is initiated immediately.

surfactant A substance formed in the lungs that helps keep the small air sacs or alveoli from collapsing

and sticking together; a low level in a premature baby contributes to respiratory distress syndrome.

term newborn Used to describe an infant born between 37 and 42 weeks' gestation.

TORCH screen A set of lab values taken to detect congenital infections, including toxoplasma IgG and IgM (1:1,024), rubella titers, urine cytomegalovirus titer, viral culture (for herpes), and culture of scrapings from any vesicular lesions.

transient tachypnea of the newborn Transient respiratory distress, lasting a few hours, in the newborn and which is secondary to retained fetal lung fluid.

vacuum caput In a newborn, an accumulation of fluid at the site where a vacuum extractor was used to assist in delivering the newborn.

volvulus Twisting of the stomach or intestine, which often has the effect of cutting off its blood supply.

Carrie K. Underwood, CCEMT-P

Objectives

1. Review the anatomic and physiologic differences between adult and pediatric patients (p 924–927).
2. Outline the differences in the general approach to critical care transport patient assessment between adult and pediatric patients (p 927–939).
3. Discuss the indications, dosage, and route of administration for medication administration in pediatric patients in the critical care transport environment (p 931–934).
4. Describe what special pediatric equipment may be needed in a critical care transport (p 939).
5. Discuss interfacility transport considerations relating to pediatric critical care transport (p 939–941).
6. Explain considerations when parents and caregivers accompany during a transport (p 941).
7. Discuss common medical emergencies in the pediatric population, including respiratory conditions, cardiac conditions, renal disorders, sepsis, and meningococcal infections, and their assessment and management in the critical care transport environment (p 943–961).
8. Examine common pediatric trauma emergencies, including head injuries, spinal cord injuries, related breathing and circulation abnormalities, fractures, and burns, and their assessment and management in the critical care transport environment (p 961–969).
9. Describe critical care transport management of a pediatric patient with suspected abuse or neglect (p 969–970).
10. Describe critical care transport management of a pediatric patient with hypothermia (p 970).
11. Describe critical care transport management of a pediatric patient with heat stroke (p 970–971).
12. Describe critical care transport management of a pediatric drowning patient (p 971).
13. Discuss how to transport a pediatric critical care patient with special health care needs (p 971–972).

Introduction

Most CCTPs experience some discomfort when caring for children who are in distress, primarily because of the limited experience that they may have with this population. Depending on the structure and the experience level of the critical care team (adult vs pediatric), these types of transports may be of high risk and low frequency. CCTPs must always remember that the pediatric patient is not a “small adult” and should be treated according to the parameters discussed within this chapter and the protocols set forth by your own agency medical director.

Pediatric patients differ anatomically, physiologically, and emotionally from adults. In addition, the

types of illnesses and injuries children sustain and their responses to them vary across the pediatric age span. When dealing with the often limited communication abilities of children, it is more difficult to rapidly and accurately assess them. For these reasons, CCTPs must tailor their approach to accommodate the developmental and social issues unique to pediatrics. Pediatric critical care transports also usually involve one or more caregivers who may be stressed or frightened themselves.

This chapter addresses some of the special considerations that will enhance the CCTP's effectiveness in caring for ill or injured children in the critical care transport environment. It discusses the special needs of children, the most common reasons for pediatric critical care transport, and critical care transport management for pediatric emergencies.

Anatomy and Physiology

Cardiovascular System

In the absence of an anomaly, the basic anatomy of the circulatory system in children is the same as it is for adults. However, there are some physiologic differences, such as different normal ranges for pulse rate and blood pressure. In addition, children have a limited duration of compensatory mechanisms. Once these mechanisms are diminished, the condition of the patient quickly deteriorates.

Respiratory System

Lung development begins in utero and continues through adolescence. Central regulation of respirations is immature in infants; therefore, the respiratory pattern of an infant is often irregular. It remains this way until the infant is older than 1 year, when the rate and depth of respiratory patterns become regular.

The lower airways of children are smaller and, therefore, more prone to obstruction and collapse **Figure 23-1**. Smaller airways cause greater resistance to airflow than do adult airways. Airways grow as the child grows, so it is logical that any disease causing narrowing of the airways, such as bronchiolitis, will be more detrimental in younger children than in adolescents or adults. Mucosa is less adherent to the airways and more prone to the development of edema, which contributes to increased airway resistance.

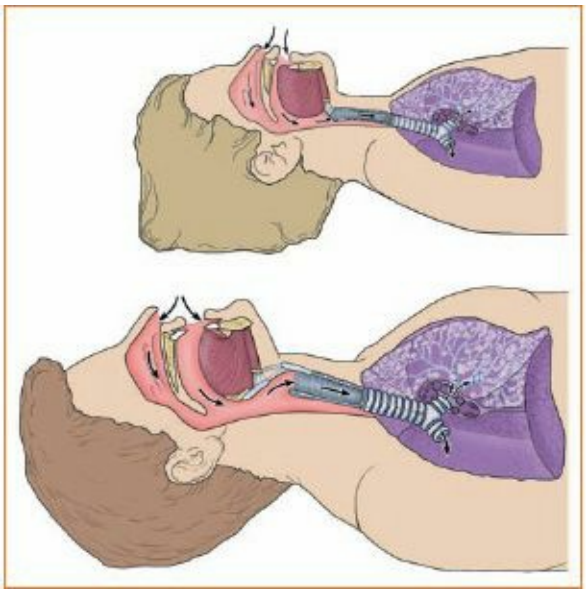

Figure 23-1 The anatomy of a child's airway differs from that of an adult's airway in several ways. The trachea is smaller in diameter and more flexible. The airway itself, including the larynx and vocal cords, is lower and narrower. The back of the head is larger, and head positioning requires more care. Finally, the mandible is proportionately smaller and the tongue is proportionately larger than in an adult.

At birth, the number of peripheral airways is limited. These airways then increase in number until about 7 years of age. The airways then increase in size through adolescence. Therefore, children up to 3 to 4 years of age are at a relatively higher risk of severe symptoms related to lower airway disease than are older children or adults.

During the first few years of life, alveoli mature from a single cell capillary bed to a double cell bed, followed by an increase in the communication between these alveoli, called collateral ventilation. Children may not be able to ventilate airways distal to an obstruction and may be at a higher risk of atelectasis.

Until adolescence, children have a relatively large tongue in relation to the size of their mouth. Another critical difference in the airway of young children is that the narrowest part of the trachea is the cricoid ring. In infants and toddlers, the epiglottis is long, floppy, and narrow compared with an adult **Figure 23-2**. The pediatric epiglottis tends to extend over the glottic opening more than in adults, and the vocal cords of children are thin and angled and have a lower attachment anteriorly. Later, we will discuss how these airway differences affect airway management.

Finally, infants have highly reactive airways, making them more prone to responses from environmental allergens, viral respiratory diseases, and hereditary factors.

Neurologic System

The basic brain anatomy and perfusion requirements in children are similar to those in adults; however, there are a few key anatomic differences. Children do not have a brain that is well compartmentalized, which means there is more room for the brain to move within the skull. This leads to an increased susceptibility to brain injuries, such as diffuse axonal injuries.

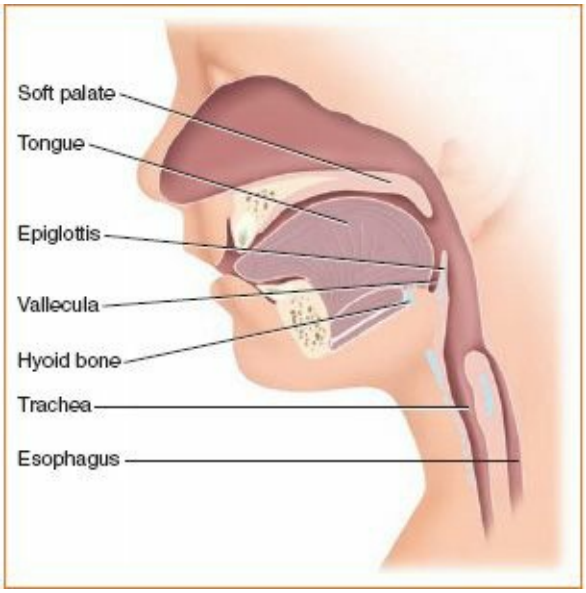

Figure 23-2 The child's epiglottis and surrounding structures.

Key anatomic and physiologic differences in the neurologic system exist between children and adults. The anterior or diamond-shaped fontanelle closes at 16 to 18 months of age, and the posterior fontanelle closes at 2 months of age **Figure 23-3**. A normal fontanelle is soft and flat but with a feeling of fullness. These differences are important to know when assessing children and infants. For example, a newborn may be born with a cephalohematoma—a collection of blood between the bone and subperiosteal space. The incidence of this condition is infrequently seen by the CCTP, but it occurs in 1% to 2% of all live births that involve mechanical trauma (forceps or vacuum-assisted delivery). This type of hematoma can occur anywhere on the skull but is found more predominantly in the parietal region of the

skull. The hematoma usually resolves in 6 to 8 weeks, and can be associated with linear skull fractures (10% to 25% of infants affected). The CCTP should note the size of the hematoma during the initial assessment and during the transport. Complications are rare, but include infection, hyperbilirubinemia, meningitis, and osteomyelitis. The blood mass does not cross the suture line and may increase in size after birth. Blood loss is minimal, but the size and location should be noted on the transport assessment documentation. Conversely, caput succedaneum is merely soft-tissue swelling and usually resolves within 24 hours.

Musculoskeletal System

Several differences exist between the musculoskeletal system of a child and an adult. First, children have fewer calcified bones. The immature bones of children are more porous than those of adults and tend to respond to kinetic forces by buckling rather than fracturing. If the forces are great enough to cause a fracture, an investigation of underlying organ injury is warranted. Epiphyseal-metaphyseal growth plate injuries account for 10% to 15% of fractures in children; however, with reduction and immobilization, most of these injuries have excellent outcomes.

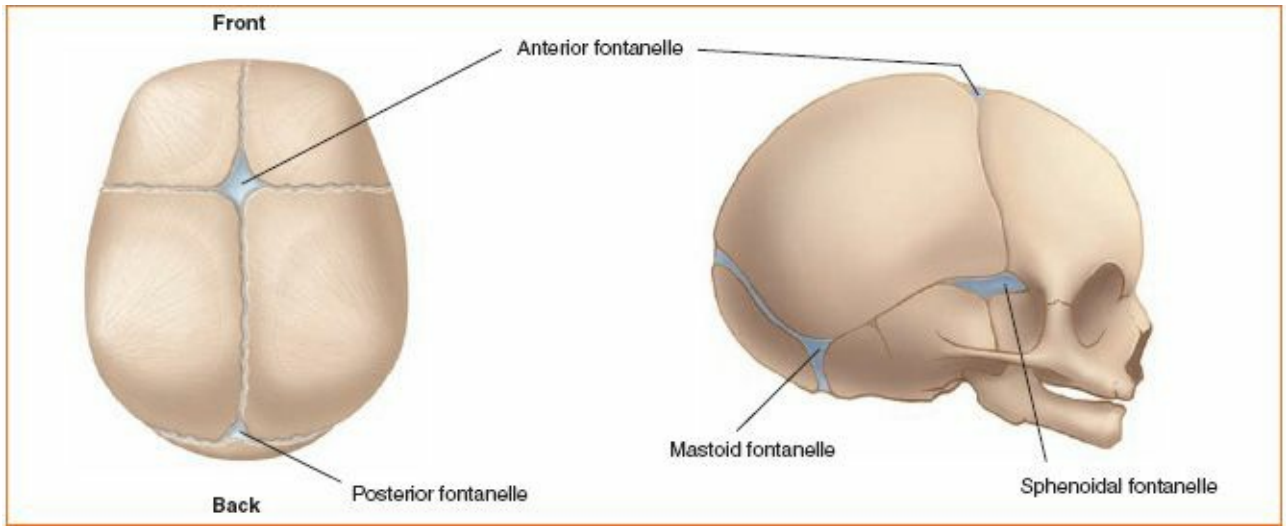

Figure 23-3 The fontanelles.

The child's thorax is pliable, meaning that it can withstand greater kinetic forces without fracturing. The chest is surprisingly resilient and can absorb a significant amount of energy compared to the child's size. However, rib fractures are not common. If a small rib fracture is detected or suspected, this suggests a large force of energy as its cause, possibly indicating a severe pulmonary contusion. In this situation, the pulmonary contusion is more of a life threat to the child than the rib fracture.

The ligaments in children are stronger and more resilient to tensile forces, thereby providing strength to the joints. As a result, dislocations are rarely found in pediatric populations compared with adult populations.

The pediatric spine has incomplete ossification, epiphyseal growth plates, and hypermobility. As a result, the cervical spine in children is highly flexible and young children tend to have avulsions rather than fractures. However, this hypermobility does not always protect the child's cervical spine. Compounding factors are that children have relatively large, heavy heads with weak neck muscles, causing the head to lean forward with a fall. This makes this age population more prone to head injuries. The saying "big heads go to ground" applies here. Rapid deceleration injuries resulting in hyperflexion and torsion forces are most commonly seen in children.

Gastrointestinal System

Several anatomic and physiologic differences increase the risk of aspiration in children. For example, the cardiac sphincter, which is the valve between the esophagus and the stomach, is located above the diaphragm until 6 months of age and does not close completely, leading to frequent regurgitation. Also, children have a smaller stomach capacity, which leads to more frequent meals. Therefore, the chances of encountering a child with a full stomach in an emergency situation are high. The child should be considered at risk for aspiration if the time of the last meal is unknown or if he or she has eaten within the past 4 hours.

Another key difference between adults and children is that the abdominal muscles are weaker in the younger child, providing less protection to the internal organs. The liver and spleen can be palpated below the costal margin; therefore, this makes these organs more susceptible to blunt abdominal trauma.

Liver function is also immature in young children, resulting in fewer glucose stores, a prolonged clotting time, and decreased clearance of drugs by the liver. For this reason, children who are critically ill or injured are susceptible to hypoglycemia. Therefore, an essential component of pediatric resuscitation is checking blood glucose levels.

Renal System

The pediatric renal system has some significant physiologic differences from the adult renal system, including that children have a higher percentage of body water than adults, making them more prone to dehydration. In addition, children are unable to concentrate urine as effectively as adults. They may be more prone to electrolyte loss because they have a higher clearance for blood urea nitrogen (BUN), creatinine, and electrolytes. The minimum urine outputs expected in pediatrics are as follows:

- Infants: 2 mL/kg/h
- Child: 1 mL/kg/h
- Adult: 0.5 mL/kg/h

Thermoregulation

Temperature regulation in infants is not fully developed, making them highly susceptible to hypothermia. Infants have thinner skin and lack a subcutaneous layer of fat. They are unable to shiver and lose heat through the head, which is proportionally larger in relationship to the body.

Children have a large body surface area to mass ratio relative to that of the adult population. This ratio can be advantageous to children when exposed to mildly warm environments and during times of intense exercise in mildly cool weather, because they have the increased ability to dissipate heat. In contrast, when this population is exposed to temperature extremes of cold and heat, their ability to dissipate heat can be a disadvantage that leads to environmental emergencies.

Metabolism

The physiology of pediatric metabolism, like other systems in this patient population, is at a higher rate compared with that of the adult population. The basal metabolic rate is accelerated in the pediatric population, which means the consumption of medications and oxygen is a concern for the transport team members. For example, an infant's consumption of oxygen is twice that of the adult patient. This known variable is important to consider when providing supplemental oxygen and when looking at the mode of transportation (for air transports, the higher the altitude, the more oxygen consumption a patient requires). The CCTP should also take into account the nature of the illness (medical vs trauma) and the likelihood of the patient decompensating during the transport. As with the rate of metabolism, the rate of onset of

hypercapnia and hypoxemia is also accelerated in this patient population, warranting close monitoring during transport.

Glucose Requirements

The pediatric population is predisposed to developing episodes of hypoglycemia secondary to several factors, such as an increased metabolic rate that ultimately depletes available serum glucose levels in the bloodstream. Infants and small children have decreased glycogen reserves and an immature liver that is not capable of stimulating glycogen stores when required. The additional stress on the body from an illness or after a traumatic event creates another opportunity for these hypoglycemic events to occur. The need to assess and reassess is paramount while caring for the pediatric patient during a transport. As with the adult patient, hypoglycemia can manifest at a rapid onset with either an asymptomatic or a classic presentation. Newborns and young infants may be asymptomatic or may have obvious nonspecific symptoms ranging from irritability to lethargy, pallor to cyanosis, and tremors to seizures. On the other hand, the older child will have a more classic presentation that mirrors adult symptoms (anxiety, diaphoresis, tachypnea, and weakness). The ideal treatment regimen for hypoglycemia varies depending on the weight and age of the patient involved. The typical hypoglycemic pediatric patient would be administered 25% dextrose at a dose of 2 to 4 mL/kg. For a neonate or preterm infant, 10% dextrose would be administered at a dose of 5 to 10 mL/kg. For an older child or adolescent, 50% dextrose would be administered at a dose of 1 to 2 mL/kg. If the hypoglycemic episode has been corrected prior to the arrival of the CCTP, then a glucose maintenance infusion should be initiated at a rate of 6 to 8 mg/kg/min or per standing protocol. Although the administration of 50% dextrose is ideal in the adult population, it is contraindicated in the pediatric population. 50% dextrose increases the plasma osmolarity in the blood, which subsequently leads to hypernatremia and cerebral edema in the pediatric patient.

Growth and Development

Physical

One of the important aspects of pediatric care is an understanding of normal growth and development. It is common for children to regress during an illness or when recovering from a serious injury. Failure to meet normal developmental milestones (such as the ability to walk or talk) may be a sign of an underlying illness, a family crisis, or a neurologic injury (ie, a lack of oxygen or blood flow to the brain that may permanently affect the child's ability to reach normal developmental milestones) **Table 23-1**. Knowledge of the child's developmental level also helps to guide safety considerations.

It is optimal to have an understanding of the child's developmental level prior to assessment so that appropriate comparisons can be made. Parents and other caregivers are the best source for information about how the child will react under normal circumstances. The parent or primary caregiver may be able to tell you the developmental age of the child, which will guide the manner in which you communicate with the child and explain procedures. Communication techniques for children who do not have language skills include using sign language, observing facial expressions, and having the child move his or her eyes to the right or left or blink a specific number of times to indicate yes or no.

TABLE 23-1 Developmental Milestones

Age, mo	Milestone

24	Talking

Psychosocial

Psychosocial concerns for pediatric patients vary tremendously based on the patient's age. An infant's primary fear is often separation from his or her parents, so efforts should be made to minimize the time of separation. Toddlers also fear separation from parents or caregivers, and they fear loss of control; allowing the toddler to help dictate the order in which you do different portions of an exam may help it go more smoothly. Preschoolers also fear loss of control, in addition to bodily injury, the dark, and the unknown; explain your actions clearly and provide plenty of reassurance. As with preschoolers, school-aged children fear body injury; simple and concise explanations should be used to describe procedures as ways to help the child. Adolescents and teenagers may have a fear of loss of control and alterations of body image; encourage the adolescent's involvement and respect the adolescent's privacy. Adolescents often have increased compliance if honest explanations are given and if they are allowed to participate in decision making regarding their own health care.

Basic care strategies for psychosocial concerns cross all age spectrums. Foster trust by speaking at eye level, using first names, and explaining medical procedures using age-appropriate words. Encourage a sense of control by offering choices whenever possible, while keeping in mind that in some situations, bargaining and negotiating may not be possible or appropriate. At all times, a calm and confident demeanor can help reassure both the parent and child.

Approach to Parents and Caregivers

CCTPs should do a self-assessment to ensure that they are prepared—academically, technically, and emotionally—to care for pediatric patients. Children of any age may be seriously ill or injured. You may be distracted with the emotional response of a child or parent. CCTPs should watch for signs of increased stress in their transport partners.

Be sensitive to the fact that the child is not the only patient; the needs of the parents, guardians, or caregivers must also be addressed. Common responses may include guilt for not preventing or recognizing the illness or injury, frustration related to not being the primary caregiver to the child during hospitalization (loss of parenting role), or helplessness from a perceived inability to protect the child. Parents often feel fearful, out of control, and uninformed, so an effort should be made to keep parents or other caregivers informed and actively involved in health care decisions. This often requires that information be repeated, sometimes on numerous occasions. Whenever possible, provide parents or caregivers with written information and involve them in the plan of care.

Approach to Pediatric Assessment

All pediatric assessment should begin with a general impression that can be accomplished using the **pediatric assessment triangle (PAT)** Figure 23-4. The PAT is an assessment tool that uses the child's appearance, work of breathing, and circulation. Appearance can be assessed using the TICLS (tickles) mnemonic: Tone, Interactiveness, Consolability, Look or gaze, and Speech or cry Table 23-2. The nature of the child's airway sounds and signs of increased breathing effort characterize work of breathing.

Circulation is assessed by observing the child for pallor, mottling, or cyanosis. By combining the three parameters of the PAT, you get a quick idea of the physiologic stability of a child and, in conjunction with the chief complaint, make decisions regarding the need for life support.

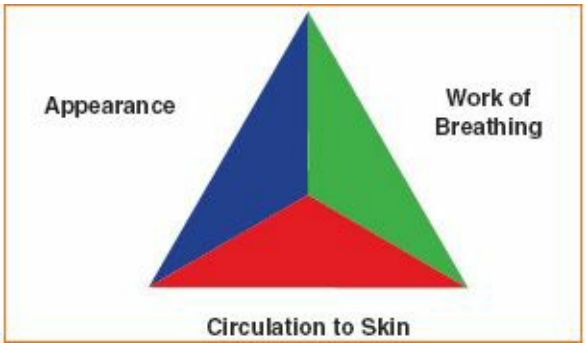

Figure 23-4 The pediatric assessment triangle. Used with permission of the American Academy of Pediatrics, *Pediatric Education for Prehospital Professionals*, © American Academy of Pediatrics, 2006.

After using the PAT to form a general impression of the patient, perform a primary assessment evaluating, in order:

- Airway patency
- Respiratory rate and quality
- Pulse rate
- Skin temperature and capillary refill time
- Blood pressure
- Neurologic status

A child's neurologic status can be obtained by forming a general impression and assessing the level of consciousness and pupillary reaction. Any abnormal finding indicates a need for immediate treatment and may require deferral of the next step (ie, if the airway is not patent as the result of an airway obstruction, intervention must be immediate). A secondary assessment should be performed on medical and trauma patients.

All pediatric patients, even the youngest children, should be assessed for pain. The quality of pain can be assessed using a numeric scale for older children and adolescents. Younger children and infants may be assessed using pain scores, such as the **FLACC scale** **Table 23-3** or the FACES scale **Figure 23-5**.

Each of the five categories that make up the FLACC scale—face, legs, activity, cry, and consolability—is scored from 0 to 2, which results in a total score between 0 and 10.

Although physiologic abnormalities are more likely to be identified by the PAT and primary assessment, the secondary assessment typically helps identify anatomic abnormalities. Sometimes this exam is not possible to perform because the patient is in an unstable condition and needs to be transported immediately. In this case, the exam should be conducted en route to the receiving facility. The secondary assessment focuses on the specific body part or body system involved.

To fully assess a child, a hands-on approach is needed in addition to the use of technical equipment. Touch can provide many clues to a child's condition, which might otherwise go unnoticed. As you assess a child's vital signs, assess skin color, temperature, and turgor. Auscultate the child's chest with a stethoscope and note the rate and quality of respirations, as well as chest and abdominal movements.

TABLE 23-2 Characteristics of Appearance: The TICLS Mnemonic

Characteristic	Features
Tone	Is the child moving or resisting examination vigorously? Does the child have good muscle tone? Is the child limp, listless, or flaccid?
Interactiveness	How alert is the child? How readily does a person, object, or sound distract the child or draw the child's attention? Will the child reach for, grasp, and play with a toy or exam instrument, such as a penlight or tongue blade? Is the child uninterested in playing or interacting with the caregiver or CCTP?
Consolability	Can the child be consoled or comforted by the caregiver or the CCTP? Is the child's crying or agitation unrelieved by gentle reassurance?
Look or gaze	Does the child fix his or her gaze on a face, or is there a "nobody home" glassy-eyed stare?
Speech or cry	Is the child's cry strong and spontaneous or weak and high pitched? Is the content of speech age appropriate or confused or garbled?

TABLE 23-3 FLACC Scale

Category	Scoring		
	0	**1**	**2**
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to, distractible	Difficult to console or comfort

Figure 23-5 Pictures such as the Wong-Baker FACES pain rating scale allow for self-assessment of pain in young children. From: Hockenberry MJ, Wilson D, Wikelstein ML: *Wong's Essentials of*

Figure 23-6 Use of a length-based resuscitation tape is one way to estimate a child's weight and to identify the correct size for pediatric equipment and medication doses.

Staff at the receiving facility will determine whether a child is weighed in triage or on arrival to the treatment area. At the facility, the actual (not estimated) weight is measured and reported in kilograms. In the critical care transport setting, you should obtain the child's weight from the parents or caregivers, and if that is not available, estimate the child's weight using a tool such as a length-based resuscitation tape (eg, Broselow tape) **Figure 23-6**.

History

A significant allergy in children who have neural tube defects is latex allergy. This can cause life-threatening reactions, and all latex products must be removed from the care areas.

Parents or caregivers can provide extensive information regarding the child's history. Pertinent questions should include those about what is the child's current behaviors, such as eating and sleeping patterns, input and output, and activity level. This information can then be compared with the child's usual behavior patterns in these areas. The history for infants and chronically ill children will also include the perinatal history, the delivery history, gestational age, and gestational weight.

Scene or situation information may be useful as well. For example, be sure to make inquiries to responders or determine from prehospital reports any information, such as heating systems, a dilapidated automobile, and other environmental factors, that may have contributed to the situation. The CCTP may discover additional information from family or other sources.

Pediatric Medication Delivery

Delivery of medications in pediatric emergencies can be quite challenging because many emergency medications are prepared using common adult doses (such as medications for cardiac arrest that come in prefilled syringes). Pediatric medication doses often require the CCTP to perform calculations, which increases the possibility of error. Doses of high-alert medications, such as narcotics, heparin, insulin, and potassium chloride, require an independent recheck before they are administered.

Several methods are available for delivery of medications. Medications may be delivered via IV push, syringe pump, or infusion pump. Because infusion pumps have been developed with safety guards, such as a flow stop, they are routinely used for the administration of fluids and medications. An additional safety tool worth mentioning is the buretrol, an inline container between the patient's IV catheter set and the bag of IV fluids. The maximum capacity of the buretrol is set to 150 mL of fluids to be infused. The rationale behind using a buretrol is to fill the buretrol to a designated level. Then, if the IV pump malfunctions, only that volume will flow into the patient, thus preventing overhydration (pulmonary edema). Buretrols are no longer commonly used in transport systems; however, they are still commonly used by many agencies. CCTPs should work with referral agencies and involve them in the discussion of best practices for pediatric infusions.

The best option for administering resuscitation medications is a vascular access device. A pediatric resource with a formulary may be helpful in determining the amount and type of diluent required for specific medications. The formulary will also list the time frame for administration. When using a syringe or infusion pump, always follow the manufacturer's recommendations for flushing and maintenance.

Controversies

Pediatric medication errors are a major focus of concern in hospitals. Measuring devices used to calculate emergency drug doses have been found to contribute to errors for hospitalized children. Although use of the measuring devices for estimation is appropriate for initial prehospital and emergency department encounters, an accurate height and weight must be obtained on admission and used to prepare an individualized dosing list of emergency medications for each child.

Figure 23-7 A nasal cannula may be the most effective way to provide oxygen to an infant in respiratory distress.

Medications used in pediatric critical care transport are summarized in **Table 23-4**.

Airway

Although adults cannot breathe and swallow at the same time, infants have this necessary skill so that they can breathe while nursing. All infants are obligatory nose breathers, meaning they only actively breathe through their mouths if they are crying. Therefore, nasal congestion to an infant can be life threatening. Normal saline spray and a bulb syringe is often all that is necessary to clear the nasal airways. Positioning the infant with the head up 30° to 45° also aids in keeping the nasal airways clear. Administration of oxygen via a nasal cannula may work well in infants with mild to moderate respiratory distress because a significant amount of tidal volume comes through their noses and they do not tolerate face masks **Figure 23-7**.

As mentioned earlier, children have a relatively large tongue in relation to the size of their mouth. Proper choice of blade size, proper positioning, and effective sweeping of the tongue are essential for successful intubation.

Numerous airway differences can interfere with airway patency. To accommodate these differences, a "twisting" technique is sometimes used to insert the endotracheal tube more easily past the vocal cords. This prevents the tube from getting caught on the angled cords. In addition, the trachea of most pediatric patients is anterior, found close to C2 to C3. As the result of the lack of cartilaginous support around the airway, the pediatric upper airway is more easily compressed. This is best managed by avoiding

hyperextension of the neck. Placing the noninjured child in the sniffing position with the aid of towel rolls provides optimal positioning **Figure 23-8**. It is also common to find large tonsils and often copious oral secretions in pediatric patients.

Figure 23-8 A shoulder roll should be used in an infant without trauma to position the airway in a neutral position.

Patency of the pediatric airway may be impaired for numerous reasons, including congenital anomaly, infections, trauma, edema, any reason that would diminish protective reflexes, or foreign body airway obstruction. Foreign body airway obstruction is of particular risk for children younger than 5 years. Diminished protective reflexes may include any condition causing a decreased level of consciousness and/or neuromuscular disorders.

Upper airway obstruction may be recognized by signs of nasal flaring and increased inspiratory effort with a prolonged inspiratory phase. Stridor, snoring, gurgling, or wheezing respirations are noted. Basic assessments include observing whether the child can open his or her mouth without difficulty, cry, and/or vocalize. The quality of these vocalizations and the quality of the air exchange should be noted. In most cases, the minutes taken in proper preparation make securing the airway faster and easier.

A child with a decreasing level of consciousness may be at risk for no longer being able to protect his or her airway and may require endotracheal intubation. Protective reflexes are lost in ascending order. The first reflex lost is swallowing, then coughing, then the gag reflex, and finally the corneal reflex. A useful intubation “pearl” is to assess the corneal reflex prior to inserting an oral airway or to assess for paralysis related to neuromuscular blocking agents. If the child does not blink when the open eyelids are stroked, the child no longer has a gag reflex. This prevents the risk of aspiration by testing the gag reflex with a tongue blade or a suction catheter, which may cause the child to vomit.

TABLE 23-4 Pediatric Medications for Critical Care Transport

Medication Class	Indications	Mechanism of Action	Commonly Used Medications	Dosage (Route of Administration Is IV, IO, or as Indicated)	Side Effects Common to This Class of Medications	Special Considerations
Airway medications						
Ultra-short-acting nonbarbiturate hypnotic agents: etomidate type	Induction agent to facilitate airway device placement	Depresses the reticular activating system by stimulating GABA receptors	Etomidate (Amidate)	0.2–0.4 mg/kg (maximum: 20 mg)	Adrenal suppression, apnea, hypotension, hypertension, tachycardia, bradycardia, myoclonus, nausea, vomiting	Multiple doses increase the likelihood of adrenal suppression. Avoid extravasation.
Ultra-short-acting nonbarbiturate hypnotic agents: ketamine type	Induction agent to facilitate airway device placement	Interrupts pathways within the cortex and limbic system; prompts release of endogenous catecholamines	Ketamine (Ketalar)	1–2 mg/kg	Hypertension, emergence reactions, increased ICP, vivid dreams, tremors	Consider premedication with benzodiazepines to prevent an emergence reaction. Ketamine may be the preferred induction agent in patients with respiratory failure.
Benzodiazepines	Sedative agents, often administered to facilitate airway device placement; maintenance sedative agents; anxiolytic agents; first-line anticonvulsant agents	Binds with benzodiazepine receptors on GABA neurons; enhances GABA inhibition of the CNS, resulting in CNS cellular depression	Diazepam (Valium) Lorazepam (Ativan) Midazolam (Versed)	0.5–1.0 mg/kg 0.1–0.4 mg/kg 0.2–0.3 mg/kg	Sedation, respiratory depression, apnea, hypotension, ataxia, vasodilation	Benzodiazepines may cause paradoxical reactions in children. They are not ideal for use as a sole agent for anesthesia induction. They may produce desirable amnesia effects. The antagonist flumazenil (Romazicon) is available for use in selected situations involving benzodiazepine overdose.
Depolarizing muscle relaxant agent	Short-term chemical paralytic to facilitate airway device placement	Activates, binds, and then occupies with acetylcholine receptor sites at the neuromuscular junction, preventing further activation, and leading to chemical paralysis	Succinylcholine (Anectine)	1–2 mg/kg	May cause or worsen hyperkalemia, causes a transient increase in ICP, may cause bradycardia (especially in children), muscle fasciculations, malignant hyperthermia	Consider pretreatment with atropine in patients prone to bradycardia. Do not administer succinylcholine in repeat doses or as an IV drip. Avoid or use with caution in patients with acetylcholinesterase poisoning. Use with caution in patients with neuromuscular disease. Provides no analgesia or sedation; must be accompanied by analgesic and sedative medications.
Nondepolarizing muscle relaxant agents	Short-term chemical paralytic to facilitate airway device placement; chemical paralytic agents for patients who require ongoing chemical paralysis for transport and certain modes of mechanical ventilation	Competitively antagonizes acetylcholine at receptor sites of the neuromuscular junction, causing extended chemical paralysis	Rocuronium (Zemuron) Vecuronium (Norcuron) Pancuronium (Pavulon) Cisatracurium (Nimbex) Atracurium (Tracrium)	0.6–1.0 mg/kg 0.1–0.3 mg/kg 0.08–0.1 mg/kg 0.15–0.2 mg/kg 0.4–0.5 mg/kg	Apnea in unventilated patients, hypotension, hypertension, tachycardia, or bradycardia; atracurium may cause bronchospasm or excessive secretions	Use cautiously in patients with neuromuscular disease. These medications provide no analgesia or sedation and must be accompanied by analgesic and sedative medications.

Respiratory medications						
Beta-agonist medications	Reactive airway disease, bronchospasm	Activate beta-2 receptors in the respiratory tract, causing bronchodilation	Albuterol (Ventolin)	Neb: 0.1–0.2 mg/kg/dose Max: 4 mg/dose in 5 mL NS every 15–20 min	Tachycardia, hypotension, hypertension, chest pain, CNS stimulation, irritability, nervousness, headache, palpitations	Prolonged use of albuterol may cause metabolic acidosis. Use with caution in patients with cardiovascular disease.
			Terbutaline (Brethire)	Neb: 0.1–0.3 mg/kg/dose Max: 3 mg/dose in 2.5 mL NS every 15–20 min		
			Epinephrine (Adrenaline)	SC: 0.01 mL/kg/dose of 1:1,000 to maximum of 0.3 mL/dose every 20 min up to 2 doses		
Anticholinergic bronchodilator medications	Reactive airway disease, bronchospasm	Block acetylcholine at bronchial smooth muscle receptor sites	Ipratropium (Atrovent)	Metered-dose inhaler only, two inhalations; repeat in 4–6 h	Palpitations, bronchitis	Administered only every 6–8 h.
Theophylline derivatives	Reactive airway disease, bronchospasm	Block phosphodiesterase and stimulate the release of endogenous catecholamines	Theophylline or aminophylline	6 mg/kg over 20 min, then continuous drip	Tachycardia, nervousness, restlessness, nausea, vomiting	Numerous food and medication interactions may occur.
Corticosteroids	Inflammatory disorders, airway edema, cerebral edema, high-altitude pulmonary edema	Suppress immune response; restore normal capillary permeability; limit neutrophil migration	Methylprednisolone (Solumedrol)	Neb: 2 mg/kg (load); 1–2 mg/kg/dose every 6 h	Insomnia, nervousness, immunosuppression, hyperglycemia	Use with extreme caution or avoid in patients with many active infections. Numerous side effects may occur, especially with long-term administration. Numerous medication interactions may occur.
			Prednisone	PO: 0.1–2 mg/kg/d in 1–4 divided doses		
			Dexamethasone (Decadron)	0.03–0.15 mg/kg/d PO, IV, IM divided twice a day to four times a day		
Cardiovascular medications						
Alpha-adrenergic antagonists, ADHD treatment	Hypertension, unwanted vasoconstriction from exogenous or endogenous catecholamines, pheochromocytoma	Block alpha receptors in vascular smooth muscle, preventing vasoconstriction from catecholamines	Clonidine	PO: 0.0005–0.010 mg/kg/d in divided doses every 6–12 h	Hypotension, tachycardia, dizziness, weakness, dry mouth, flushing	Phentolamine is infiltrated into subcutaneous tissues affected by extravasation of vasoconstrictor medications to prevent tissue necrosis.
Antiarrhythmic class I medications	Treatment of various atrial or ventricular arrhythmias (different class I agents are appropriate for different types of arrhythmias)	Block fast sodium channels, inhibit depolarization of neuronal cells, and decrease myocardial conduction velocity and automaticity	Lidocaine	1 mg/kg per dose	Hypotension, nausea, vomiting, unwanted conduction disturbances, cardiovascular collapse (numerous others)	Correct any electrolyte disturbances. Avoid use in patients with any significant cardiac conduction abnormality without an appropriately functioning pacemaker.
			Lidocaine infusion	20–50 µg/kg/min		

Antiarrhythmic class III medications	Various atrial or ventricular arrhythmias	Block potassium channels, which delay phase 3 repolarization and increase the effective refractory period	Amiodarone	5 mg/kg	QT interval prolongation, hypotension, bradycardia, other conduction abnormalities, flushing, edema, numerous cardiac arrhythmias, cardiovascular collapse (numerous additional side effects)	Amiodarone affects sodium, potassium, and calcium channels along with alpha- and beta-blocking properties. Amiodarone has an exhaustive list of side effects and medication interactions.
Antiarrhythmic medications: adenosine	Paroxysmal supraventricular tachycardia with or without Wolff-Parkinson-White syndrome	Replicate endogenous nucleoside, which slows or interrupts reentry pathways through the AV node	Adenosine (Adenocard)	0.1–0.2 mg/kg (maximum strength dose, 12 mg)	Flushing, headache, dyspnea, hypotension, ECG changes, hyperventilation; prolonged asystole is possible	Administer rapidly through the largest proximal vein possible. Expect a significant sinus pause immediately following IV administration. Warn patient, family, or other bystanders of this event. Several significant medication interactions occur with adenosine.
Anticholinergic medications	Bradycardia, asystole, acetylcholinesterase inhibitor toxicity may be given to prevent bradycardia in patients undergoing rapid-sequence intubation; may also be used as a mucolytic agent in certain circumstances	Block acetylcholine receptors in the parasympathetic nervous system; counteracts excessive vagal stimulation	Atropine	0.02 mg/kg per dose Minimum dose: 0.1 mg Maximum single dose: 0.5 mg in child; 1.0 mg in adolescents	Arrhythmias, flushing, tachycardia, dry mucous membranes (may be beneficial), various CNS changes	Extreme quantities may be required for severe acetylcholinesterase inhibitor toxicity. Tachycardia is not an indication to withhold atropine in patients with acetylcholinesterase inhibitor toxicity.
Catecholamines and sympathomimetic agents	Bronchospasm, airway edema, cardiac arrest, allergic or anaphylactic reactions, profound hypotension, profound bradycardia; certain medications may also be used when inotropic support or renal perfusion is needed	Mimic various effects and functions of the sympathetic nervous system through stimulation of alpha, beta-1, beta-2, and dopamine receptors in blood vessels, tissues, and organs	Dobutamine (Dobutrex) Dopamine (Inotropin) Epinephrine (Adrenaline)	2.5–20 µg/kg/min 2.0–20 µg/kg/min Bradycardia/asystolic/pulseless arrest: 0.01 mg/kg (1:10,000) ET: 0.1 mg/kg (1:1,000)	Hypertension, tachycardia, worsening CHF, increased myocardial oxygen consumption, cardiovascular collapse, peripheral vasoconstriction/ischemia, anxiety, nervousness, restlessness (numerous others)	Continuous hemodynamic monitoring is essential for any of these medications. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis if the IV line infiltrates. Many vasoactive medications will worsen myocardial performance in compromised patients. Avoid using sodium bicarbonate in the same IV lines.

Phosphodiesterase inhibitors	Indicated in situations in which both vasodilation and inotropic support are required	Inhibits cAMP in myocardial and vascular tissues	Milrinone (Primacor)	50–75 µg/kg over 10 to 60 min followed by 0.5 to 0.75 µg/kg/min	Hypotension, arrhythmias, nausea, vomiting	Do not use during or immediately after an acute myocardial infarction.
Neurologic medications						
Opioid antagonist medications	Reversal of opioid intoxication following accidental, intentional, or therapeutic overdose	Displace opioids and bind with opioid receptor sites in the CNS	Naloxone (Narcan)	< 20 kg use 0.1 mg/kg IV or 0.2–0.5 mg/kg ET; > 20 kg use 2.0 mg IV or 5 mg ET	May precipitate withdrawal symptoms in patients addicted to opioids	Carefully titrate naloxone intervals and dosing to reverse opioid-induced respiratory depression and sedation without precipitating withdrawal symptoms. Many opioids have a longer duration of action than naloxone, risking undetected return of toxic symptoms.
Miscellaneous medications						
Alprostadil (prostaglandin E)	Maintains patent ductus arteriosis in neonates with certain ductal-dependent congenital heart defects	Prostaglandin, which causes direct relaxation of ductus arteriosis and vascular smooth muscle		0.05–0.1 µg/kg/min IV infusion	Apnea, flushing, fever, bradycardia, tachycardia, hypotension, hypertension, cardiac arrest	Anticipate more than 10% chance of apnea. Consider early rapid-sequence intubation or airway management. Consult appropriate specialist when managing neonatal patients who require alprostadil.
Calcium chloride, calcium gluconate	Documented or presumed hypocalcemia, hyperkalemia with ECG changes, magnesium toxicity, hydrofluoric acid exposure	Replacement of lost or sequestered body calcium; membrane stabilizer that promotes normal cell function		Calcium chloride: 10–20 mg/kg (0.2 mL/kg) Calcium gluconate: 30–100 mg/kg (0.6–1 mL/kg)	Hypercalcemia, tissue necrosis following extravasation, arrhythmias, hypotension, bradycardia	Avoid IV calcium in patients with cardiac glycoside toxicity. Closely monitor peripheral IV sites for signs of infiltration.
Magnesium sulfate	Hypomagnesemia, ventricular arrhythmias	Stabilizes excitable cell membranes, slows SA node conduction, decreases acetylcholine in motor nerve terminals, electrolyte essential for ion movement across cell membranes		25–50 mg/kg (maximum dose: 2 g) over 10 to 20 min; faster for torsade de pointes	Flushing, hypotension, respiratory depression/apnea, vasodilation, cardiac conduction abnormalities	Have IV calcium available when administering magnesium sulfate. Monitor respiratory status, blood pressure, and deep tendon reflexes in patients receiving a continuous magnesium infusion.
Sodium bicarbonate	Certain types of metabolic acidosis, for enhanced elimination of certain toxic exposures, severe hyperkalemia, rhabdomyolysis	Powerful alkalinizing agent that stabilizes various cell membranes, increases serum and urinary pH, promotes renal excretion of weak acids and myoglobin		1 mEq/kg per dose	Cerebral hemorrhage, edema, worsening of congestive heart failure, hypernatremia, metabolic alkalosis, hypocalcemia, hypokalemia, altered hemoglobin oxygen affinity	Drug is not indicated for routine administration during cardiac arrest unless hyperkalemia or metabolic acidosis is documented. Monitor serum potassium during and after administration.

Abbreviations: ADHD, attention-deficit/hyperactivity disorder; AV, atrioventricular; cAMP, cyclic adenosine monophosphate; CHF, congestive heart failure; CNS, central nervous system; ECG, electrocardiogram; ET, endotracheally; GABA, gamma-aminobutyric acid; ICP, intracranial pressure; IM, intramuscularly; IO, intraosseous; Max, maximum; Neb, nebulizer; NS, normal saline; PO, orally; SA sinoatrial; SC, subcutaneous.

Breathing

Children with a lower airway obstruction may experience end-expiratory grunting. Grunting occurs when the child is trying to exhale against a partially closed glottis. This is a physiologic positive end-expiratory pressure (PEEP) when they are attempting to "pop open" their alveoli.

Another significant respiratory consideration related to children is that the diaphragm is the chief muscle for ventilation. If the diaphragm fails, the child may develop paradoxical breathing. The breathing pattern is described as a seesaw type motion, because the abdomen and chest are moving in opposite directions. Intercostal and accessory muscles are not fully developed until the child is school aged.

The chest wall of infants and children is very compliant and, therefore, is more prone to retractions when conditions increase airway resistance, such as when disease is present. This ineffective breathing pattern is evidenced by increased attempts to use the accessory muscles. These measures are typically

unsuccessful and lead to greatly increased work of breathing and eventual fatigue. Children who are having difficulty breathing usually cannot hide it, which makes assessing the work of breathing easier. Tools used to qualify the work of breathing may include an assessment of stridor, snoring, retractions, head bobbing, accessory muscle use, tripoding, nasal flaring, wheezing, and grunting.

Children having respiratory difficulties often place themselves in a tripod position **Figure 23-9**, which allows for better gas exchange because the lungs are located more anteriorly in the chest. Respirations and ventilations rarely improve in a supine position. In addition, as the stomach fills up with air (aerophasia), secondary to the increased respiratory rate, the child may be at a higher risk of aspiration.

The respiratory rate and depth can indicate the child's impending respiratory status. The most effective way of increasing a child's minute ventilation is to increase the depth of respirations. This is seen in diabetic ketoacidosis when a child presents with Kussmaul respirations. However, when disease states are primarily pulmonary related, the increased airway resistance and lower chest wall compliance leads to rapid, shallow respirations (tachypnea).

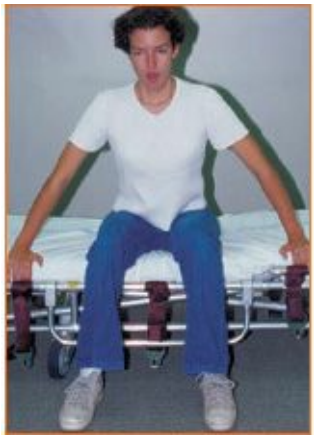

Figure 23-9 A child in a tripod position is maximizing his or her accessory muscles of respiration.

The same factors that can increase the heart rate can increase the respiratory rate, including pain, fear, and fever. For every 1°C rise over 37°C, a child's respiratory rate can increase by 10 breaths per minute. As respiratory distress progresses, respiratory rate may become slower and more irregular. Bradypnea (a slow respiratory rate) is a late sign of respiratory distress and predicts impending respiratory failure. Immediate interventions are required to prevent complete respiratory and/or cardiac collapse. Children have a high metabolic rate and, consequently, a high oxygen demand. Oxygen demand for infants is 6 to 8 mL/kg/min compared to adults (3 to 4 mL/kg/min). Therefore, the pediatric populations are at risk of developing hypoxia sooner than adults. Parameters for pediatric vital signs are presented in **Table 23-5**.

As with every patient population, it is imperative to assess the patient and not the numbers or monitors. A decreasing respiratory rate may indicate improvement if accompanied by improved mental status or a decrease in air hunger; however, a decreased rate with worsening mental status may be an ominous clinical sign. Assessment of the child's level of consciousness during the primary/initial assessment, with particular emphasis on appearance, work of breathing, and circulation (the pediatric assessment triangle), provides critical clues to the child's oxygenation status. Brain tissue has a high level of oxygen consumption, and hypoxia can result in an altered mental status. A child with mild to moderate hypoxia may appear agitated and anxious. As the hypoxia progresses, the child may become quiet and sleepy. Do not be falsely reassured that the child is better. Key assessment points should be focused on ascertaining whether the child can maintain and protect his or her airway. In addition, determine whether the child can maintain the current respiratory effort and determine the likelihood of deterioration en route

to the treatment facility. It is imperative for the CCTP to monitor the patient's respiratory rate, pattern, oxygen saturations, and electrocardiographic (ECG) waveform for any changes in heart rate (tachycardia or bradycardia) or increased cardiac ectopic foci (premature atrial contraction, premature junctional contraction, or premature ventricular contraction).

TABLE 23-5 Normal Pediatric Vital Signs

Stage	Respiratory Rate (breaths/min)	Pulse Rate (beats/min)	Minimal Systolic Blood Pressire (mm Hg)
Infant	25–50	70–160	> 70
Toddler	20–30	90–150	> 80
Preschool-aged child	20-25	80–140	> 80
School-aged child	15–20	70–120	> 80
Adolescent	12–16	60–100	> 90

Palpation of the chest is useful when assessing chest excursion. Excursion should be equal from left to right and sufficient in quality. This means there is a noted rise and fall of the chest that suggests adequate ventilations. However, chest wall movement does not necessarily equal adequate air movement. The chest wall may be working, but there may be inadequate gas exchange related to upper and/or lower airway impedance.

Auscultation is another tool used to assess breathing adequacy. Children may exhibit the same adventitious breath sounds as adults. This may include fine rales or crackles, coarse crackles, rhonchi, wheezing, or a silent chest. Children have thin chest walls that are conductive to referred sounds. Care must be taken to compare lung sounds from both lungs. Lung sounds may be heard over a partially collapsed lung (pneumothorax), but they are referred sounds coming from the intact lung. Noting the pitch is the important factor. The collapsed lung may have a deeper and less loud pitch than the lung that is inflated. Consider if the absence of lung sounds is from consolidation, no air movement, or a pneumothorax. High suspicions can lead to very different prehospital treatment modalities, depending on findings of the history and physical exam.

Measurements commonly used in the field to help determine breathing adequacy include oxygen saturation as measured by pulse oximetry (SpO_2) and end-tidal carbon dioxide ($ETCO_2$) values. SpO_2 readings have been found to be a reliable, useful tool in the prehospital setting. SpO_2 only measures the percentage of hemoglobin molecules that are bound with oxygen, which does not provide a direct correlation with respiration (the exchange of oxygen and carbon dioxide). A child with profound anemia may have an SpO_2 of 100% because all the hemoglobin molecules are saturated. However, if there are insufficient hemoglobin molecules available, the child's end-organ tissue needs for oxygen are not being met. In carbon monoxide (CO) poisoning, CO has a higher affinity to hemoglobin than oxygen, so it readily binds to the hemoglobin molecule. The SpO_2 is 100%, but it is not measuring oxygen bound to hemoglobin, but rather oxygen bound to CO. Again, the child's end-organ tissue needs for oxygen are not being met. Other factors that can interfere with the reliability of SpO_2 measurements include poor perfusion and whether the measured extremity is cold.

Measurement of $ETCO_2$ is the standard of care for assessing adequate respiration in intubated patients. CO_2 is the byproduct of respiration and is more reliable for measuring adequate gas exchange. $ETCO_2$ monitors are available for tracheal tubes and nasal cannulas. Normal values for $ETCO_2$ are 35 to 45 mm Hg, which are the same values found in arterial blood gas (ABG) samples.

Finally, ABG determinations can provide information not only on gas exchange but also on compensatory mechanisms. ABG determinations may be most useful for children when the need for intubation is not clear-cut. Those children who present in obvious respiratory failure or impending failure need to have immediate interventions and should not wait for laboratory confirmation. ABG determinations are also useful when assessing the adequacy of mechanical ventilators. Be careful to weigh delays at the bedside with information obtained from an ABG determination (it usually takes about 20 minutes to receive ABG results, which may be too long to wait).

Circulation

Physical assessment of a child's cardiovascular system begins with observing the child's general appearance and level of consciousness. A child who is well perfused will be watching the CCTP and other activity in the room. Observation of the chest may reveal the child's heart beating through the skin (precordial activity); this is a normal finding in pediatric patients. Assessment of the fingers and toes should be conducted to look for evidence of clubbing. Clubbing is the broadening of a child's fingers and toes in response to chronically low oxygen levels for longer than 3 months.

Poor cerebral perfusion can be manifested with agitation, confusion, or a progressive decrease in response to external stimuli. The brain is the last vital organ to be affected by hypoperfusion. A change in level of consciousness, therefore, is significant.

In septic shock or traumatic brain injury, the mean arterial pressure (MAP) may be more important in guiding therapy. MAP is a better measure of end-organ perfusion. The MAP may be measured by an arterial line or a noninvasive blood pressure monitor. MAP may also be calculated with the following formula,

$$MAP = DBP + 1/3\,(SBP - DBP)$$

where DBP indicates diastolic blood pressure and SBP indicates systolic blood pressure.

Vital Signs

After obtaining a general impression of the child's circulatory status, it is appropriate to obtain vital signs. The position of a child's heart in the thoracic cage is identical to that of an adult. When you are auscultating the pulse rate of an infant, it may be useful to place the stethoscope over the second intercostal space at the midclavicular line. For older children, auscultation may be easiest over the fourth intercostal space at the midclavicular line. Cardiac sounds should be absent of rubs, murmurs, gallops, or secondary sounds. Keep in mind that heart sounds heard over the apex of the heart represent precordial activity and not necessarily a perfusing pulse.

Again, remember to assess the patient and not the numbers because an increase in the heart rate may have an expected etiology, such as crying, fever, or anxiety. For every 1°C above 37°C, the child's heart rate may increase by as much as 20 beats/min. Tachycardia is also the first sign of hypovolemia. Assess the quality of the pulses to determine if they are absent, thready/weak, normal, full, or bounding.

Doppler ultrasound may be useful if a pulse cannot be palpated; however, if the pulse cannot be palpated, cardiac activity and/or perfusion is considered inadequate. In addition to assessing the presence and quality of pulses, compare the pulses bilaterally and in the upper and lower limbs. In an older child (> 1 year), the pulse rate should be assessed in the carotid, radial, femoral, and dorsalis pedis arteries.

To assess a pulse in an infant younger than 1 year, use the brachial and femoral arteries. Palpating carotid pulses in infants is difficult because of their thick, short necks. The carotid pulse is only palpated by hyperextending the neck.

Stroke Volume

Typically, the younger the child is, the higher the pulse rate. Stroke volume is smaller in children than in adults. An increase in heart rate is the chief compensatory mechanism in children to increase end-organ perfusion and to maintain blood pressure. It is logical that bradycardia in children results in hypoperfusion and hypotension.

Skin Condition

An assessment of the child's skin is a good indicator of circulation and whether hypoperfusion exists. Early compensatory mechanisms shunt blood from the skin to the vital organs. Skin that is well perfused should be warm, dry, and the appropriate color for race. As a child becomes hypoperfused, the skin becomes cool, pale, mottled, or cyanotic. As perfusion deteriorates, the child's hands and feet are typically affected first. Clammy or diaphoretic skin may also be present in the child with poor perfusion. Capillary refill is also an excellent indicator of peripheral perfusion. Normal capillary refill in pediatric patients is usually immediate; however, up to 3 seconds is considered an acceptable limit. Capillary refill of greater than 4 to 5 seconds represents a significant delay. Keep in mind that ambient temperatures may affect capillary refill time, as seen with hypothermia.

Blood Pressure

After the immediate assessment of the child's pulse, level of consciousness, and skin, more specific values may be obtained, such as blood pressure. Children, at least initially, compensate well during hypoperfusion. They respond by releasing catecholamines that cause vasoconstriction, an increased pulse rate, and increased contractility. In addition to tachycardia, a normal blood pressure may be maintained until compensatory mechanisms are depleted. For example, in hypovolemia, a child can lose up to 25% to 30% of total volume before hypotension is noted.

A common problem when measuring blood pressure in a child is ill-fitting cuffs. A cuff that is too large and exceeds two thirds the length of the child's arm will give a reading that is falsely low; a cuff that is too small or is less than half the length of the upper arm will give a falsely elevated reading. Often, providers choose to measure blood pressure in a lower extremity, because it is well tolerated by children. Blood pressure values obtained from the lower extremities have been shown clinically to correlate well with values obtained from upper extremities; however, it is advised that both upper and lower extremity blood pressure values be documented to ensure correlation. Always consider the child's normal range and clinical condition. Pain, fear, and anxiety often increase a child's blood pressure.

For some disease processes, such as traumatic brain injury, the MAP may be a more important measurement in guiding treatment than blood pressure. The MAP may be a better measure of end-organ perfusion and may be measured by either an arterial line or a noninvasive blood pressure monitor.

Fluid Volume and Access

Understanding circulating blood volumes for children is useful for quantifying volume loss and calculating fluid replacements. Estimate 80 mL/kg of body weight for a child's circulating volume. Any trauma or medical condition that causes fluid losses, such as blood, emesis, urine, or insensible losses (those that cannot be quantified), requires IV access for volume replacement. IV access can be obtained via a peripheral or central route. The use of intraosseous (IO) access has become common in infants or children requiring urgent interventions with fluids, blood, or medications, in whom rapid venous access cannot be obtained. The most common site for IO insertion is the anterior tibia **Figure 23-10**. Alternative

sites include the distal femur, medial malleolus, and anterior superior iliac spine. IO insertion is recommended over a venous cutdown because success and procedure time are superior; venous cutdown was used in the past, but is no longer practiced given the advancements in IO devices. There are contraindications to this procedure, which include, but are not limited to, osteogenesis imperfecta (brittle bone disease or Lobstein's syndrome), osteopetrosis, and fractures of the ipsilateral (same side) extremity.

Additional IO devices include the EZ-IO and the Bone Injection Gun (BIG). The EZ-IO features a hand-held battery-powered driver, to which a special IO needle is attached **Figure 23-11**. This device is used to insert an IO needle into the proximal tibia of adults and children when IV access is difficult or impossible to obtain. The battery-powered driver of the EZ-IO is universal, but different sizes of needles are available for adults and children.

The BIG is a spring-loaded device that is used to insert an IO needle into the proximal tibia of adult and pediatric patients. It comes in an adult and a pediatric size **Figure 23-12**, although both versions offer the same operational features.

Figure 23-10 Standard pediatric intraosseous needle.

Figure 23-11 EZ-IO intraosseous infusion system.

Figure 23-12 Pediatric Bone Injection Gun.

For any sign of hypovolemia, a 20-mL/kg bolus of normal saline should be given, and repeated as necessary, up to 60 mL/kg during transport. If, during transport, a 60-mL/kg bolus fails to improve the patient's physiologic status, blood replacement and or inotropes should be considered depending on the underlying condition. Blood replacement is calculated as 10 mL/kg of body weight.

Urine output can be an objective guide in measuring pediatric circulatory status and the effectiveness

of volume replacement. Signs of poor kidney perfusion include a low urine output. In children wearing diapers, this means fewer than six wet diapers in a 24-hour period. In children with a urine catheter in place, this means less than 0.5 to 1 mL/kg/h. An adequate urine output is typically 1 to 2 mL/kg/h.

Neurologic Assessment

During the primary assessment, evaluate the child's general appearance. How is this child responding to the environment—is the child responsive or unresponsive, awake or lethargic? Assessment of the fontanelles is important. A sunken fontanelle may indicate dehydration, and a tense or bulging fontanelle may indicate increased intracranial pressure (as the intracranial pressure rises above normal limits, the fontanelle allows for expansion).

The Glasgow Coma Scale (GCS) is the most sensitive indicator of mental status. The score can be used to communicate the child's status to other caregivers and to guide treatment. For example, a child with a GCS of 8 or less from a head injury requires assisted ventilations. The GCS is modified when examining infants and children **Table 23-6**.

Another important component of the neurologic assessment is checking the child's pupil size and response to light. As with adults, very constricted or pinpoint pupils are consistent with narcotic overdose. A single dilated pupil is consistent with brain injury.

A good indicator of motor function is muscle tone. Children normally have flexed elbows and knees. Completely flaccid extremities are an abnormal finding. Another measure of motor function is the presence of normal reflexes, such as the **Moro reflex**, which occurs when the infant jumps or is startled in response to a loud noise. The **stepping reflex** is when an infant is held up in the air and moves his or her legs up and down as if marching. Finally, the **Babinski reflex** is different in infants and adults. In adults, the toes in a normal Babinski reflex point downward; flaring toes indicate brain injury. In children who are not yet walking, a normal Babinski reflex is just the opposite; flaring toes are normal and toes pointing downward indicate brain injury.

In a child with a decreased level of consciousness, the presence of protective reflexes can determine whether a child needs endotracheal intubation for airway protection. Protective reflexes are lost in ascending order—the swallow reflex, the cough reflex, the gag reflex, and, finally, the corneal reflexes. The cough and gag reflexes can be assessed using a suction catheter to elicit a response.

Renal Assessment

Assessment of the renal system typically begins with evaluation of hydration status. This assessment is often initially made by history. Parents or caregivers can offer information about the amount of intake delivered and information about the number of wet diapers, voids, stools, and frequency of emesis.

Physical assessment of the child may include assessment of the fontanelles (if the patient is an infant), assessment of skin turgor, the presence or absence of tears when crying, and sunken eyes. The measurement of wet diapers may be somewhat subjective because parents may change diapers that are not completely saturated. A good question to ask caregivers is whether the diapers are *different* than they normally are. A more objective measurement is weighing diapers, because 1 mL of urine equals 1 g of weight. Daily weights are also an objective measurement because they may be an early indication of fluid loss. Acute weight loss may be an early indication of fluid loss.

TABLE 23-6 Glasgow Coma Scale

Activity	Score	Description	Score	Description
Eye opening	4	Opens spontaneously	4	Opens spontaneously
	3	Opens to speech or sound	3	Opens to speech
	2	Opens to painful stimuli	2	Opens to pain
	1	No response	1	No response
Verbal	5	Coos, babbles	5	Oriented to person, place, and time
	4	Irritable cry	4	Confused
	3	Cries to pain	3	Inappropriate words
	2	Moans to pain	2	Incomprehensible words/sounds
	1	No response	1	No response
Motor	6	Normal spontaneous movement	6	Obeys verbal commands
	5	Withdraws to touch	5	Localizes pain
	4	Withdraws to pain	4	Withdraws to pain/nonpurposeful movement
	3	Abnormal flexion (decorticate)	3	Abnormal flexion (decorticate)
	2	Abnormal extension (decerebrate)	2	Abnormal extension (decerebrate)
	1	No response (flaccid)	1	No response (flaccid)

Fluid overload is much less common in children, although it may occur in patients with congenital heart defects or renal insufficiency. Signs of fluid overload in children may be vague and may initially have a more subtle presentation. For example, in pulmonary edema, hypoxia and grunting are two early signs. Other early signs, such as tachypnea, a cough, and increased oxygen needs, also may be discounted as other etiologies because of their vague presentation. Later signs are more obvious as they may include rales and pink frothy sputum associated with pulmonary edema. Pulmonary edema is later confirmed by a chest x-ray. Additional signs of fluid overload include weight gain, edema, and history of intake greater than output.

Exposure Considerations

Temperature regulation needs attention in all patients, especially in children. Environmental concerns regarding hypothermia or hyperthermia need to be addressed. Because of an infant's physiologic differences and inability to shiver, resuscitation of infants and children must include measures to maintain body temperature, being careful not to overwarm the patient.

Hyperthermia is related to increased oxygen consumption. Children who may be at risk for hyperthermia include those left in cars for extended periods of time, athletes, and those who are intoxicated with drugs and alcohol, which impair heat dissipation.

Heat loss can be minimized by replacing blankets on areas of the child that have been already assessed and by increasing the temperature in the transport vehicle. Be sure to leave heating/cooling measures in place in transport units while the patient is being prepared for transport.

Transport Considerations

Dedicated pediatric specialty teams are ideal for transporting the ill or injured child, but they may not be available or fiscally feasible. Essential knowledge includes understanding differences in pediatric physical assessment, airway management, ventilator management, vascular access, fluid and medication administration, and specific illnesses and injuries that are common in children. Essential skills include pediatric hemodynamic monitoring, intracranial pressure monitoring, mechanical ventilation, and the use of thermoregulation devices. It is helpful to practice new skills using the equipment you will find on the vehicle in which you will be working. In addition, although didactic education is required, it cannot substitute for hands-on pediatric experience including, but not limited to, routine pediatric care, critical pediatric care, and experience with pediatric intubations. Professionals who anticipate caring for critically ill or injured children should consider partnering with professional colleagues who care for

pediatric patients on a regular basis.

Equipment

It is essential to ensure that appropriate equipment is available when transporting pediatric patients. ECG monitoring with SpO_2 and $ETCO_2$ is the standard of care for all intubated pediatric patients. It is important to carry various sizes of ECG leads, pulse oximetry probes, and blood pressure cuffs to ensure accurate vital sign values. A transport ultrasound device may be helpful in verifying the presence of peripheral pulses in poorly perfused children **Figure 23-13**. The transport environment should also be *latex free*, including barriers such as gloves and monitoring and resuscitation equipment. Allergic reactions to latex are extremely dangerous, and it is especially important to remember the extremely high likelihood of latex allergies among special needs children. It is estimated that 73% of pediatric spina bifida patients have a latex sensitivity or a known history of an allergic reaction to latex, so the CCTP must be aware of this issue and make sure that non-latex equipment is available to care for this special population during the transport.

IV fluid administration in pediatric patients should be done with an infusion pump that delivers medication infusions calibrated to at least one decimal place. Fluid boluses and medications for resuscitation should be delivered with a syringe and stopcock technique. Fluid and medication formulas should be standardized and calculated prior to transport. It is also important to carry equipment for thermoregulation, such as a disposable gel-heated mattress or an incubator. Finally, know the capabilities of the transport ventilator for your service. Common requirements for ventilating children include pressure modes of ventilation, capacity for pediatric ventilator settings, and pediatric circuits.

All equipment and supplies in the vehicle should be secured prior to transport to reduce the possibility of causing injury from flying debris in the event of a crash.

Interfacility Considerations

When you are conducting an interfacility transport, there are several important pieces of information that will help to determine the mode of transport, the team configuration, and any specialized equipment that is needed. This information includes the age and weight of the patient, diagnosis, reason for transfer, physical exam findings, lab and other diagnostic tests results, IV access, and consent. It is helpful to develop a standardized intake form that will help the transfer team ask questions to determine the need for airway management or other procedures to stabilize the patient for transport. For example, for patients with an altered mental status, ask the sending facility for the patient's GCS score and the presence of a cough and gag reflex to determine the need for emergent airway management. Any treatment recommendations must be recorded on the transfer documentation.

Figure 23-13 Appropriately sized equipment should always be accessible for transport of pediatric patients.

Once the CCTPs arrive at the sending facility, it is important to assess the patient immediately to determine the need for additional procedures prior to preparing the patient for transfer. Although it is important to ensure that all lines and tubes have been secured and to double-check all fluid and medication rates, a standardized team approach to the patient care hand-off is best. Using communication tools such as SBAR, which stands for situation, background, assessment, and recommendation, helps to standardize the exchange of information so that each provider has an expectation for what is to be discussed, even if the transport is time critical. This method can also be used to frame the conversation with other providers.

Baseline vital signs should be obtained, including temperature measurement and a plan to maintain body temperature. Trauma patients should have their immobilization status evaluated and enhanced as necessary until the cervical spine has been radiographically and clinically cleared at the receiving trauma center.

The sending facility must prepare copies of the medical records and films for transfer. Most facilities will not accept reports of radiographs because the films will need to be examined by a radiologist at the receiving facility.

Briefing for a contingency plan for resuscitation of the child if there is deterioration in the child's condition during transport is also important. The contingency plan may be covered in transport protocols or standing orders or may require consultation with a physician at the receiving hospital in the event of a specialized condition. For children with special needs, ask the parent or receiving physician for an explanation of the disease and any required modifications of resuscitation or transport procedures.

As in all transports, it is important to have a cohesive approach to transport. The driver should maintain a constant awareness of location, nearby hospitals, and, in the case of flight transport, potential landing zones in case of a sudden change in status of the patient or if weather issues prevent the completion of the transport.

Mode of Transport

To ensure the safe transport of pediatric patients, it is important to remember that children must be adequately restrained in the event of a motor vehicle (or flight) crash. Particular attention must be paid to the positioning and placement of child passenger safety restraints. Methods for restraining infants and young children include an isolette or similar device to maintain body temperature with attached straps, a child safety seat or a similar device that can be secured to the ambulance stretcher, and a pediatric immobilization device or backboard, although pediatric immobilizers are not approved by the Federal Aviation Administration. For children older than 4 years, the standard stretcher straps may be used. Generally, if the child requires resuscitation, he or she should be positioned supine and secured to the stretcher. If there is no likely threat to physiologic stability, the child should be transported in an upright, secured position **Figure 23-14**.

Figure 23-14 Transport the child in an upright, secured position if there is no likely threat to physiologic

stability.

All health care providers should be secured in the vehicle, and protective gear that is appropriate to the transport environment should be employed. For safety reasons, it is best to minimize the use of lights and sirens during transport. It is also best to perform as many anticipated interventions as possible that are needed to stabilize the patient prior to initiating the transport.

In patients with diseases or conditions that may be worsened by the effects of altitude, air medical transport may be limited to a specific altitude or may be contraindicated **Table 23-7**. Also, during air medical transport, always remember to take the following precautions to address the potential effects of altitude:

- Assess the patient for evidence of a pneumothorax and decompress any pneumothorax greater than 15% prior to the flight.
- Always vent gastric tubes during the flight and never clamp gastric tubes or indwelling urinary catheters when traveling above 8,000′.
- Be sure to monitor endotracheal (ET) cuff pressures with a pressure gauge and, if needed, fill the ET cuff with fluid to reduce the risk of cuff rupture or tracheal necrosis from increased pressure.
- Be sure to vent the mattress cover in an incubator to avoid an unexpected rupture.

Hypoxia worsens with higher altitudes and may require the administration of oxygen. It is good practice to give supplemental oxygen to all children being transported. In general, oxygen saturation levels should be greater than 90%. Exceptions include pediatric patients with cyanotic congenital heart disease and children with specific target saturations. Be prepared to provide assisted ventilations to children who require high doses of supplemental oxygen prior to flight.

TABLE 23-7 Altitude Restrictions

Altitude	Restriction
Sea level	Chest tube removal within 72 h Venous or arterial grafting performed less than 21 d ago Ventriculography or pneumoencephalography Decompression sickness Air emboli HAPE HACE
2,000″	Gas inclusion in body cavities Untreated perforated injuries of the eye Severe cardiac disease with cyanosis Retinal injuries Congestive heart failure Increased intracranial pressure or skull fracture Sickle cell crisis Ventricular arrhythmias GI disturbances
	Any two of the following:

4,000″	Clinical cyanosis Cor pulmonale Respiratory acidosis Anemia (acute or chronic) Sickle cell disease RBC < 25% Acute head injuries CVA Loss of consciousness Coma Severe cardiac disease with cyanosis Recent eye surgery Severe pulmonary emphysema
6,000″	Myocardial infarction Respiratory disease with increased vital capacity Space-occupying lesions of the lung Angina pectoris Sickle cell disease Alveolar block with cyanosis Clinical cyanosis Cor pulmonale Respiratory acidosis
8,000″	Marked ventilatory restriction from pregnancy, pleural effusion, or pleural fibrosis Alveolar exchange difficulties
10,000″	Any symptomatic or suspected cardiorespiratory disease

Abbreviations: CVA, cerebrovascular accident; GI, gastrointestinal; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema; RBCs, red blood cells.

As discussed in Chapter 4, humidity also decreases with altitude. It is ideal to humidify supplemental oxygen and moisturize the eyes if the patient is unresponsive.

The condition of a patient with an air-filled cavity will worsen in higher altitudes because the cavity will expand. Examples include eye injuries with increased intraocular pressure and gastrointestinal conditions with a risk of intestinal perforation. Patients with abnormal arterial oxygen levels, such as children with cyanotic heart disease or chronic lung disease, are also adversely affected by altitude changes. CCTPs should be aware of local, regional, and national protocols and recommendations that address these issues.

Other factors to consider are related to additional stressors of flight, including barometric pressure changes, dehydration, noise, vibration, gravitational changes, cold, and tissue third spacing. Several measures can be taken to reduce these additional stressors. First, to help prevent ear pain from changes in barometric pressure, an alert infant or toddler can be given a pacifier to suck on during flight. To reduce the risk of dehydration, all children who are restricted to nothing by mouth should be started on maintenance IV fluids. To help decrease the stress of the noise and vibration of the aircraft, ear protection should be used with all patients. Forward or rear-facing positioning should be discussed prior to transport to minimize gravitational forces on landing; this is especially critical for children with closed

head injuries.

Children are at increased risk of hypothermia with air transport, so body temperature should be monitored during transport and warming measures should be initiated with all patients.

Accompanying Parents and Caregivers

The decision to transport parents or caregivers along with a child should be discussed, and guidelines should be put in place long before a child needs transport. In general, the presence of a parent or caregiver decreases a child's anxiety and emotional distress, which may also have a positive physiologic effect. For example, if a child in respiratory distress becomes more anxious and upset because of separation from a caregiver, the child's respiratory effort may increase and his or her physiologic status may deteriorate. The safe transport of the child has priority, however, and the situation must be assessed for the caregivers' comfort level and potential for disruption of care during transport. Consideration must be given to the seating of the parent or caregiver, and guidelines should be discussed with the caregiver prior to transport, particularly the need to remain seated and restrained in a vehicle restraint. No child should ever be held on a caregiver's lap for any reason while a vehicle is in motion.

Airway Management Devices

There are several oxygen delivery adjuncts used with pediatric patients in the critical care environment. These include devices commonly used in the prehospital environment, such as the nasal cannula, simple mask, partial rebreathing mask, non-rebreathing mask, Venturi mask, oxygen tent, and bag-mask device. However, flow-inflating bags, self-inflating bags, and oxygen hoods are not as common in the prehospital environment and will be discussed here for that reason. Shortened tracheal tubes and blade options for children will also be discussed.

Figure 23-15 A flow-inflating bag.

Figure 23-16 A self-inflating bag.

The American Academy of Pediatrics (AAP), via their Pediatric Advanced Life Support course, recommends that self-inflating bags be used for resuscitation. Most of this discussion will then involve the self-inflating bag; however, a brief review of flow-inflating bags will be discussed.

Flow-Inflating Bag

Flow-inflating bags have been routinely used for anesthesia. Features of flow-inflating bags are that they require an outside gas source to inflate and they have a pressure gauge port, a flow inlet dial, and an overflow port **Figure 23-15**. The volume of flow-inflating bags is 500 mL for infants and 600 to 1,000 mL for children.

Self-Inflating Bag

Safe and effective ventilations are possible with self-inflating bags **Figure 23-16**. However, they require more experience and more manipulation of the equipment to achieve adequate ventilations. For this reason, they are not recommended for resuscitation of infants and children outside of an environment where health care professionals have not received extensive training. Continued discussions will now focus on self-inflating resuscitation bags.

Figure 23-17 An oxygen hood.

Self-inflating bags come in different sizes to accommodate the various pediatric populations. A neonatal ventilation bag has a volume of 250 mL. Caution is advised because this small tidal volume may be inadequate for full-term newborns and infants. CCTPs may choose to use a pediatric ventilation bag that has a minimum volume of 450 to 500 mL and a maximum volume of 750 mL.

Features of self-inflating bags are that they do not require a compressed gas source, free flow may be delivered, and they have a pressure release valve (pop-off valve). The pop-off valve is a safety feature that releases when pressures exceed 40 cm H_2O. This helps to prevent excessive airway pressures while bagging children and minimizes the complication of a pneumothorax.

Oxygen Hood

An oxygen hood is an oxygen delivery system that is used in infant populations **Figure 23-17**. Children older than approximately 1 year are physically too big to fit in the oxygen hood. The hood allows for oxygen concentrations of 80% to 90% as well as humidified and warmed air. Oxygen delivery is reliable and allows for easy access of the child's body.

Shortened Tracheal Tube

A shortened tracheal tube may be used as an alternative nasal tube and may offer an advantage in that it is more rigid and less likely to be compressed; however, this rigidity may also be responsible for more

tissue trauma with insertion. Accidental advancement of the shortened tracheal tube is prevented by the 15-mm adapter cap at the end of the tracheal tube.

Blade Options

As you know from Chapter 6, the laryngeal blade is available in two shapes. The Miller blade is a straight blade and usually the choice for infants and younger children. A straight blade is preferred in these children because the epiglottis is cephalad in shape and the glottic opening is more anterior. Therefore, the straight blade allows better visualization for these anatomic considerations.

TABLE 23-8 Pediatric Blade Sizes

Age	Blade Size No.
Premature neonate	0
Term neonate	1
≤ 8 y	3
> 8 y	4

The MacIntyre blade is curved in shape and fits into the vallecula. This blade may be the choice for older children and adolescents because it better displaces the relatively large tongue, thereby allowing better visualization of the glottic opening.

Actual blade selection size is dependent on the child's size, as opposed to age. However, **Table 23-8** may guide the health care professional in size selection.

Respiratory Conditions

Respiratory illness is a common reason for pediatric transport. Respiratory compromise or failure can be caused by any airway, pulmonary, or neuromuscular disease that interferes with oxygen and carbon dioxide exchange. Four types of respiratory conditions that lead to respiratory failure include the upper airway conditions, lower airway conditions, parenchymal diseases, and abnormal control of ventilation, including neurologic causes.

Upper airway obstructions are most commonly caused by a foreign body aspiration or infection characterized primarily by inspiratory stridor. Partially obstructed airways cause turbulent airflow. The obstruction can be above or can include the glottis, pharynx, and trachea. The child's voice will be muffled or hoarse. If the obstruction is subglottic or subtracheal, stridor will be present but the child's voice will sound normal.

Lower airway disease may include the trachea and mainstem bronchi as well as the peripheral airways. Lower airway aspiration most commonly occurs in children younger than 3 years. A diagnosis of lower airway disease is often made after a day of aspiration and may range in presentation from mild coughing and wheezing to severe respiratory distress.

Peripheral airway diseases that are common indicators for transport include asthma, bronchiolitis, and bronchopulmonary dysplasia.

Respiratory distress is characterized by a noted increase in the work of breathing. The effort to breathe is labored and is recognized by an increased rate (tachypnea) and possibly depth (hyperpnea) of breathing. Nasal flaring, retractions, and accessory muscle use are usually noted. Although the amount of effort to breathe is dramatically increased, the child may still have adequate gas exchange of oxygen and

carbon dioxide. In addition, this change in the respiratory pattern may be for compensatory reasons. For example, in diabetic ketoacidosis, an increased respiratory rate and depth is necessary to exhale excessive amounts of CO_2.

Respiratory failure is characterized as inadequate oxygen or the inadequate exchange of oxygen and carbon dioxide. There currently are no strict guidelines for defining respiratory failure because it depends on the child's baseline respiratory function. A need for intervention to prevent respiratory or cardiac collapse is paramount regarding this patient population. If there are any known indications in this patient prior to departing the referring facility or if there are worsening signs and symptoms while en route, the CCTP should take all measures (per protocol) to maintain and preserve a patent airway and hemodynamic status. It is possible for a patient to experience respiratory failure without signs of respiratory distress. For example, a child who is unconscious and apneic after a traumatic head injury will not demonstrate increased work of breathing but rather inadequate or absent breathing.

Croup

Croup (laryngotracheobronchitis) is a common viral infection of the upper airway that affects the larynx but may also extend into the trachea and bronchi. Symptoms include a low-grade fever and hoarse "barking seal" cough that often is worse at night. Croup is most common in children younger than 3 years. In these children, the diameter of the cricoid area is smallest, so swelling may cause severe symptoms. Children most commonly present with mild distress but severe respiratory effects have been reported. The CCTP should be familiar with the hallmark sign of croup being the harsh "barking seal" cough.

Management of croup depends on the severity of the child's symptoms. A child in mild distress may be best managed by maintaining a calm environment. Humidified oxygen is the initial therapy. Allow the parents to sit next to the child to hold the humidified oxygen to the child's face using a mask or blow-by method. If airway obstruction (stridor) is more severe, racemic epinephrine (2.25% with 2.0 to 3.5 mL of normal saline) via a nebulizer usually improves airflow. It may be administered in the following dosages: 0.25 mL (age < 6 months), 0.5 mL (child), or 0.75 mL (adolescent). Racemic epinephrine is subtly different in chemical makeup from epinephrine, and it stimulates both alpha- and beta-adrenergic receptors, with a preference for beta-2-adrenergic receptors that causes bronchodilation. The vasoconstrictive effects of racemic epinephrine are temporary and remain only until the drug is metabolized, which should be considered with long transport times. Once the drug is metabolized, the swelling ("rebound worsening") may return to the same level as before or may worsen. In rare circumstances in which the obstruction is so severe that the child is no longer able to protect his or her own airway, oral intubation may be considered. When you suspect that the airway is edematous, the size of the ET tube chosen may be ½ to 1 size smaller than the tube typically used.

Signs and Symptoms

Croup

- Low-grade fever
- Hoarse, "barking seal" cough
- Mild distress
- Stridor

Differential Diagnosis

Croup

- Acute laryngeal fracture
- Angioneurotic edema
- Arnold-Chiari deformity
- Bacterial tracheitis
- Burns or thermal injury
- Dandy-Walker syndrome
- Diphtheria
- Epiglottitis
- Extrinsic obstruction by a vascular ring
- Foreign body
- Laryngeal papillomatosis
- Laryngomalacia
- Neoplasm or hemangioma
- Peritonsillar abscess
- Retropharyngeal abscess
- Smoke inhalation
- Subglottic stenosis
- Viral croup
- Vocal cord paralysis

Transport Management

Croup

- Administer humidified oxygen using a mask or blow-by method.
- For more severe obstruction, administer racemic epinephrine via a nebulizer.
- If the child is no longer able to protect the airway, consider oral intubation.

Epiglottitis

Epiglottitis (or supraglottitis) is a bacterial infection caused by *Haemophilus influenzae* that most commonly occurs in children aged 3 to 5 years. Symptoms include rapid onset of fever, stridor, and pronounced signs of toxicity. The child may appear anxious, have a muffled voice, and be in a tripod position with pronounced drooling because of supraglottic swelling and excess secretions. Remember the four Ds for epiglottitis: dysphagia, dysphonia, drooling, and distress. Children with epiglottitis are at a tremendous risk of acute and complete airway obstruction. Invasive procedures should be kept at a minimum so as not to aggravate and increase the child's work of breathing.

Management of suspected epiglottitis in the prehospital setting is controversial because this condition can worsen rapidly, leading to a complete airway obstruction. The use of racemic epinephrine with this condition is contraindicated because it can cause additional swelling to the affected inflamed tissues. There is consensus that a calm environment should be maintained so as not to precipitate complete obstruction. There is also agreement that a definitive airway should be secured prior to transport. However, these children are often difficult to intubate and may require specialized teams or

specialized tools, such as retrograde intubation, direct bronchoscopy, or possibly tracheostomy if intubation is unsuccessful. Therefore, the decision to secure definitive airway management in the prehospital setting is multi-factorial, including EMS protocols, skill, and experience of the transport teams, and the time and distance of the transport.

Signs and Symptoms

Epiglottitis

- Rapid onset of fever
- Stridor
- Pronounced signs of toxicity
- Distress
- Muffled voice
- Drooling
- Tripod position

Differential Diagnosis

Ep glotttis

- Bacterial tracheitis
- Foreign body ingestion
- Mononucleosis
- Anaphylaxis
- Croup or laryngotracheobronchitis
- Pertussis
- Pharyngitis
- Pneumonia
- Peritonsillar abscess
- Retropharyngeal abscess
- Caustic ingestion

Transport Management

Ep glotttis

- Maintain a calm environment.
- Secure a definitive airway prior to transport.

Foreign Body Airway Obstruction

Foreign body airway obstruction remains a significant source of morbidity and mortality in pediatric populations. More than 9% of deaths in children younger than 5 years are related to foreign body

aspiration. The onset may be dramatic, with an immediate life threat or with varying severity.

Removal of the foreign body should only be attempted in the prehospital setting by following the guidelines set forth by the American Heart Association and AAP to include the use of chest thrusts in infants and the Heimlich maneuver in older children, leading to direct laryngoscopy with Magill forceps to remove the foreign body. This includes specific algorithms, including only using back blows on infants younger than 1 year **Figure 23-18**. Direct visualization of the trachea and removal of the foreign body should only be considered in the event of impending respiratory failure.

Figure 23-18 Back blows are only recommended on infants (children younger than 1 year).

Signs and Symptoms

Foreign Body Airway Obstruction

- Choking or gagging when the object is first inhaled or swallowed
- Sudden onset of coughing or cough that gets worse
- Stridor
- Wheezing
- Inability to speak
- Pain in the throat or chest
- Hoarse voice
- Blueness around the lips
- Not breathing
- Unconscious

Differential Diagnosis

Foreign Body Airway Obstruction

- Asthma
- Croup
- Myocardial infarction
- Anaphylaxis
- Acute epiglottitis

Transport Management

Foreign Body Airway Obstruction

- Removal of the foreign body is attempted only following AHA and AAP guidelines: chest thrusts in infants or Heimlich maneuver in older children.
- Direct laryngoscopy with Magill forceps.
- Back blows on infants younger than 1 year.
- Direct visualization of the trachea and removal of the foreign body only in the event of impending respiratory failure.

Inflammation

Generalized inflammation of the upper airway may be a result of inhalation burns or allergic and/or anaphylactic reactions. These airway insults are often precipitous in their presentation; early recognition and intervention are imperative to lessen morbidity and mortality. Therapeutic measures to treat all upper airway obstructions include the basics of a calm environment, supplemental humidified oxygen, providing a position of comfort, and preparing for deterioration of the airway status.

Asthma

Asthma, a chronic inflammatory disorder of the lower airways, results in significant inflammation, bronchospasm, and edema. Recurring episodes present with shortness of breath, wheezing, and chest tightness and occur more frequently at night or in the early morning. Increased hyperreactivity of airways may be noted with inflammation caused by a variety of stimuli, including allergens, exercise, emotions, infections, and cold air. The incidence of asthma in the pediatric population is 5% to 15%, making it a significant source of pediatric transports.

Reactive airway disease (RAD) is a term often used synonymously with asthma. Reactive airway disease occurs in children younger than 3 years; the conditions of 30% of children with RAD progress to asthma. Recall that all infants have highly reactive airways, making them more prone to responses from environmental allergens, viral respiratory diseases, and hereditary factors.

Parents of children who experience chronic exacerbations of asthma are usually successful at treating the symptoms or preventing rapid deterioration while at home. Typically, when CCTPs are needed to transport a child with an exacerbation of asthma, traditional treatments have failed and more advanced therapies are required. Obtain a history from the child and parents (caregivers) at the referring facility if they are available, and also obtain a detailed report from the transporting EMS crew (if available), the bedside nurse, and/or the referring physician. For example, if a child has a history of requiring numerous intubations for severe asthma, the child should receive all available treatment during rapid transport to the hospital.

Management of a child with an asthma exacerbation includes oxygen therapy because there is a significant ventilation/perfusion mismatch. A bronchodilator, most commonly a beta-2 agonist, is administered (albuterol, 2.5 to 5.0 mg via hand-held nebulizer). Beta-2 agonists work to relieve the bronchospasm by relaxing and dilating the bronchioles, allowing more unobstructed airflow. Corticosteroids are the cornerstone for anti-inflammatory therapy. They are used to manage both acute and chronic episodes of asthma. The effects of corticosteroids are often not seen for approximately 4 to 6 hours; therefore, they should be administered early in the course of an acute exacerbation of asthma. Corticosteroid use should not take the place of aggressive beta-2 agonist therapy, but should be

administered in conjunction with it.

Signs and Symptoms

Asthma

- Shortness of breath
- Wheezing
- Chest tightness

Differential Diagnosis

Asthma

- Airway obstruction with a foreign body
- Bronchitis
- Pneumonia/bronchiolitis
- Cystic fibrosis
- Bronchopulmonary dysplasia (in premature infants)
- Dysmotile cilia syndrome
- Alpha-1 antitrypsin deficiency
- Immunodeficiencies (National Heart, Lung, and Blood Institute 1997; National Heart, Lung, and Blood Institute 2003)

Transport Management

Asthma

- Administer a bronchodilator, commonly a beta-2 agonist.
- Administer corticosteroids early in an acute exacerbation.

Bronchiolitis

Bronchiolitis is a viral infection most commonly caused by respiratory syncytial virus (RSV) but may also be caused by a host of other viruses. Bronchiolitis primarily affects infants and young children. Infants and young children are at risk for inflammation, edema, and bronchospasms because of immature lower airways. The infection then causes airway obstruction and wheezing. The presentation for children may vary; some may merely have mild wheezing or they may have severe respiratory distress recognized by tachypnea, nasal flaring, and retractions.

Treatments for bronchiolitis are similar to asthma in that both require the administration of supplemental oxygen and IV fluids (avoiding overhydration, which may lead to pulmonary edema), but bronchodilators should be used with caution. Patients with bronchiolitis require the administration of ribavirin (child), an antiviral drug that has been shown to reduce the need for mechanical ventilation in children with lower respiratory tract infections caused by RSV. Diligent assessment must be made regarding the child's work of breathing prior to transport and frequently en route. Infants and young

children have limited energy stores and may fatigue easily with labored breathing.

Signs and Symptoms

Bronchiolitis

- Mild wheezing
- Tachypnea
- Nasal flaring
- Retractions

Differential Diagnosis

Bronchiolitis

- Asthma
- Gastroesophageal reflux
- Foreign body aspiration
- Vascular ring
- Enlarged adenoids
- Congestive heart disease
- Chronic lung disease

Transport Management

Bronchiolitis

- Administer supplemental oxygen and fluids.
- Administer ribavirin.
- Assess the child's work of breathing before and frequently during transport.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is a chronic lung disease that develops in preterm neonates who have been treated with oxygen and positive-pressure ventilation. Neonates at risk for developing BPD are those born before 30 weeks of gestation and those weighing less than 1,200 g at birth. This is a complicated disease in which the pathologic progression of the disease and the healing process are not well understood. The relevance of this topic to this chapter is that infants who survive BPD have pulmonary hypertension and abnormal pulmonary vascular development. Children with BPD are at tremendous risk for severe symptoms during lower respiratory tract infections, and they are at very high risk of pulmonary morbidity and mortality during the first 2 years of life.

Management of the child with BPD can be challenging because the child is usually already receiving oxygen therapy and has a chronic underlying pulmonary dysfunction. Therapy often consists of bronchodilators, corticosteroids, and antibiotics. Dosage depends on the assertiveness of the referring facility. Children with BPD have decreased lung compliance and may require higher peak inspiratory

pressures if oxygenated via bag-mask device or mechanical ventilator. The specifics of ventilation for pediatric patients are discussed next.

Signs and Symptoms

Bronchopulmonary Dysplasia

- Pulmonary hypertension
- Abnormal pulmonary vascular development

Differential Diagnosis

Bronchopulmonary Dysplasia

- Aspiration pneumonia
- Bronchiectasis
- Bronchogenic cyst
- Congenital lobar emphysema
- Cystic fibrosis
- Emphysema
- Esophageal atresia/tracheoesophageal fistula
- Hyaline membrane disease
- Patent ductus arteriosus
- Neonatal pneumonia
- Viral pneumonia

Transport Management

Bronchopulmonary Dysplasia

- Administer bronchodilators, corticosteroids, and antibiotics.
- Oxygenate via bag-mask device or mechanical ventilator.

Mechanical Ventilation

Pressure-cycled ventilation evaluates the inspiratory tidal volume for assessing lung compliance. A target tidal volume of 7 to 10 mL/kg is recommended. Tidal volumes of less than 7 mL/kg may result in hypoventilation and atelectasis. Tidal volumes of greater than 10 mL/kg may result in overdistention of alveoli, compressing the pulmonary capillary bed and causing barotrauma.

Volume-cycled ventilation evaluates the peak inspiratory pressures (PIP) to assess lung compliance. The initial PIP setting should be the lowest possible value that results in adequate chest excursion. Most children should be able to be adequately ventilated with a PIP of 20 to 30 cm. Children with lung disease may require higher PIPs in the 30s. PIPs of greater than 40 cm increase the risk of barotrauma and spontaneous pneumothorax. Many pediatric critical care practitioners will consider an alternative type of mechanical ventilator if the patient requires a PIP of over 40 cm. **Table 23-9** lists age-appropriate

ventilator settings.

TABLE 23-9 Age-Appropriate Ventilator Settings

Setting	Infant	Child
FIO_2	0.21–1.0	0.21–1.0
I time, s	0.5–0.8	0.6–0.8
I:E ratio	1:1 to 1:2	1:1 to 1:2
Tidal volume, mL/kg	7–10	7–10
PIP, cm	15–18	16–24
PEEP, cm	3–5	3–5
PS, cm	5–15	5–20
Rate, breaths/min	25–30 (neonates: 30–50)	20

Abbreviations: PEEP, positive end-expiratory pressure; PIP, peak inspiratory pressure; PS, pressure support.

Controversies

Practitioners accustomed to managing complex mechanical ventilation of adults will find much dissimilarity in the pediatric population. One important consideration is positioning. In adults, sideways rotation to elevate a difficult-to-ventilate lung often improves oxygenation. For reasons poorly understood, the opposite effect is often seen in children.

Physiologic PEEP for infants and children is 3 to 5 cm. Higher levels of PEEP may help with alveolar recruitment and may improve oxygenation. Higher levels of PEEP also increase intrathoracic pressure, resulting in decreased venous return to the heart. The decreased venous return may cause hypotension in children with decreased intravascular volume status or cardiovascular instability. PEEP levels of 8 to 12 cm increase the risk of barotraumas and spontaneous pneumothorax. Many pediatric critical care practitioners will consider an alternative type of mechanical ventilator if the patient requires PEEP values of greater than 12 cm.

The use of pressure support is most helpful in patients who ventilate best with a spontaneous respiratory pattern and in patients who are being weaned from mechanical ventilation. Increasing pressure support increases the tidal volume of the patient's spontaneous breaths. This may be helpful in patients who have an adequate spontaneous rate but an inadequate tidal volume. A patient with status asthmaticus, for example, generally is more effectively ventilated with a spontaneous pattern such as pressure support. The initial rate is set based on age-appropriate values and then titrated based on blood-gas findings and exhaled carbon dioxide values.

In infants and children with severe lung disease, an alternative type of ventilator is an oscillator. An oscillator delivers smaller tidal volumes with very rapid respiratory rates (60 to 1,000 breaths/min) that reduce the risk of barotrauma and pneumothorax. The availability of an oscillator may be the reason for

transporting the child to another facility.

Ventilator Setting Changes

Another difference in ventilator management in infants and children is the manipulation of ventilator settings to improve oxygenation or ventilation. In both pressure- and volume-cycled ventilation, increasing FIO_2, inspiratory time, and PEEP will all improve oxygenation. Increasing PIP and tidal volume within the target range will also improve oxygenation. The strategies to improve ventilation depend on the patient's initial rate. In patients with a rate of 20 breaths/min or less, increasing the rate will improve ventilation and lower the carbon dioxide value. In patients with a higher respiratory rate, increasing the rate may actually worsen ventilation because the expiratory time will be decreased.

For example, consider a patient with an inspiratory time of 0.8 seconds and a rate of 12 breaths/min. The total time for each breath cycle is 5 seconds. This time frame is determined by dividing 60 seconds by the rate of 12. The expiratory time is calculated by subtracting the inspiratory time from the total time for each breath cycle. In this case, 5 seconds – 0.8 seconds = 4.2 seconds. If the rate is increased to 15, then the total time for the breath cycle is 4 seconds. This means that the expiratory time is now 3.2 seconds. This leaves the patient plenty of time for adequate expiration.

Now let's look at a patient with an inspiratory time of 0.8 seconds and a rate of 30 breaths/min. In this case, the total time for each breath cycle is 2 seconds. The expiratory time is 2 seconds – 0.8 seconds = 1.2 seconds. This gives the patient an I:E ratio of 1:2. If the rate is increased to 33, then the total time for the breath cycle is 1.8 seconds. This changes the expiratory time to 1 second, and the I:E ratio changes to 1:1.25. In the second case, increasing the respiratory rate would worsen ventilation because it decreases the time available for exhaling carbon dioxide. In this case, increasing PIP or tidal volume is a better strategy. The CCTP might also consider decreasing the rate or the inspiratory time to lengthen the time available for expiration. This strategy is particularly helpful in patients with bronchospasm, in whom elevated carbon dioxide levels might be a result of air trapping.

Pneumonia

Pneumonia is a type of parenchymal lung disease that occurs in the lung itself. Pneumonia in infants and young children may not be tolerated as well as in older children and adults. Transport treatment includes a vigilant assessment of work of breathing and hydration status. Antibiotic therapy is required and may have begun at the initial facility prior to transport.

Signs and Symptoms

Pneumonia

- Fever
- Grunting
- Cough
- Congestion
- Irritability
- Decreased feeding
- Shortness of breath
- Sweating
- Shaking and chills
- Pleurisy

- Headache
- Muscle pain
- Fatigue

Differential Diagnosis

Pneumonia

- Airway foreign body
- Asthma
- Bronchiolitis
- Bronchioectasis
- Bronchitis
- Cystic fibrosis
- Gastroesophageal reflux
- Congestive heart failure
- Human immunodeficiency virus
- Pertussis

Transport Management

Pneumonia

- Be vigilant in assessing the child's work of breathing and hydration status.

Acute Respiratory Distress Syndrome

The presentation of acute respiratory distress syndrome, also called adult respiratory distress syndrome, is similar in children and adults. Regardless of the underlying cause, the cardinal determinant of acute respiratory distress syndrome is intrapulmonary shunting that has minimal or no response to oxygen therapy. In addition to reversing the underlying etiology, management is primarily supportive, including mechanical ventilation with the use of judicious PEEP and cardiovascular support.

Signs and Symptoms

Acute Respiratory Distress Syndrome

- Shortness of breath
- Rapid breathing
- Cough
- Fever
- Low blood pressure
- Confusion
- Extreme tiredness

Differential Diagnosis

Acute Respiratory Distress Syndrome

- Goodpasture's syndrome
- Hypersensitivity pneumonitis
- Multisystem organ failure from sepsis
- Pneumonia
- Respiratory failure
- Bacterial sepsis
- Septic shock
- Hemorrhagic shock
- Toxic shock syndrome

Transport Management

Acute Respiratory Distress Syndrome

- Provide support, including mechanical ventilation.

Near–Sudden Infant Death Syndrome vs Sudden Infant Death Syndrome

A **near–SIDS** (near–sudden infant death syndrome) event or an apparent life-threatening event is an acute episode of apnea accompanied by choking or gagging, skin color change (erythema, pallor, or cyanosis), and a noted change in muscle tone (limp or increased muscle tone) by the observer of the event (eg, a parent or a caregiver). Recent studies have indicated that several etiologies associated with this diagnosis include, but are not limited to, gastroesophageal reflux disease, viral lower respiratory tract infections, seizures, sepsis, and meningitis. Even with a comprehensive hospital evaluation, the differential diagnosis may conclude to be idiopathic in nature, which should heighten the CCTP's need for a detailed report from the receiving hospital caregivers and/or the parent(s) present at the time of the event. Laboratory results (complete blood cell count, to include a urinalysis to rule out a urinary tract infection) and any related radiographic studies will also be needed to rule out pneumonia. In most cases, near-SIDS patients only require supportive care and immediate transport to a higher level of care for further studies (electroencephalography, polysomnography/sleep studies) or consultation (cardiologist for ECG or electrophysiology studies to rule out a long QT syndrome or preexcitation arrhythmias).

Sudden infant death syndrome is the sudden death of an infant younger than 1 year that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history. The incidence of SIDS is highest during the first 4 months of life and becomes more uncommon after the age of 6 months. Based on the CDC and the National Center for Health Statistics reports, the incidence of SIDS has declined by 50% since 1983. This decrease in death rates has been contributed to the adoption of such campaigns as "Back to Bed" and "Back to Sleep," which instruct that to prevent SIDS, infants should be placed on their backs when being laid down to sleep. This approach is supported by many organizations, such as the American College of Pediatrics. Unfortunately, there are still 2,500 cases of SIDS each year in the United States, which are attributed to risk factors such as low-birth-weight infants, prematurity, gender (61% males), lack of prenatal care or nutrition, and exposure to secondhand smoke.

CCTPs must be aware of the impact of care, and must be sensitive when communicating with parents (caregivers) of infants who experienced SIDS. If the infant arrests while en route to the receiving facility, follow standing orders per your agency protocol or contact medical control to request orders to continue or discontinue resuscitative measures. In most cases, all necessary medical interventions will be initiated in this scenario, especially if one of the patient's parents is being transported with the patient.

If your patient dies during the transport, this parent may become the patient. The CCTPs may have to shift attention to the parent's reaction, which could include denial or anger. As in all situations, the crew's safety must be paramount regardless of the mode of transport. Parents having to deal with such a tragic event may require emotional support from the transport team members or the receiving hospital's support staff on arrival.

Signs and Symptoms

Near SIDS

- Choking or gagging
- Skin color change (erythema, pallor, or cyanosis)
- Noted change of muscle tone (limp or increased muscle tone)

Transport Management

Near-SIDS

- Provide supportive care.
- Transport immediately to a higher level of care.

Transport Management

SIDS

- Follow standing orders or contact medical control to request orders to continue or discontinue resuscitative measures.
- Care for the parent if a parent accompanies the child during transport.

Cardiac Conditions

Pediatric cardiac conditions that have an effect on the circulatory system are common indications for transport. Conditions range from those acquired, such as hypovolemia related to trauma, or congenital conditions, such as structural heart defects that are addressed later in this chapter. The CCTP will routinely be involved in four different classifications of heart disease or conditions, which include a known cardiac defect, an unknown or suspected cyanotic defect (based on patient presentation), a cardiac arrhythmia, and some form of shock (cardiogenic, septic, hemorrhagic, neurogenic, or anaphylactic).

Shock

As discussed in Chapter 9, shock may lead to rapid death or may be more progressive, as in the example

of multi-organ failure.

Shock is categorized as compensated or uncompensated. A child in early or even moderate stages of shock is able to maintain perfusion. Pediatric patients will maintain the compensatory mechanism until they suddenly crash without warning. Once the child's compensatory mechanisms are depleted, the blood pressure falls and the shock classification becomes uncompensated. At this stage, coronary and cerebral perfusions are grossly inadequate. Immediate interventions must be performed to mitigate dysfunction and prevent continued cellular death.

Signs and Symptoms

Shock

- Lightheadedness
- Tachycardia
- Decreasing blood pressure
- Confusion or loss of consciousness (coma)
- Chest pain
- Diarrhea
- Kidney failure
- Pale, clammy skin

Transport Management

Shock

- Assess airway, breathing, and circulation.
- Attempt to control obvious bleeding with direct pressure.
- Obtain a fingerstick blood glucose level to make sure hypoglycemia is not present.
- Administer oxygen.
- Administer IV medications per protocols.

Blood pressure is not the only reliable parameter on which the CCTP should base assessment findings. Other indicators, such as the child's level of consciousness, heart rate, skin temperature, respiratory rate and pattern, and urinary output, are also valid markers of hemodynamic status.

Hypovolemic Shock

Hypovolemic shock is the most common cause of shock in pediatric populations and is characterized by inadequate intravascular volume. Volume loss related to blood in children is most commonly associated with trauma. Fluids lost through vomiting and diarrhea are often underestimated; these losses are particularly significant in young children because they have minimal volume reserves. Another form of fluid loss is excessive urination, as is seen in children with diabetes. Finally, volume losses related to severe allergic reactions may be related to increased capillary permeability and fluid escaping into the interstitial spaces.

When a child's intravascular volume falls, there is inadequate venous return and decreased cardiac output. Cardiac output is a primary factor in end-organ perfusion. Inadequate volume may be related to a

deficit in the circulating fluid volume, resulting in not enough volume.

Hypovolemic shock is categorized into four stages. In most cases of stage 1 hypovolemic shock, the child appears asymptomatic. In stage II, the child attempts to accommodate for volume losses but compensatory mechanisms are being maximized. Blood pressure may still be compensated at this time, but the child is dangerously close to decompensating if interventions are not rapidly applied. In stage III, the child is no longer able to compensate and hypotension occurs. In addition to traditional signs of shock, the child demonstrates mental status changes and significantly decreased urine output. Many children now require blood transfusions for resuscitation to be successful. Finally, in stage IV, death is imminent if the volume loss is not eliminated and aggressive volume replacement, including crystalloids and blood products, is not initiated.

Regardless of the etiology of the volume loss, the principles of resuscitation are identical. Stop the source of volume loss: bleeding, vomiting and diarrhea, and vasodilation.

The next step is to replace the lost volume. Fluid resuscitation for children is 20 mL/kg of crystalloid solutions and 10 mL/kg of blood products. Fluid resuscitation for infants is 10 mL/kg. Fluid boluses of crystalloid solution may be repeated up to three times. If volume remains a deficit, blood products need to be administered. If a child has a cardiac history or concurrent cardiogenic shock, fluid boluses should be at 10 mL/kg. Ultimately, the child may receive up to three boluses of 20 mL/kg but in smaller increments. Successful resuscitation is measured by a return to a normal heart rate, respiratory rate, blood pressure, improved mental status, and improved skin condition.

Transport Management

Hypovolemic Shock

- Stop the source of volume loss (ie, bleeding, vomiting, diarrhea, and vasodilation).
- Replace the lost volume with fluid boluses and blood products.

Cardiogenic Shock

Some causes of cardiogenic shock include, but are not limited to, congenital cardiac defects, drug toxicity, metabolic causes, hypovolemia, myocarditis, and arrhythmias. Congenital defects are much more likely to be the cause of cardiogenic shock than other etiologies. The child with cardiogenic shock will present with traditional signs of shock, including tachycardia, tachypnea, hypoxia, mental status changes, and changes in skin condition. The child in cardiogenic shock often presents with pulmonary congestion resulting in rales heard on auscultation and jugular venous distention. A chest radiograph will also often reveal cardiomegaly.

Signs and Symptoms

Cardiogenic Shock

- Traditional signs of shock include tachycardia, tachypnea, hypoxia, mental status changes, and changes in skin condition
- Pulmonary congestion resulting in rales heard on auscultation
- Jugular venous distention

Transport Management

Cardiogenic Shock

- Resuscitate with fluids.
- Provide inotropic support, including dopamine, dobutamine, epinephrine, milrinone, and norepinephrine.
- Treat primary pathologies or impedances.
- Support cardiac function pharmacologically until myocardial function returns.

Treatment principles concentrate on improving cardiac function with fluid resuscitation and inotropic support to include dopamine, dobutamine, epinephrine, milrinone (dosages listed in Table 23-4), and norepinephrine (0.01 to 0.5 µg/kg/min [rarely used]). Primary pathologies or impedances are treated, and cardiac function may be supported pharmacologically until myocardial function returns.

Distributive Shock

The major treatment goals for distributive shock include stopping the vasodilation, returning volume to the intravascular space, and improving tissue perfusion. Types of distributive shock include neurogenic shock, anaphylactic shock, dissociative shock, and septic shock.

Neurogenic Shock

Treatment for neurogenic shock often necessitates vasoactive medications; however, volume replacement with crystalloids must occur first. The principle of "fill the tank first and then make the container smaller" is the cornerstone of treatment.

Transport Management

Neurogenic Shock

- Replace volume with crystalloids.
- Administer vasoactive medications.

Anaphylactic Shock

Children in anaphylactic shock often present with increased general body edema, hypotension, rash, urticaria, anxiety, and warm, flushed skin. Bronchospasm and laryngeal edema may also be life threatening.

Signs and Symptoms

Anaphylactic Shock

- General body edema
- Hypotension
- Rash
- Urticaria

- Anxiety
- Warm, flushed skin
- Bronchospasm
- Laryngeal edema

Transport Management

Anaphylactic Shock

- Remove the allergen.
- Replace volume.
- Administer epinephrine.

Management of anaphylactic shock involves removing the allergen, volume replacement, and epinephrine. Epinephrine dilates the bronchials; relaxes the smooth muscle, causing vasoconstriction; and decreases vascular permeability, thereby inhibiting more volume loss.

Dissociative Shock

Dissociative shock is a rare form of shock in the pediatric population and is often not included in traditional classifications of shock. In dissociative shock, the hemoglobin molecule is unable to give up oxygen to the tissues. Tissue perfusion is normal, however, and the release of oxygen is abnormal.

Some examples of dissociative shock are carbon monoxide poisoning, methemoglobinemia, dyshemoglobinemia, and cyanide poisoning. In each case, the agents causing the condition have a higher affinity to hemoglobin and oxygen is displaced.

Treatment is early recognition, removal of the cause, oxygen administration, and supportive therapy.

Transport Management

Dissociative Shock

- Remove the cause of shock.
- Administer oxygen.
- Provide supportive therapy.

Septic Shock

Another cause of abnormal distribution from massive vasodilation is related to septic shock. This form of shock is caused by an overwhelming release of proinflammatory mediators, which are initially released to help damaged cells repair. In sepsis, however, the response is so large that it causes more tissue and capillary injury. Management of septic shock includes treating the underlying infection and providing multisystem support—oxygen, volume replacement, and often vasoactive medications.

The treatment of septic shock in the pediatric population is focused on managing the elements of hypovolemia and cardiogenic shock. The inflammatory response in sepsis is a result of an infectious agent or its contained toxins. Most of these infectious agents are bacterial, but sepsis may also be caused by a virus, a fungus, or other microorganisms. The CCTP must be aware of the two phases of septic shock,

which consist of the warm phase and the cold phase. The patient in the warm phase presents with a period of vasodilation or the appearance of well-perfused organs. On assessment, the skin is warm and the pulses are bounding on palpation. The cardiac output is within normal limits or elevated, but kidney function is diminished, and metabolic acidosis and a change in mental status will be noted. If left untreated, the patient will present with the signs and symptoms of the cold phase of shock, which represents a continually failing cardiac output with decreased contractility, poor perfusion status, and extremities that are cool to the touch. The CCTP may use the following formula for calculating normal systolic blood pressure in this patient population in order to compare this with the patient's actual blood pressure:

$$\text{Systolic Pressure} = 80 + (\text{Age in Years} \times 2)$$

According to the 2007 update from the American College of Critical Care Medicine, the clinical diagnosis of septic shock is made in children who (1) have a suspected infection manifested by hypothermia or hyperthermia and (2) have clinical signs of inadequate tissue perfusion, including any of the following: decreased or altered mental status; prolonged capillary refill of greater than 2 seconds (cold shock), diminished pulses (cold shock), mottled cool extremities (cold shock), or flash capillary refill (warm shock); bounding peripheral pulses; wide pulse pressure (warm shock); or decreased urine output of less than 1 mL/kg/h. The goal of treatment by the CCTP as previously stated is to focus on the resolution of hypovolemia and to improve the perfusion status caused by cardiogenic shock. The resuscitation management of the septic pediatric patient is detailed in **Figure 23-19**, which depicts a time-sensitive algorithm. This algorithm focuses on the maintenance or restoration of the following: airway management to include oxygenation and ventilation support; circulatory/perfusion status to include blood pressure, vascular access, fluid volume resuscitation, and use of inotropic/vasoactive drug support; and the use of extracorporeal membrane oxygenation (ECMO) in refractory shock.

Signs and Symptoms

Septic Shock

Warm Phase

- Period of vasodilation or appearance of well-perfused organs
- Warm skin
- Bounding pulses on palpation
- Normal or elevated cardiac output
- Diminished kidney function
- Metabolic acidosis
- Changed mental status

Cold Phase

- Failing cardiac output with decreased contractility
- Poor perfusion
- Extremities cool to touch

Transport Management

Septic Shock

- Administer oxygen and provide ventilation support.
- Establish IV/IO access.
- Administer fluids.
- Use inotropic/vasoactive drug support.
- Use ECMO in refractory shock.

Cardiac Anomalies

Approximately 1 of every 100 infants has a congenital heart defect. Depending on the severity of the congenital heart disease, some patients may need immediate medical management or surgical intervention to repair the defect. Other patients may only need supportive care until later in life, when they are able to tolerate such surgical intervention.

The pediatric population most likely to have an undiagnosed cardiac anomaly is the neonate. Typically, older children have cardiac defects diagnosed and surgical repair or pharmacologic interventions initiated. Congenital cardiac anomalies may not be diagnosed until the neonate is 1 to 2 weeks of age because the ductus arteriosus remains patent and allows adequate mixing of oxygenated and deoxygenated blood. For a neonate who has a relatively small lesion and a more subtle presentation, diagnosis may not be made until 2 to 8 weeks of age when the characteristic murmur may be heard. The murmur may not be apparent until this age because of high pulmonary and arterial pressures present immediately after birth. In addition, the initial presentations of pallor, poor perfusion, lethargy, and cyanosis may mimic sepsis. This may confuse early diagnosis of the cardiac anomaly, which may be classified as either an acyanotic or a cyanotic defect.

Children with a known or new-onset cardiac condition may present with a defect in their cardiac pump. The defect may have many possible etiologies. Often the outflow or filling of the heart is impeded, which prohibits forward flow of blood and results in edema. The pediatric patient may present in a similar fashion as an adult, with pulmonary edema, jugular venous distention, and hepatic venous congestion. Peripheral edema may also be assessed in common places, such as around the eyes, the lower back, or the top of the foot.

Cardiac Defects That Do Not Cause Cyanosis

A cardiac lesion is a cardiac defect or anomaly present at birth. Certain cardiac lesions do not cause cyanosis. They may cause obstruction of the left side of the heart or cause a left-to-right shunt of blood **Figure 23-20**. Lesions that cause a left-to-right shunt of blood cause systemic circulation to flow into the pulmonary vasculature. The higher pressure in the left side of the heart forces blood into the right side of the heart that has lower pressure. The resulting increased blood volume in the right side of the heart causes high pulmonary arterial blood flow and pressure and symptoms of tachypnea, poor feeding, irritability, failure to thrive, and, if left untreated, congestive heart failure. Examples of cardiac lesions that can create a left-to-right shunting of blood include ventricular septal defects, atrioven-tricular canal defects, atrial septal defects, aortic stenosis, patent ductus arteriosus, and pulmonary stenosis.

Signs and Symptoms

Cardiac Anomalies

Congenital Cardiac Anomaly

- Heart murmur

- Pallor
- Poor perfusion
- Lethargy
- Cyanosis

Defect in the Cardiac Pump

- Pulmonary edema
- Jugular venous distention
- Hepatic venous congestion
- Peripheral edema around the eyes, lower back, or top of the foot

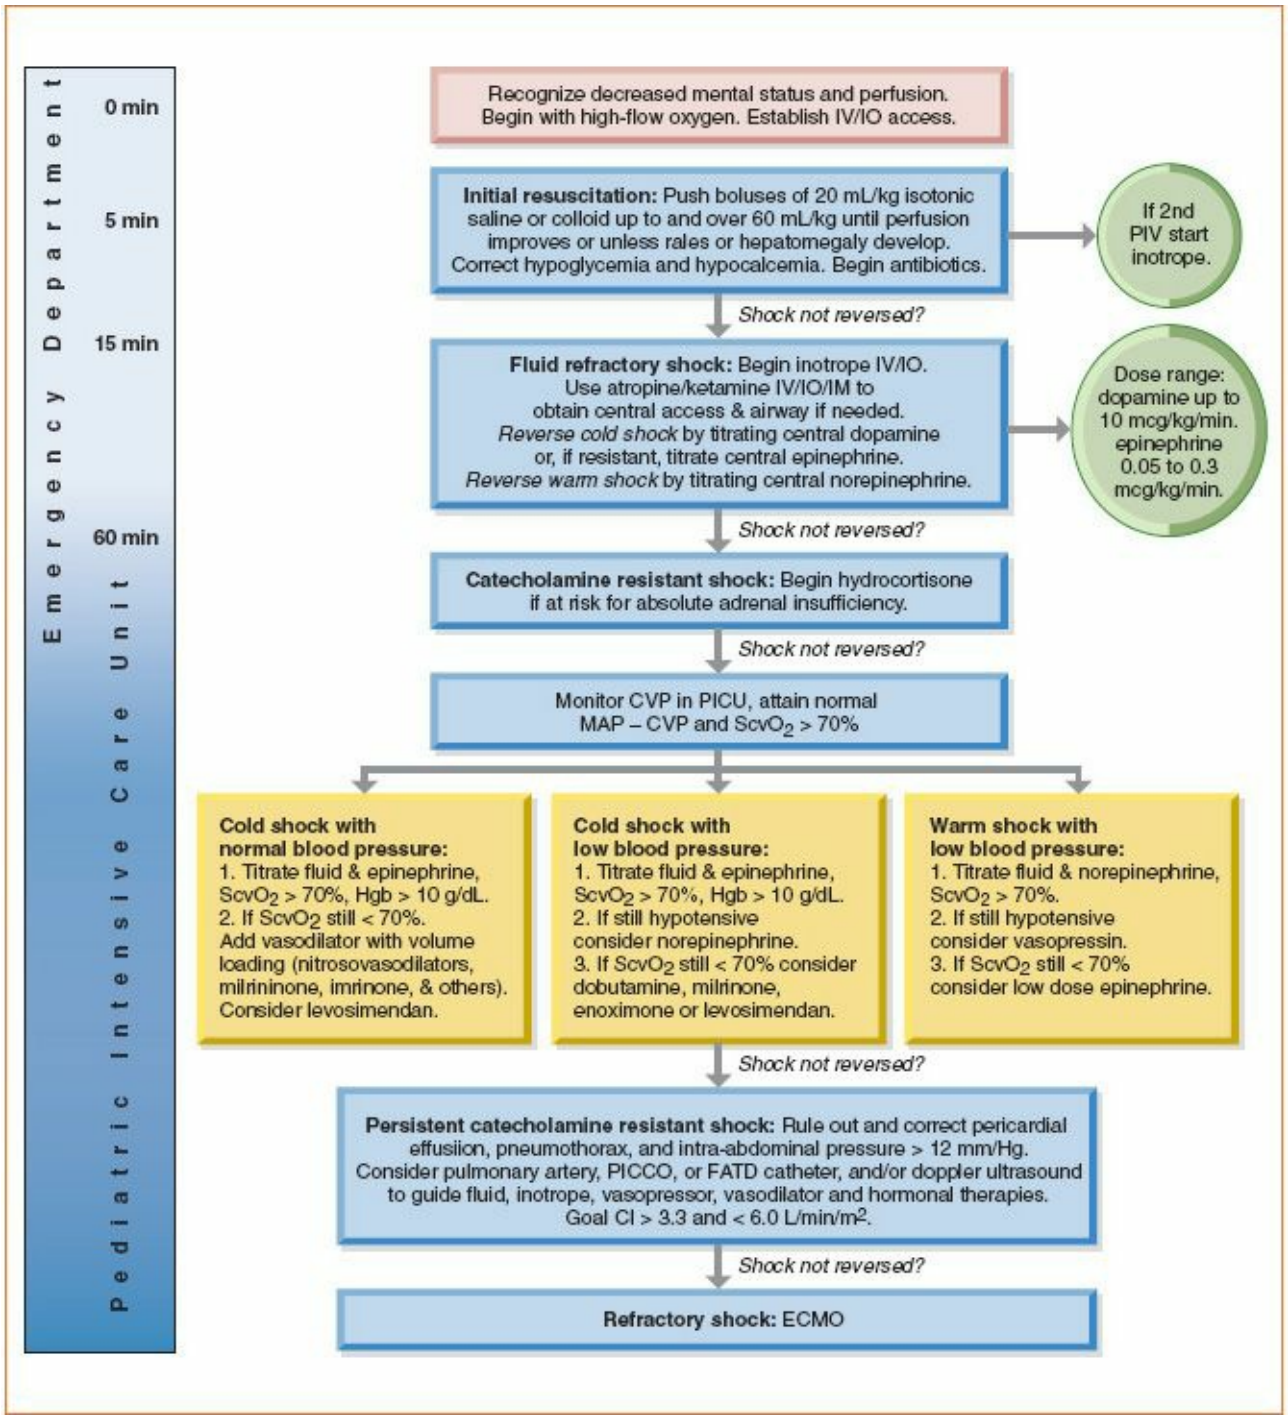

Figure 23-19 Algorithm for time-sensitive, goal-directed, stepwise management of hemodynamic support in infants and children. Proceed to next step if shock persists.

Abbreviations: CI, cardiac index; CRRT, continuous renal replacement therapy; CVP, central venous pressure; ECMO, extracorporeal membrane oxygenation; FATD, femoral arterial thermodilution; Hgb, hemoglobin; IM, intramuscular; IO, intraosseous; IV, intravenous; MAP, mean arterial pressure; PICCO, pulse contour cardiac output; PICU, pediatric intensive care unit; PIV, peripheral intravenous line; $ScvO_2$, mixed central venous oxygen saturation.

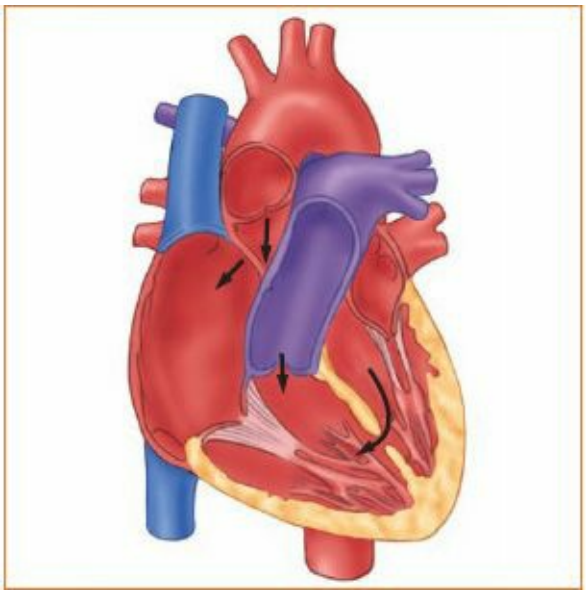

Figure 23-20 Left-to-right shunt of blood.

Locations of various cardiac lesions are shown in **Figure 23-21**. A **ventricular septal defect (VSD)** is a hole in the septum between the ventricles, in which blood from the left ventricle flows into the right ventricle. An **atrioventricular canal defect** is a hole in both the atrial and ventricular septal walls that allows blood to flow from the left side of the heart to the right side of the heart. It usually involves defects of both the mitral and tricuspid valves. **Atrial septal defects (ASDs)** occur as a hole in the atrial septal wall that allows blood to flow from the left atrium into the right atrium. **Aortic stenosis** is a narrowing of the aortic valve, and **pulmonary stenosis** is narrowing of the pulmonary valve. If the aortic and pulmonary stenosis is severe in these lesions, the patient may be cyanotic. Finally, **patent ductus arteriosus (PDA)** is a situation in which the ductus arteriosus, which assists in fetal circulation, does not transition as it should after birth to become the ligamentum arteriosum. The result is that the connection between the pulmonary artery and the aorta remains, allowing some oxygenated blood to move back into the heart rather than all of it moving out of the aorta and into the systemic circulation **Figure 23-22**.

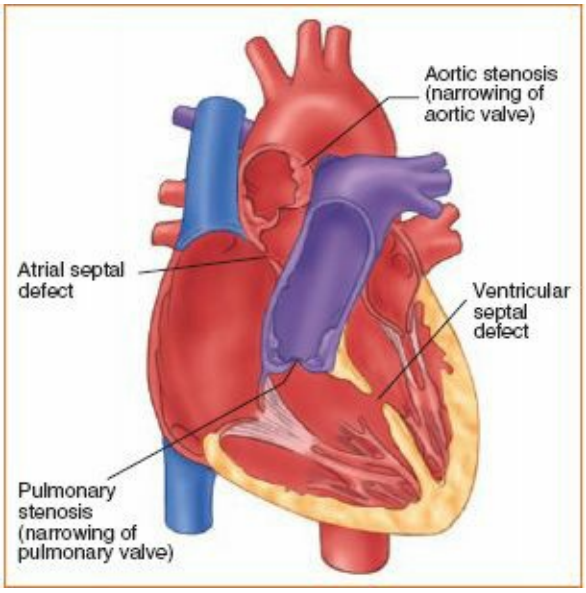

Figure 23-21 Locations of various cardiac lesions. Atrioventricular canal defect is not shown; it is a hole in both the atrial and ventricular septal walls.

Signs and Symptoms

Acyanotic Cardiac Anomalies

- Tachypnea
- Poor feeding
- Irritability
- Failure to thrive
- Congestive heart failure

Left Heart Obstruction Defects

Aortic stenosis, hypoplastic left heart syndrome, and coarctation of the aorta are all examples of obstructions that cause impaired left ventricular output that may be treated in the critical care transport setting. The neonate presents with symptoms of shock near the second week of life because this is when the PDA begins to close. These lesions are dependent on the PDA because it prevents pulmonary hypertension and congestion. As the PDA begins to close and pulmonary hypertension increases, symptoms of tachypnea, poor feeding, and congestive heart failure become evident. Untreated, this leads to cardiogenic shock.

Persistent pulmonary hypertension (PPHN) in the newborn is caused by an abnormally elevated pulmonary vascular resistance resulting in hypoxia. The typical presentation consists of low APGAR scores, hypoglycemia, or a congenital diaphragmatic hernia. In severe cases, these patients will present with marked cyanosis, decreased peripheral perfusion, and metabolic acidosis. The manifestation of congestive heart failure stems from the increased pressure overload on the right ventricle, which is typically a low-pressure system.

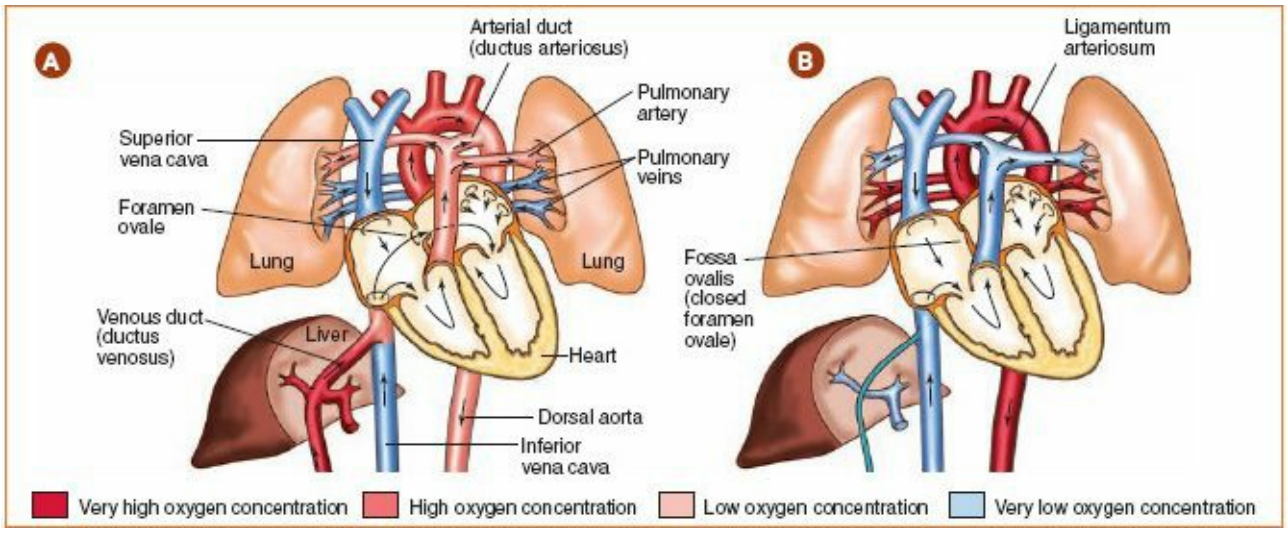

Figure 23-22 The ductus arteriosus plays a role in fetal circulation before birth **(A)** and normally transitions to become the ligamentum arteriosum after birth **(B)**.

Extracorporeal membrane oxygenation (ECMO) is a supportive intervention that is typically only used for short durations and is indicated for patients with PPHN and congenital diaphragmatic hernia. It provides oxygenation to a patient whose lungs and possibly heart may be failing, and does so by removing the patient's blood to a heart and lung machine that does the work normally done by the lungs and heart, then transfusing it back into the patient's circulation. The most common forms of ECMO in the transport setting include venoarterial and venovenous. Venovenous ECMO cannulates the venous circulation, whereas venoarterial ECMO cannulates the arterial circulation. Venovenous ECMO has a lower Pa_{O_2}, requires a higher perfusion rate, maintains pulmonary blood flow, and does not provide cardiac support to assist systemic circulation. Conversely, venoarterial ECMO has a higher Pa_{O_2}, requires a lower perfusion rate, bypasses the pulmonary circulation, and provides cardiac support to assist systemic circulation.

In the neonatal patient population, venoarterial ECMO is the form most predominately used. Exclusion criteria for the initiation of ECMO in the neonatal population consist of the following: birth weight of less than 2,000 g or younger than 35 weeks' gestation, evidence of grade II intraventricular hemorrhage or bleeding, mechanical ventilation with high F_{IO_2} and pressure settings for more than 7 to 10 days, and any signs of irreversible or fatal congenital anomalies. For pediatric and adult populations, there are no set inclusion or exclusion criteria for ECMO.

The decision to perform ECMO is usually based on the overall prognosis of the patient and the level of expertise of the institution involved. To date, there are only a few ECMO transport teams in the United States that have the capability of performing this type of transport. Patients undergoing ECMO are extremely fragile and require a multi-disciplinary transport team consisting of a physician, a neonatal/pediatric nurse, and a respiratory therapist who has specialty training and familiarity with these complex and intricate transports. Prior to the decision to transport, the referring physician and transport personnel need to ensure that the patient's parents have been educated on the severe instability of the child's health and the potential for deterioration or even cardiac arrest during transport to the receiving facility.

Hypoplastic left heart syndrome (HLHS) is the underdevelopment of the aorta, aortic valve, left ventricle, and mitral valve. This defect involves the entire left side of the heart. This cardiac lesion is dependent on a PDA, patent foramen ovale (PFO)/ASD for survival. **Coarctation of the aorta (CoA)** is a pinching or narrowing of the aorta that obstructs blood flow from the heart to the systemic circulation.

Signs and Symptoms

Acyanotic Cardiac Defects

- Tachypnea
- Poor feeding
- Irritability
- Failure to thrive
- Congestive heart failure, if untreated

Cardiac Defects That Cause Cyanosis

Some cardiac lesions are diagnosed early after birth because cyanosis is present. Most children with such lesions are identified early as neonates; the small percentage who are not identified early are due to the PDA sometimes allowing sufficient mixing of oxygenated and deoxygenated blood. An example of this may be **tetralogy of Fallot (TOF)**. This cardiac anomaly consists of four defects: ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and overriding aorta. When the PDA closes, these neonates develop tachycardia, tachypnea, and cyanosis. TOF is the most common heart defect seen beyond infancy. The CCTP should be aware of a hypercyanotic spell, also called a TET spell. TET spells present with marked cyanosis, irritability, tachypnea, pallor, and even a loss of consciousness. The cyanosis involved may be related to a transient increase in the obstruction of the right ventricular outflow tract. The CCTP should expect the following medications/interventions to be ordered, or to follow their agency protocols. Such orders may consist of supplemental oxygen, morphine, propranolol, and placing the patient in a knee-chest position.

Transposition of the great arteries (TGA) is a defect in which the great vessels are reversed **Figure 23-23**. The aorta is connected to the right ventricle, thereby perfusing the body with deoxygenated blood. In addition, the pulmonary artery is connected to the left ventricle, thereby carrying oxygenated blood back to the lungs. This creates a parallel circulation that is dependent on an ASD/PFO, VSD, or PDA to provide mixing of oxygenated and deoxygenated blood; if a defect allows oxygenated blood to eventually reach the systemic circulation, the body can still remain perfused to some extent. Because of a large VSD or ASD, a small percentage of these neonates, about 10%, will not develop cyanosis until the PDA closes. As the PDA closes, these neonates will present with classic signs of cyanosis, especially during episodes of crying or while feeding. Unsupported or uncorrected, this cyanosis will lead to hypoxia and metabolic acidosis.

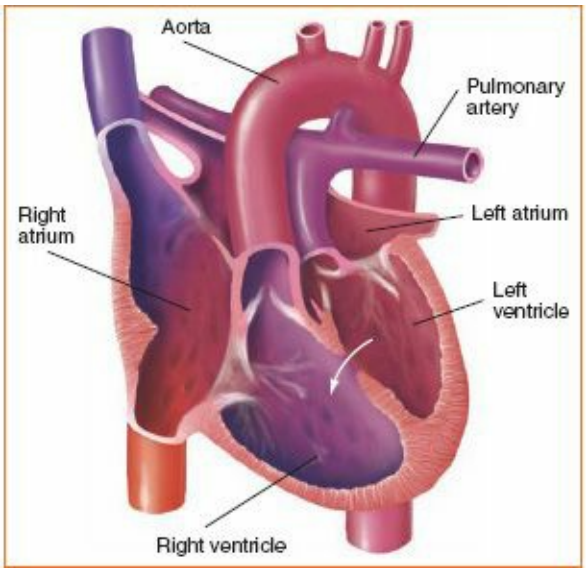

Figure 23-23 Transposition of the great arteries. Note that a ventricular septal defect is shown here as well.

Signs and Symptoms

Cyanotic Cardiac Defects

- Tachycardia
- Tachypnea
- Cyanosis
- TET spell (tetralogy of Fallot)

General Management Priorities

As with any critical care event, management priorities begin with patient assessment and support of the patient's airway, breathing, and circulation. All pediatric patients with congestive heart failure, regardless of age, require diuretics. Fluid boluses that may be required related to hypotension are given at 10 mL/kg. The CCTP must monitor for a situation in which fluid boluses may not be helpful and may increase pulmonary edema related to congestive heart failure. At that point, switching to a vasopressor may be a better option.

Any cardiac lesion that is dependent on the ductus arteriosus requires the administration of a prostaglandin E1 (PGE1 [Prostin VR]) infusion. PGE1 is usually initiated at the sending facility by the pediatric intensive care unit physician. The initial dose is 0.05 to 0.1 µg/kg/min, with a maintenance dose of 0.01 to 0.05 µg/kg/min. Pertinent side effects of prostaglandin are jitteriness, fever, hypotension, and apnea. Concerns for airway management must be considered before transport.

A child who shows persistent signs of hypoperfusion and/or cardiogenic shock may require the inotropic benefits of dopamine and dobutamine administration. These medications can increase peripheral vascular resistance, thus improving blood pressure, perfusion, and cardiac contractility. The neonatal dosage for dopamine (Intropin) is 5 to 10 µg/kg/min; the pediatric dosage is 2.0 to 20 µg/kg/min. The neonatal dosage for dobutamine (Dobutrex) is 2 to 10 µg/kg/min; the pediatric dosage is 2.5 to 20 µg/kg/min.

Transport Management

Cardiac Anomalies

- Assess and support the patient's ABCs.
- Administer diuretics.
- Monitor fluid bolus administration to determine if administration becomes unhelpful and increases pulmonary edema.
- Administer prostaglandin infusion, if required.
- Administer dopamine and dobutamine, if required.

Figure 23-24 Pediatric critical care transport patient with electrocardiographic (ECG) leads placed. A 12-lead ECG is not as common in children.

Pediatric ECG Interpretation

The interpretation of an ECG rhythm in children is different from that in an adult. To decrease the amount of respiratory artifact, it is helpful to avoid placing the ECG leads at the level of the diaphragm. The leads may be placed on the lower abdomen or on the patient's thighs. A 12-lead ECG is not as common in children but is obtained for children with abnormal findings on the rhythm strip, arrhythmias, congenital heart disease, acquired heart disease, chest trauma, or suspected cardiotoxic ingestions **Figure 23-24**.

The first aspect of rhythm strip interpretation is assessing whether the rate is appropriate for the child's age. The next step is evaluating the components of the rhythm, including the PR interval and the width of the QRS complex. Normal values for these components vary with age. A general guideline for children is a PR interval of 0.16 or less and a QRS complex of 0.08 or less. A PR interval of greater than 0.16 indicates a first-degree heart block. A QRS complex of greater than 0.08 indicates a wide complex arrhythmia. In tachyarrhythmia, it may be helpful to increase the ECG monitor sweep speed (typically 25 mm/s) to assess for the presence of a P wave. By increasing the ECG monitor sweep speed, the CCTP can identify subtle nuances in the components of the ECG (P, QRS, T wave).

Renal Disorders

Acute renal failure is defined as profound deterioration of renal function associated with increasing levels of solute (BUN or creatinine). Actual urine volume can vary from normal urine output to oliguria. Causes are generally divided into three categories—**prerenal, intrarenal**, and **postrenal**. Prerenal acute renal failure is caused by decreased perfusion of an intact nephron. Intrarenal acute renal failure is caused by damage of an actual nephron. Postrenal acute renal failure is caused by downstream obstruction with initially intact nephrons. **Table 23-10** includes common causes of acute renal failure.

Prerenal

Prerenal causes are the most common in children and are primarily related to dehydration and decreased renal perfusion. Dehydration results from fluid losses or acute blood loss. The patient may present with a range of signs and symptoms—nausea, vomiting, diarrhea, diabetic ketoacidosis, all forms of shock, and burns. A decreased circulating blood volume results in decreased renal perfusion.

Other causes of decreased renal perfusion may be related to any cardiac condition that results in decreased cardiac output, such as congestive heart failure. In patients with sepsis or burns, there may actually be sufficient or increased extracellular fluid volume as a result of increased vascular permeability, but the intravascular volume is greatly depleted.

Intrarenal

Intrarenal or parenchymal causes are diverse; all etiologies, however, lead to nephron damage and loss of glomerular function as a result of damage to the glomerular basement membrane. Damage to the arterioles and glomerular capillaries may be the result of coagulation, inflammation, barotraumas, or prolonged ischemia.

The proximal tubular cells of the kidneys have high metabolic demands that make them more susceptible to ischemic insults. Nephrotoxins cause sloughing and necrosis of cells in the proximal tubule and ascending loop of Henle, which result in obstruction of tubular blood flow and leakage of fluid into the peritubular space and plasma.

Occlusion of the renal arteries from emboli or thrombosis causes infarction as a result of decreased renal blood flow. Another example includes vascular congestion and hemorrhagic necrosis as a result of renal vein thrombosis.

Hemolytic uremic syndrome (HUS) is one of the most common causes of intrarenal failure seen in infants and children younger than 4 years. The classic triad identified in HUS is microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure (ARF).

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is a serious condition in which the patient develops ATF. It is thought to be caused by several bacterial and viral infectious organisms; however, verotoxin-producing strains of *E. coli* have been associated with 75% of cases. The primary pathology is thought to be related to endothelial cell injury in the renal cortex that leads to localized vascular coagulation and fibrin deposits. As the red blood cells pass through the fibrin strands in the renal vasculature, they become fractured and cause microangiopathic anemia. Thrombocytopenia is the result of localized intravascular coagulation-consuming platelets.

Presentation typically follows a gastroenteritis-type illness, and symptoms include vomiting, abdominal pain, and bloody diarrhea. As the gastrointestinal symptoms subside, the child again becomes acutely ill, presenting with irritability, pallor, and signs of fluid overload, including peripheral and pulmonary edema, hypertension, and petechiae.

TABLE 23-10 Common Causes of Acute Renal Failure

Type of Failure	Causes	Examples
Prerenal (decreased perfusion of an intact nephron)	Hypovolemia	Hemorrhagic shock Dehydration (GI losses and DKA) Insensible losses (prematurity, burns) Sodium and water losses (renal, adrenal, endocrine) Hypoproteinemia
	Hypotension	CHF Decompensated shock Congenital heart disease
	Renal vessel injury with obstruction	N/A
Intrarenal (damage of the actual nephron)	Primary parenchymal disease	Hemolytic uremic syndrome Post-strep (acute) Glomerulonephritis Lupus erythematosus Henoch-Schonlein purpura Pyelonephritis Malignant hypertension
	Acute tubular necrosis	Ischemia (prolonged prerenal ARF) Nephrotoxins (heavy metals, uric acid, NSAIDs, ACE inhibitors, aminoglycoside antibiotics, beta-blockers, diuretics, radiocontrast, myoglobin, organic solvents)
	Large-vessel occlusion	Renal vein thrombosis Renal artery stenosis Thrombosis or emboli
	Congenital abnormalities	Renal agenesis Infantile polycystic kidney disease Bilateral multicystic kidneys
	Neoplasm	N/A
Postrenal (downstream obstruction with initially intact nephrons)	Obstructive uropathy	Posterior urethral valves Prune belly syndrome Neurogenic bladder UPJ syndrome Tumor Nephrolithiasis Renal calculi Trauma to the collecting system Ureterocele

Abbreviations: ACE, angiotensin-converting enzyme; ARF, acute renal failure; CHF, congestive heart failure; DKA, diabetic ketoacidosis; GI, gastrointestinal; N/A, not applicable; NSAID, nonsteroidal

anti-inflammatory drug; UPJ syndrome, ureteropelvic junction syndrome.

Laboratory studies show fragmented red blood cells (RBCs), thrombocytopenia, and evidence of ARF, including elevated BUN and creatinine levels, hyperkalemia, and metabolic acidosis. Urine studies show proteinuria and hematuria with or without anuria.

Treatment of HUS is primarily supportive and includes fluid and metabolic balance, control of hypertension (treatment of diastolic pressure above 120 mm Hg with labetalol, nifedipine, or hydralazine), transfusion of packed RBCs and platelets if required, and aggressive treatment of renal failure with possible dialysis (peritoneal) in the hospital. The prognosis is usually excellent when aggressive treatment is initiated early.

Signs and Symptoms

Hemolytic Uremic Syndrome

- Gastroenteritis-type symptoms: vomiting, abdominal pain, and bloody diarrhea
- After the Gl symptoms subside: irritability, pallor, signs of fluid overload, including peripheral and pulmonary edema, hypertension, and petechiae

Transport Management

Hemolytic Uremic Syndrome

- Support fluid and metabolic balance.
- Control hypertension.
- Transfuse packed RBCs and platelets if required.

Signs and Symptoms

Acute Poststreptococcal Glomerulonephritis

- Gross hematuria with urine the color of tea or cola
- Congestive heart failure
- Peripheral and pulmonary edema
- Hypertension

Transport Management

Acute Poststreptococcal Glomerulonephritis

- Restrict fluids.
- Administer loop diuretics.

Acute Glomerulonephritis

Acute glomerulonephritis (AGN) is a histopathologic diagnosis that is associated with edema, hypertension, and hematuria. AGN results from the deposits of circulating immune complexes in the kidney basement membrane, which ultimately causes reduced glomerular filtration. This syndrome can be induced by a variety of organisms, but the most common is group A beta-hemolytic streptococci. **Acute poststreptococcal glomerulonephritis (APSGN)**, or AGN following an infection by streptococci, can occur following a skin infection or a pharyngeal infection. APSGN occurs most commonly in school-aged children and more commonly in males than females.

The pathology of APSGN is thought to be an activation of the complement pathway leading to inflammation that causes glomerular damage. This occurs as a result of immune complex deposition in the basement membrane of the glomeruli.

Presentation typically manifests 1 to 2 weeks after the streptococcal infection, and a classic symptom is gross hematuria with urine the color of tea or cola (soda pop). The severity of presentation runs the spectrum from mild and not requiring hospitalization, to severe oliguria with symptoms of overload including congestive heart failure, peripheral and pulmonary edema, and hypertension.

Laboratory urinalysis values reveal RBCs and proteinuria. White blood cells represent glomerular inflammation and not pyelonephritis (inflammation of the kidney linings). In addition, expected evidence of renal insufficiency includes elevated BUN and creatinine levels, hyperkalemia, hyponatremia, and acidosis. Elevated antibody titers (or the presence and amount of antibodies in the blood) of streptococci confirm APSGN.

Treatment of severe APSGN is primarily supportive and includes fluid restriction of IV solution to avoid promoting peripheral and pulmonary edema. Loop diuretics are useful in treating mild hypertension, edema, and fluid overload. The prognosis is good, and full recovery is expected in more than 98% of all children.

Acute Tubular Necrosis

Acute tubular necrosis (ATN) is a condition that results in damage to the tissue of the kidneys' tubules. Like most renal pathologies, it can have numerous etiologies; however, the most common is renal ischemia precipitated by hypovolemia. Tubular damage can also occur following a toxic insult, such as heavy metal poisoning or as a result of myoglobin or hemoglobin accumulating in the tubules following a severe crush injury, burn, or hemolytic crisis.

With ATN, the renal tubular cells die when they do not get enough oxygen or if they are exposed to a toxic drug. Injury of the tubular cells is most prominent in the straight portion of the proximal tubules and in the loop of Henle. In addition to decreased filtration, there is also an increase of casts and debris obstructing the tubule lumen that causes a leak of filtrate through the damaged epithelium. In addition, decreased perfusion also leads to diminished production of vasodilators such as nitric oxide, leading to further vasoconstriction and hypoperfusion.

ATN is clinically defined in three phases. The first period is the oliguric phase, during which severe oliguria lasts approximately 10 days. Renal recovery of ATN is highly unlikely if the oliguria or anuria persists longer than 3 to 6 weeks. The second phase is the diuretic phase in which there is passage of large volumes of isothenuric urine containing sodium levels of 80 to 150 mEq/L. Finally, the third phase is the recovery phase in which signs and symptoms resolve rapidly as a result of regeneration of tubular epithelial cells. However, polyuria may be present for days to weeks, although the mechanism of the diuresis is not completely understood.

Transport treatment usually consists of fluid and electrolyte replacement. Ultimately dialysis is required to remove the toxins.

Signs and Symptoms

Acute Tubular Necrosis

- Severe oliguria lasting approximately 10 days
- Diuretic phase: passage of large volumes of isothenuric urine
- Recovery phase: signs and symptoms resolve rapidly
- Polyuria

Transport Management

Acute Tubular Necrosis

- Replace fluids and electrolytes.

Postrenal

Postrenal or obstructive failure has numerous etiologies. In most cases, unilateral obstructive abnormalities do not result in failure. Flank and/or abdominal pain is often present. Prolonged, unrelieved obstruction causes irreversible parenchymal damage because of infection and increased hydrostatic pressure. Obstruction of urine outflow in the renal system causes an increase in hydrostatic pressure at the proximal tubule and glomerulus, resulting in a decrease in glomerular filtration and renal function.

Complications

There are five potential life-threatening events that can occur in acute renal failure. The first event includes electrolyte imbalances such as hyponatremia, hypocalcemia, and hyperkalemia. **Hyponatremia** is most often dilutional (low sodium levels as a result of excessive fluid intake) secondary to volume overload, is asymptomatic, and is simply treated with fluid restrictions. Severe hyponatremia may cause seizures and is managed by infusing a hypertonic (3%) saline solution.

Hypocalcemia is caused by hyperphosphatemia and is not usually treated unless symptoms such as tetany, seizures, or decreased cardiac contractility are present. Rapid correction of hypocalcemia may result in the deposit of calcium salts in body tissues. Treatment includes oral dosing of calcium carbonate or, in emergent cases, cautious administration of IV calcium gluconate (10%) at a dose of 50 to 100 mg/kg).

Hyperkalemia has the potential to cause life-threatening arrhythmias by producing membrane excitability. ECG changes may include a peaked T wave, a widened QRS complex, and eventual bradycardia. An elevated serum potassium level is treated based on lab values and the presence of ECG abnormalities. Management may include careful monitoring and the removal of potassium chloride from IV fluids to pharmacologic treatments and, in rare circumstances, the use of dialysis. Possible medications include the following:

- **Kayexylate (sodium polystyrene sulfonate resin)**: An ion exchange resin that acts in the colon or ileum. Usual dosing is 1 g/kg every 2 to 4 hours and may be mixed with sorbitol.
- **Calcium gluconate:** Has no direct effect on the serum potassium but stabilizes the myocardial membrane and ventricular rhythm by changing the cell action potential. Monitor the heart rate and stop the infusion if the child's pulse rate drops by more than 20 beats/min.

- **Glucose and insulin:** Potassium can be moved intracellularly by administering a glucose infusion of 5% dextrose in water or 5% dextrose and 0.25 normal saline and a concurrent insulin infusion. The goal is to maintain the glucose level between 120 and 300 mg/dL. This has a rapid effect on lowering the serum potassium level; however, careful assessment of glucose blood levels is necessary to prevent hypoglycemia.
- **Sodium bicarbonate:** Sodium bicarbonate can be used even in the absence of acidosis. Calcium gluconate is not compatible with $NaHCO_3$ and IV lines must be flushed prior to administration.
- **Albuterol:** Nebulized albuterol causes a shift of extracellular potassium into the cell and can lower the serum potassium by 1.0 to 1.5 mEq/L. Albuterol also helps to protect against insulin-induced hypoglycemia.

Another life-threatening complication related to acute renal failure is related to volume losses or pulmonary edema and fluid overload. If it has been determined that there is prerenal ARF related to volume losses, immediate fluid replacement should occur to prevent possible progression to ATN. Initially, a fluid bolus of 20 mL/kg may be administered for a total of three infusions (3 doses) using a crystalloid solution. Once the source of the loss is treated and hypovolemia is corrected, maintenance fluids are initiated. The degree of fluid restriction depends on whether the patient is anuric, oliguric, or nonoliguric.

Volume overload may be best managed with the aid of a central venous pressure monitor, which adequately measures fluid resuscitation to avoid overhydration. The use of diuretics is controversial except in cases of ARF secondary to myoglobinuria or hemoglobinuria. In these cases, furosemide (1 mg/kg) or mannitol (0.5 to 0.75 mg/kg/dose) may be used. The use of furosemide in the presence of fluid overload may be therapeutic; in cases of euvolemia and oliguria, furosemide may stimulate urine production and filtration of waste products and improve renal function by increasing blood flow to this organ.

Hypertension that may progress to hypertensive encephalopathy is also life threatening. Hypertension is usually caused by sodium and water retention. Hypertensive encephalopathy is hypertension associated with neurologic symptoms such as nausea, vomiting, headache, visual changes, seizures, and mental status changes. As with any hypertensive crisis, it is important to aim for a MAP reduction of 15% to 25%. A more precipitous or pronounced drop in MAP that returns the child to normal blood pressure parameters may lead to hypoperfusion of the end organs. Septic shock may occur secondary to obstruction and/or infection.

Signs and Symptoms

Meningococcal Infections

- Fever
- Chills
- Nuchal rigidity
- Vomiting
- Photophobia
- Headache
- Back pain
- Seizures (in older children)

Infants and Young Children

- Poor feeding
- Marked irritability and agitation
- Characteristic high-pitched cry with bulging fontanelles
- Poor cry
- Decreased muscle tone
- Jaundice
- Weight loss
- Hypothermia
- Apnea
- Cyanosis
- Seizure activity

Transport Management

Meningococcal Infections

- Ensure that standard universal precautions are followed.

Meningococcal Infections

The presentation of the pediatric patient with a meningococcal infection depends largely on the age of the child, the type of organism, and the present state of health of the child. The onset of symptoms is typically abrupt, with hallmark signs that include fever, chills, nuchal rigidity, vomiting, photophobia, headache, back pain, and seizures in older children. Infants and young children may present with some of the same symptoms as the older child, but also may experience poor feeding, marked irritability and agitation, and a characteristic high-pitched cry with bulging fontanelles. The CCTP may test for or inquire whether the patient has a positive Brudzinski sign and Kernig sign on arrival to the bedside.

Kernig sign is the inability of the patient to straighten his or her leg with the hips flexed at a right angle. To evaluate for this condition, have the patient lie supine with the legs flexed at the hip and the knees flexed; the CCTP then tries to extend the knees. An abnormal response is present if there is pain and resistance to knee straightening (positive Kernig sign). If pain and resistance are present bilaterally, then meningeal irritation is likely present.

Brudzinski sign is flexion of the legs and thighs with forceful flexion of the neck onto the chest. Testing for this condition should not be performed if a cervical spine injury is suspected. Have the patient lie supine while the examiner flexes the head and neck in an attempt to have the chin touch the chest. An abnormal response includes flexion of the legs and hips during this process (positive Brudzinski sign).

The neonate patient may be extremely difficult to assess, and it is also difficult to make the diagnosis of meningococcal infection in a neonate because the symptoms are usually vague in nature and challenging to differentiate from other septic etiologies. The CCTP should inquire about the infant's feeding and sucking ability. The infant may also present with a poor cry, decreased muscle tone, jaundice, weight loss, hypothermia, apnea, cyanosis, and seizure activity.

Standard universal precautions should be taken with all pediatric patients with a suspected diagnosis of meningococcal infections, considering the close proximity of the patient/provider depending on the mode of transport.

Trauma

Trauma is the leading cause of death of children from 6 months of age through young adulthood. The most common pediatric injuries related to trauma are the result of motor vehicle (passenger), pedestrian, bicycle, submersion, burn, and firearm injuries. The systematic approach taken in the assessment and management of pediatric trauma patients is the same as in the adult population.

There are two different resources for CCTPs when assessing the severity of a pediatric patient. The most common is the GCS score that has been altered for pediatric patients, presented earlier in this chapter. The pediatric trauma score is another resource that accounts for weight, airway status, central nervous system (CNS) status, systolic blood pressure, fractures, and wounds.

Reprinted from *J Pediatr Surg*. 22(1), Tepas JJ III, Mollitt DL, Talbert JL, Bryant M. The pediatric trauma score as a predictor of injury severity in the injured child, 14–18, Copyright 1987, with permission from Elsevier (http://www.sciencedirect.com/science/journal/00223468).

A value is calculated for each of the components, as shown in **Table 23-11**. The values are then added to determine the total score. Scores are categorized as follows:

- A score of 9 to 12 indicates minor trauma. Follow local guidelines/protocols for treatment.
- A score of 6 to 8 indicates a potentially life-threatening condition. Consider transporting to a trauma center.
- A score of 0 to 5 indicates a life-threatening condition. Transport to a trauma center.
- A score of less than 0 indicates a condition that is usually fatal. This patient needs to be transported to the nearest trauma center equipped to care for this critically ill pediatric trauma patient.

Head Injuries

Head trauma is the leading cause of morbidity and mortality in children and accounts for 70% to 80% of all pediatric deaths from trauma. The death rate from head injury is five times higher than the next most common cause of pediatric mortality—leukemia. The main source of head trauma is motor vehicle accidents involving passengers, pedestrians, or bicyclists. Less common sources of head injury include sports-related injuries, falls, and abuse.

Injuries to the brain are traditionally evaluated as primary or secondary injuries. Primary injuries that result from penetrating, rapid deceleration or rotational injuries occur at the moment of impact and cause physical and mechanical destruction of brain tissue; they can include parenchymal injury, diffuse axonal injuries, and cerebral edema. In comparison with primary injuries, many factors may improve or worsen secondary brain injury, which involves a complicated cascade of cellular destruction. The primary brain injury causes a certain amount of tissue and cellular death. There may be injured areas of the brain (penumbra) surrounding the dead tissue that may remain viable. These injured areas are vulnerable to hypoxic, ischemic, and inflammatory responses. Aggressive management to prevent hypoxia, hypotension, and progressive edema is required to protect this unstable brain tissue. If

uncorrected, secondary brain injury leads to irreversible brain damage and death.

Increased Intracranial Pressure

Increased intracranial pressure (ICP) can be from numerous etiologies. The most common cause of increased ICP in pediatric populations is related to trauma or a failed cerebral spinal fluid shunt.

Possible signs and symptoms of increased ICP include headache, irritability, fever, dizziness, nausea, projectile vomiting, lethargy, visual changes, unsteady gait, high-pitched cry, bulging fontanelle, pupillary dilation, seizures, coma, and Cushing's triad. The symptoms become more progressive and severe as the ICP rises.

Treatment modalities may include inserting a monitor to measure ICP. This treatment is more pertinent for interfacility transports as opposed to prehospital transports. A ventricular catheter is placed in the ventricles connected to an external ventricular drain. This drain evacuates fluid within the ventricle and measures objective ICP. A subarachnoid bolt placed in the subarachnoid space can also measure ICP. This bolt cannot drain fluid and does not sound an alarm for increased pressure. Normal ICP is 0 to 10 cm H_2O. An acceptable ICP is usually below 15 to 20 cm H_2O. Cerebral perfusion pressure should be a minimum of 50 to 60 mm Hg for adequate brain perfusion.

Management goals include the following:

- Mild hyperventilation ($PaCO_2$ between 30 and 35 mm Hg)
- Maintain the cerebral perfusion pressure at greater than 50 to 60 mm Hg (increased MAP to maintain adequate cerebral perfusion pressure)
- Place the stretcher so that the patient's head is raised 15° to 30° to promote cerebral venous drainage
- Normothermia or mild hypothermia to decrease metabolic rate
- Administer mannitol (0.5 to 0.75 mg/kg/dose) (must administer with a filter)

Signs and Symptoms

Increased Intracranial Pressure

- Headache
- Irritability
- Fever
- Dizziness
- Nausea
- Projectile vomiting
- Lethargy
- Visual changes
- Unsteady gait
- High-pitched cry
- Bulging fontanelle
- Papillary dilation
- Seizures
- Coma
- Cushing's triad

Transport Management

Increased Intracranial Pressure

- Maintain cerebral perfusion pressure at greater than 50 to 60 mm Hg.
- Position the patient so the head is raised 15° to 30°.
- Maintain a normal or slightly elevated temperature.
- Administer mannitol.
- Manage pain.

- Pain management
- Possible coma from barbiturates (decreases the cerebral metabolic rate and oxygen consumption)

Concussion

A **concussion** is the most commonly seen head injury in the pediatric population. It is described as a transient interruption of normal neurologic function. There may be a brief loss of consciousness and posttraumatic amnesia. The CCTP's role in transporting a pediatric patient with a concussion is to provide supportive measures while en route to a receiving facility. As with any neurologic injury, it is necessary to frequently perform and document a neurologic assessment (baseline and continuous) during the transport. The patient's pain level and tolerance of the transport process should also be documented.

Transport Management

Concussion

- Provide supportive measures.
- Frequently perform and document a neurologic assessment (baseline and continuous).
- Document the patient's pain level and tolerance of transport.

Cerebral Contusion

A **cerebral contusion** most commonly occurs at the point of impact and/or on the side opposite the impact, such as with a coup-contracoup injury. A cerebral contusion is a focal hemorrhage in the brain that may be associated with a concurrent concussion.

Epidural Hematoma

Epidural hematomas typically include arterial bleeding from contusions or lacerations, most commonly of the middle meningeal artery. This blood vessel is located just outside the dura and may be torn when there is a parietal skull fracture. Another cause of epidural bleeding may be from damage to the diplotic veins in the posterior cranial fossa, although the most common cause is a lateral temporal fossa injury. Accumulation of blood in these injuries does not "touch" the brain tissue.

The classic pattern of an epidural hematoma includes a lucid period followed by rapid neurologic deterioration; however, this classic pattern only occurs in a minority of pediatric patients with an epidural hematoma. Children may never have a loss of consciousness or a lucid period.

Subdural Hematoma

A subdural hematoma is five to ten times more common than an epidural hematoma, especially in infants.

This injury is caused by shearing forces that slide the fragile brain tissue over the rough base of the skull. The hematoma occurs just below the dura, and as a result, blood comes into contact with brain tissue. Subdural hematomas are usually caused by a disruption of bridging veins or venous sinus beneath the dura. A subdural hematoma can be a result of child abuse such as shaken baby syndrome. Shaking an infant violently causes acceleration-deceleration forces that shear the bridging veins in the subdural space.

Risk Assessment and Management

Many children who experience closed head trauma may have only minor injuries. Children who have low-risk injuries are often asymptomatic, with normal neurologic findings on exam. Management at home with responsible adult supervision may be all that is necessary.

Children with moderate-risk injuries will present with an altered level of consciousness, progressive headache, or vomiting and may have an associated injury. They often require basic trauma care, including basic wound management and cervical spine immobilization with radiologic evaluation.

Children with high-risk injuries will present with a depressed level of consciousness and possible neurologic deficits or signs of increased ICP. These children often require immediate surgical interventions. Good patient outcome relies on early recognition and treatment, including an early consultation with a neurosurgeon for children with high-risk injuries.

As with any traumatic injury, initial management involves stabilization of the cervical spine, airway, breathing, and circulation. If clinical conditions warrant, ET intubation should be implemented. Proper sedation and analgesia should be administered to prevent spikes in ICPs.

With manual ventilation of the child, hyperventilation should be avoided. Only in impending herniation should short, intermittent episodes of hyperventilation be used. Although routine hyperventilation is not recommended for treatment of increased ICP, it may be used emergently to transiently decrease cerebral blood flow and blood volume. The benefit of creating “more room in the vault” is short lived because decreased blood flow causes hypoxia to already injured brain tissues.

Any source of bleeding in the head, including the brain, face, mandible, and scalp, can cause significant blood loss in the pediatric patient. Hypovolemia is of great concern, particularly in infants, who have a proportionally larger amount of blood volume in their heads. Even in older children, an open scalp laceration can be a significant source of blood loss that needs to be stopped while administering aggressive fluid resuscitation. The treatment goal is euvolemia because cerebral perfusion pressure depends on the MAP (CPP = ICP – MAP). Maintaining the patient’s head at 30° and midline also improves venous outflow from the head.

The child’s mental status may be altered for a number of reasons. The most life-threatening situation involves herniation syndromes in which increased pressure in the cranial vault causes the brain to shift. The brain may be shifted laterally or down through the foramen magnum. Possible treatments may include short-term hyperventilation or use of an osmotic diuretic (mannitol, 0.5 to 0.75 mg/kg/dose) or a loop diuretic (furosemide) to decrease the volume of water or cerebrospinal fluid (CSF) in the cranial vault.

Spinal Cord Injuries

Of all children who experience traumatic injuries, 3.8% have an injury to the spine and/or spinal cord. Although this is a relatively small incidence, mortality related to spinal cord injury in children is more than twice that in adult populations. Serious neurologic injuries are more common in older children and are often associated with sports injuries, diving injuries, or falls. The incidence of spinal cord injury dramatically increases in adolescents between 15 and 18 years of age. Of all sports-related injuries and reported spinal cord injuries, 30% to 50% involve the cervical spine and result in quadriplegia and/or severe disability.

Injuries in children younger than 8 years are most commonly found in the occiput (C1) to C3 area, and older children and adults tend to have injuries in the lower C-spine **Figure 23-25**. Because of the anatomic spine differences between adults and children, children are more prone to sustain cervical spine injuries of greater severity. By comparison, older children and adults incur injuries that are more evenly distributed throughout the cervical and thoracic spine.

Similar to brain injury, spinal cord injury may occur with a primary insult and then a secondary insult. The primary insult occurs from hyperflexion (most commonly), extension, rotational injury, or compression injuries. The secondary injuries occur from biochemical reactions, including oxygen-free radical production that damages endothelial cells within the brain, ion fluxes involving extracellular potassium, ischemia, or edema.

The most important intervention in the treatment of children with known or suspected spinal cord injury is proper immobilization. Initially, the child's cervical spine is secured manually while the airway is being assessed. Rigid infant and pediatric collars must be available in a range of sizes to ensure use of the proper size. A properly fitting cervical collar prevents flexion, extension, and head rolls or blocks prevent lateral head movement **Figure 23-26**. Ideally, pediatric backboards should be used because they allow for the relatively large size of the child's head by providing an occiput cut-out or head well. If a pediatric backboard is not available, the child may be placed on the standard backboard and neutral neck extension is provided by padding the child's torso to lift it relative to the head. The child should be placed on the backboard using a log roll technique **Figure 23-27**. One provider maintains manual stabilization of the head and neck while a minimum of two providers log roll the child. Care is taken to control movement of the torso completely.

When the child is confirmed to be in a neutral position, the child is secured to the backboard. Secure the child with straps over a minimum of three anatomic points, such as the thighs, pelvis, and shoulders. Care should be taken not to secure the child with straps over the diaphragm and abdomen because the straps could interfere with the muscles needed for breathing and may increase the potential for vomiting. Also, the shoulder straps need to be placed over the child's shoulder girdle and not the chest because this will also interfere with respirations. An infant would be secured with a pedi-mate or other type of restraining device.

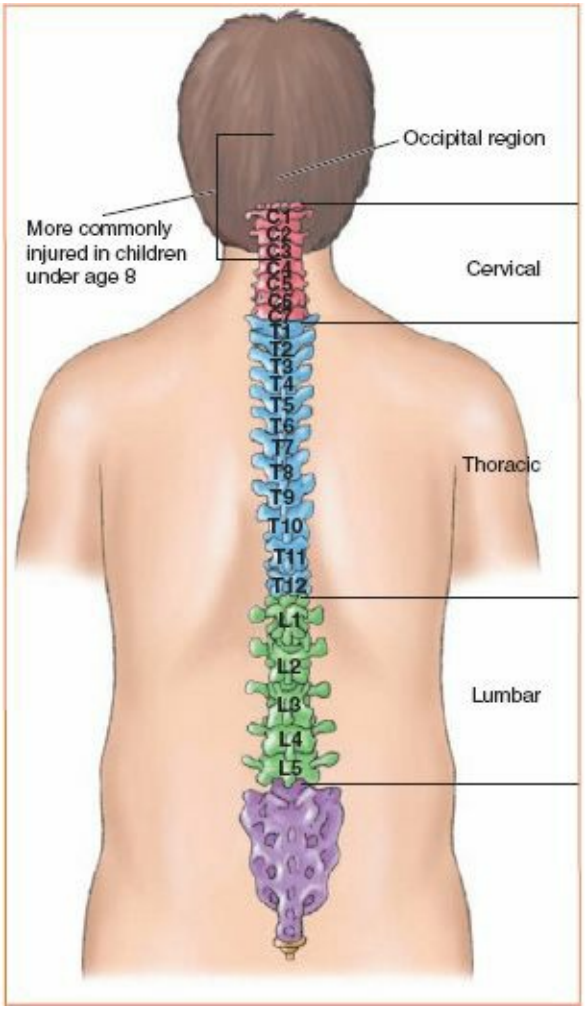

Figure 23-25 Injuries in children younger than 8 years are most commonly found in the occiput region to C3 area. Older children and adults tend to have injuries in the lower C-spine.

Figure 23-26 Use a properly fitting cervical collar and head rolls or blocks to stabilize the pediatric patient's spine.

Figure 23-27 Place the child onto the backboard or immobilization device using the log roll technique.

After the child's body is secured, the head is secured with tape, straps, and head rolls. After the head is secured to the backboard, manual stabilization of the cervical spine may be released. Reassess the child's neurologic status, including gross motor and sensory function. Frequent assessment must be made during transport to detect the possibility of ascending lesions. For example, an older child may initially have a cervical spine injury at C6, thereby having no respiratory involvement. During transport, the C6 lesion could ascend up to the level of C3. This progression of the spinal cord injury would now affect the child's ability to maintain respiration.

Methylprednisolone has been used clinically to minimize the progression and treat the inflammation of spinal cord injuries. Limited studies demonstrate documented benefits; the treatment carries a low risk, however, and any benefit obtained is desired. The drug regimen includes 30 mg/kg IV over 15 minutes followed in 45 minutes by a continuous infusion of 5.4 mg/kg/h for 23 hours. Initiation of this treatment should be within the first 8 hours to improve the chance of neurologic recovery.

Because children have relatively weak spinal ligaments and increased mobility of the spine, they may sustain damage to the spinal cord and spinal ligaments without damage to the spinal vertebrae. This damage is called **SCIWORA**, which is an acronym that stands for spinal cord injury without radiographic abnormalities. SCIWORA should be suspected when there are clinical signs or symptoms of spinal cord injury in the presence of normal cervical spine radiographs. This condition is often associated with a poor neurologic outcome, a high proportion of complete neurologic injuries (those in which there is no sensory or motor function below the level of injury), and a high susceptibility of delayed neurologic deficit. If a child reports pain, has difficulty with range of motion, or is unresponsive, spinal immobilization should remain in place until additional studies can confirm no injury or until a skilled pediatric specialist clears the spine.

Transport Management

Spinal Cord Injuries

- Manually secure the child's cervical spine while assessing the airway.
- Immobilize the child on a pediatric or standard backboard; secure the child's body first, then the head.
- Release manual stabilization of the cervical spine.
- Reassess the child's neurologic status, and continue to assess frequently during transport.

Breathing Abnormalities

Trauma and the effects of trauma may also cause upper airway obstruction. Facial trauma and soft-tissue swelling can block the upper airway. There may be direct trauma to the upper airway in the example of hanging injuries or "clothes-line" injuries, or there may be secondary injury related to the trauma. Hanging injuries occur in the toddler population from crib accidents and window cords. Hanging injuries may also occur in adolescents as a method of suicide, or during a "choking game," in which an individual at the point of near strangulation escapes to enjoy an altered mental state. A clothes-line injury is most common in ATV (all-terrain vehicle) crashes, and occurs when the patient in motion is struck in the anterior neck by a stationary object (ie, a clothes-line wire).

Head injury may cause a decrease in the level of consciousness and result in the patient's tongue

obstructing the airway. Life threats that may be encountered include simple pneumothorax, tension pneumothorax, open pneumothorax, hemothorax, and flail chest. Flail chest is unusual in pediatric trauma because rib calcification is poor, except in adolescents.

Management of these injuries in the pediatric population is usually exactly the same as with adult patients. The following sections discuss only the differences in managing these injuries in pediatrics. For a complete discussion of these injuries, refer to Chapter 10.

Transport Management

Tension Pneumothorax

- For older children and adolescents, insert a 14- to 16-gauge angio-needle in the second to third intercostal space, midclavicular on the affected side.
- For infants, insert a 21- to 23-gauge butterfly needle anteriorly at the fourth intercostal space. Attach to a stopcock and a 20-mL syringe. Empty the chest of air or fluid until the infant's condition improves.

Tension Pneumothorax

Treatments for tension pneumothorax include a 14- to 16-gauge angio-needle decompression for older children and adolescents in the second to third intercostal space, midclavicular on the affected side **Figure 23-28**. For infants, treatment is a 21- to 23-gauge butterfly needle inserted anterior at the fourth intercostal space (nipple line). The needle is then attached to a stopcock and a 20-mL syringe. The chest is emptied of air or fluid until the infant's condition improves.

Hemothorax

Treatment for a hemothorax includes inserting an appropriately sized chest tube in the fifth intercostal space, anterior, and midaxillary. Ideally, the chest tube is attached to a fluid collection or suction system that allows for autotransfusion. Large amounts of blood can accumulate within the pleural cavity; as long as the blood does not become contaminated by an open wound, it can be returned to the child's circulation. This relieves the concern about draining too much blood from the pleural space. If autotransfusion collection is an option for the CCTP, then it should be used to reduce the risk of donor transfusions. If autotransfusion collection is not possible, there is controversy in the literature regarding how much blood should be accumulated before clamping the thoracostomy tube. Advanced Trauma Life Support® (ATLS) guidelines state that approximately 20% of total blood volume is suggested. Pediatric patients have a circulating blood volume of 80 mL/kg. Clamping the chest tube is a temporary measure until an open thoracotomy is performed. Adequate fluid resuscitation with blood or crystalloids, without overload, must also be considered to prevent and treat the impending hypovolemic shock.

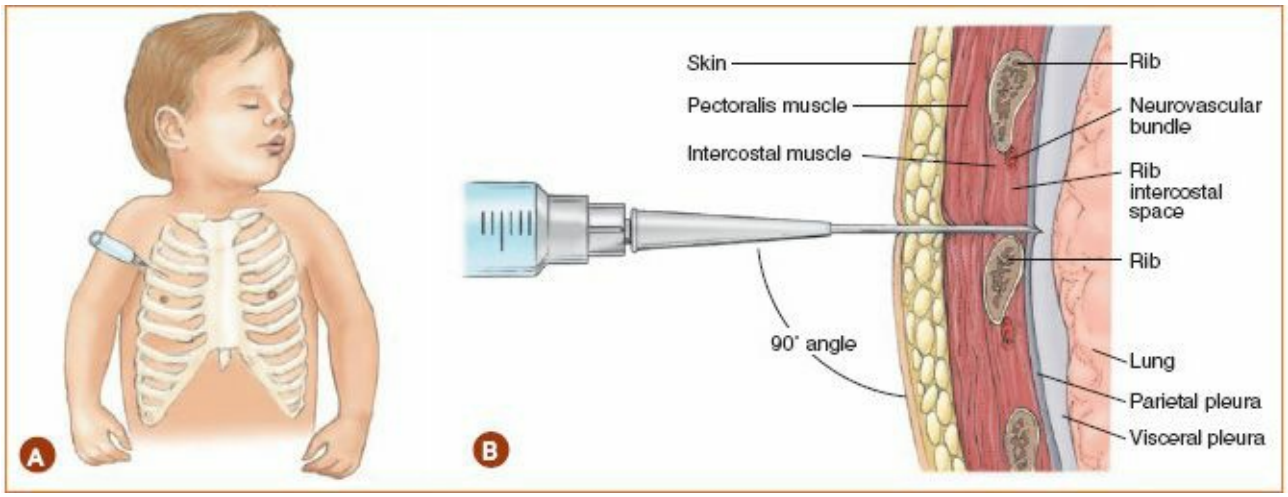

Figure 23-28 Decompression of a tension pneumothorax. **A.** The needle should be inserted into the second or third intercostal space, midclavicular on the affected side. **B.** Insert the needle at a 90° angle and listen for the release of air.

Transport Management

Hemothorax

- Insert an appropriately sized chest tube in the fifth intercostal space, anterior, and midaxillary.
- If available, attach the chest tube to a fluid collection or suction system that allows for autotransfusion.
- If autotransfusion collection is not possible, follow ATLS guidelines regarding how much blood should be accumulated before clamping the thoracostomy tube.
- Fluid resuscitation with blood or crystalloids may be necessary.

Circulation Abnormalities

Life threats related to circulation that must be assessed include bleeding, hypovolemia, arrhythmias, and pericardial tamponade. Hypovolemia and arrhythmias were discussed earlier in this chapter, and bleeding management follows the same principles and procedures learned in earlier training. Pericardial tamponade is a hemodynamic emergency, usually the result of a blunt or penetrating injury to the chest and, more specifically, the sternum.

Acute pericardial tamponade is assessed clinically, typically with a history of trauma, tachycardia, hypotension, jugular venous distention, and muffled heart tones. Muffled heart tones may be difficult to assess in the transport setting. Treatment in the field, pericardiocentesis, may also be challenging. Pericardiocentesis treatment involves inserting a 14-to 20-gauge IV or spinal needle to a syringe. The needle is inserted just inferior to the xiphoid process and advanced slowly toward the left shoulder. When the needle pierces the pericardial sac, blood is aspirated. Removing as little as 15 to 20 mL of blood may improve the patient's condition, because it allows improved cardiac filling and cardiac output. This intervention may be beyond the scope of some CCTPs depending on protocol. It is further recommended that this procedure not be done in a moving ground or air vehicle. The appropriate treatment during transport is a rapid IV fluid bolus (20 mL/kg of a crystalloid solution for a total of three infusions, then blood products or colloids at 10 mL/kg). An IV fluid bolus greatly increases preload and improves cardiac filling and cardiac output.

Transport Management

Circulation Abnormalities

- Administer a rapid IV fluid bolus of a crystalloid solution for a total of three infusions, followed by blood products or colloids.

Fractures

As mentioned earlier, children have less calcified bones. The immature bones of children are more porous than those of adults and tend to respond to kinetic forces by buckling rather than fracturing. Therefore, if the forces are great enough to cause a fracture, investigation of underlying organ injury is warranted. However, with reduction of misaligned structures and immobilization by either the physician or the CCTP (depending on agency protocol and extremity vascular status), most of these injuries have excellent outcomes.

The ligaments in children are stronger and more resilient to tensile forces, thereby providing strength to the joints. As mentioned earlier, this is the reason that dislocations are more rarely found in pediatric populations compared with adult populations.

The pediatric spine has incomplete ossification and epiphyseal growth plates and may have hypermobility. As a result, the cervical spine in children is highly flexible and young children tend to have avulsions rather than fractures. However, this hypermobility does not always protect the child's cervical spine. Compounding factors are that children have relatively large, heavy heads with weak neck muscles. Rapid deceleration injuries resulting in hyperflexion and torsion forces are most commonly seen in children.

Pelvic fractures can be responsible for massive internal hemorrhaging that is difficult to quantify and will lead to profound deterioration of the pediatric patient.

Although they are falling out of fashion, the PASG is one option for stabilizing a pelvic fracture for transport. Depending on the CCTP's protocols, a sheet can be wrapped around the pelvis or a commercial device known as a SAM splint can be used to stabilize an unstable pelvis and prevent further vascular and neurologic damage while en route to the trauma center. Remember that with pelvic fractures, a significant amount of blood can be located in the retroperitoneal cavity. The CCTPs must be prepared for a rapid decline in the patient's condition as a result of this blood loss and have crystalloids and colloids available.

A femur fracture, although rare in young children, is an injury that can lead to a significant amount of blood loss in the pediatric population **Figure 23-29**. Older children and adolescents are most at risk for femur fractures. The two most common causes are motor vehicle collisions and pedestrian injuries. For a femur fracture in the very young child who has not started walking, traction splinting may not be necessary as a result of the underdeveloped quadriceps muscles. In children, these muscles will not contract and cause the pain commonly seen in older children and adults. Other techniques for immobilization for transport include an air splint, rigid splint, PASG, or simple padding using pillows or blankets **Figure 23-30**. The ultimate goal is patient comfort; remember crystalloids for fluid replacement of a 20-mL/kg bolus and of a 10-mL/kg colloid bolus, as well as adequate pain management with analgesics and sedatives.

Figure 23-29 Radiograph of a femur fracture.

Figure 23-30 Transporting a child with a femur fracture can be accomplished using a portable traction splint like the one pictured. Distal sensory and motor function should be checked frequently during transport of these patients.

Transport Management

Fractures

Pelvic Fracture

- Stabilize the pelvic fracture.
- Be prepared to administer crystalloids and colloids if necessary.

Femur Fracture

- Immobilize the injury.
- Administer analgesics and sedatives as necessary for pain management.
- Administer crystalloids and colloids for fluid replacement.

Figure 23-31 With orthopaedic injuries from motor vehicle crashes, children experience similar injury patterns as adults.

Orthopaedic Injuries

Anatomic differences in relation to injury patterns are the main differences when dealing with the pediatric population and orthopaedic injuries. In vehicles, children younger than 8 years or weighing less than 80 lb should be in some sort of weight-appropriate child restraint system. These seats are designed to decrease morbidity and mortality when used correctly. Because newer vehicles are equipped with front passenger airbags, current National Highway Traffic Safety Administration recommendations (and laws in many states) require that children in this group occupy the rear seat of the vehicle (if equipped). A child who weighs less than 40 lb, depending on the make and model of the car seat, must be restrained in a 4-point harness. The goal of the booster seat is to protect the older child from damage caused by the seatbelt being improperly positioned over the child's shoulder. The booster does what it says; it boosts the child up so that the vehicle's seatbelt is in the correct position across the child's chest and resting over the clavicle. The CCTP should still be aware that children will experience similar injury patterns as adults **Figure 23-31**. These seats are designed to decrease injury but not prevent injury completely.

The main differences with regard to a pedestrian crash of an adult vs a child are the injury patterns that will be seen. As discussed in Chapter 10, an adult's primary injuries are to the pelvis and lower extremities; however, the pediatric patient's most common injuries involve the head and chest. A child is commonly run over by the vehicle or thrown by the impact. It is important for the CCTP to find out what occurred and be alert for these injury patterns.

Burns

Burns are the second most common cause of accidental death in children, second only to injuries from motor vehicle collisions. The peak incidence of burn injuries occurs in children between 1 and 5 years of age. Most of these injuries involve burns from scalding liquids. The incidence of house fires has decreased in recent history, but they still account for half of all burn-related deaths. Other sources of burns include chemical, electrical, and contact burns. Children have a higher mortality rate than adults for the same total body surface area and severity of the burn injury **Figure 23-32**.

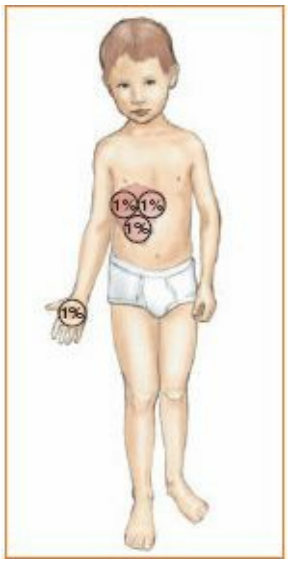

Figure 23-32 Use the size of the child's palm to estimate the burned body surface area. The palm generally represents 1% of the child's body surface area.

Direct thermal, chemical, or electrical injury causes cell death. There is immediate release of tissue local mediators such as histamine. These mediators are responsible for the profound increase in vascular permeability. This vascular permeability is further increased by the release of serotonin and prostaglandins. As the intravascular volume moves into the interstitial spaces, profound peripheral edema is noted. This edema not only promotes tissue ischemia to already damaged tissue, it also causes a relative hypovolemia within the intravascular space. Left unresolved, profound hypovolemic shock ensues for patients experiencing moderate to severe burns. The final depth of a burn may be delayed for 4 to 5 days because the ischemic injury may extend 3 to 7 times more deeply than the level of the original injury.

Regardless of the degree of burn, initial burn therapy always begins with removing the source of the burn. Prompt removal of burning or scalding clothing should occur. Remove constrictive jewelry such as rings, earrings, or necklaces.

Small area burns may be initially cooled with tepid water for a few minutes only and then a moist dressing may be applied. However, larger surface area wounds should have dry sterile dressings applied, because the risk of hypothermia is high in pediatric burn patients. Skin integrity is lost as a result of the burn, thereby eliminating one purpose of the skin, which is to maintain body temperature. In addition, recall that children have a large body surface area, leaving more area exposed for cooling.

Chemical burns should be copiously rinsed with warm water for a minimum of 20 to 30 minutes or until the skin no longer has a "slippery" feel to it. While you are irrigating a chemical burn, ensure that the chemical is not spread to other body areas of your patient or to yourself.

Initial burn assessment includes an evaluation of airway issues related to facial and laryngeal edema. Even if no body surface burns are visible, inhalation burns can be responsible for rapid loss of the airway. Assess for singed eyebrows, nasal hairs, or carbon material in the oral or nasal airways. Early intubation is usually the treatment of choice because progressive edema increases breathing difficulty and loss of airway control.

Breathing concerns for burn patients include injury to the lungs related to a direct thermal burn or injury related to the indirect effects of smoke inhalation and CO production. In addition, significant burns to the chest, especially circumferential burns, may impede chest movement during respiration; 100% oxygen is administered to all children with a chance of smoke inhalation. Carbon monoxide toxicity may lead to severe neurologic deficits as the carboxyhemoglobin level rises. CO will displace oxygen on the

hemoglobin molecule; 100% oxygen administration cuts the CO level in half every 30 minutes.

Circulation concerns result from dramatic increased vascular permeability and fluid losses from the intravascular space. Methods for replacing depleted volumes of fluid should be based on the practices and standards of the local referral burn center, and collaborative guidelines should be discussed and in place before encountering the care of a burned child. As discussed in Chapter 12, the Parkland formula may be used (4 mL/kg per percentage total body surface area administered over the first 24 hours; half of the total fluids are administered over the first 8 hours, and the remainder are administered over the next 16 hours).

After initial life threats are addressed, the CCTP may consider other treatments or procedures, including insertion of an indwelling urinary catheter because this will be the primary means of assessing urine output, assessing for myoglobinemia (port-wine-colored urine), and measuring the success of fluid resuscitation. For the child with suspected inhalation injuries, a beta-2 agonist medication such as albuterol (2.5 to 5.0 mg via hand-held nebulizer) may be warranted for bronchospasm and/or wheezing.

Transport Management

Burns

- Remove the source of the burn.
- Cool a small area burn with tepid water for a few minutes, then apply a moist dressing.
- Rinse chemical burns copiously with warm water for a minimum of 20 to 30 minutes or until the skin no longer has a slippery feel.
- Assess airway tissues and look for singed eyebrows, nasal hairs, or carbon material in the oral or nasal airways.
- Administer 100% oxygen to children who may have inhaled smoke.
- Administer fluids based on the practices and standards of the local burn center.
- Insert an indwelling urinary catheter after initial life threats have been addressed.
- Wrap the burn in dry, sterile gauze. Follow agency policies and procedures regarding applying a topical antimicrobial agent to the burn dressing.
- Cover the child with a warm blanket.
- Administer analgesia and sedation for pain.
- Monitor the patient's pain scale, and respiratory, hemodynamic, and mental status, during transport.

Wound care involves wrapping the burn in dry sterile gauze. For large surface area burns, a sterile burn dressing or trauma dressing may be used. Warmed blankets may then be used to maintain or improve the child's body temperature. The application of a topical antimicrobial agent to the burn dressing is controversial for transport. Often, the burn center team prefers to have an unobstructed view of the patient's burns and will apply the antimicrobial agent after patient evaluation and debridement. Refer to your own specific system policies and procedures.

Most burns are extremely painful, and adequate analgesia and sedation must be delivered to these children. Morphine sulfate should be administered at a dosage of 0.1 to 0.2 mg/kg IV/IO for analgesia while the CCTP monitors the patient's pain scale and respiratory, hemodynamic, and mental status while en route to a burn center for definitive treatment. Continued reassessment and medication administration should occur.

Abuse and Neglect

The incidence of child abuse and neglect has unfortunately been regarded as an epidemic in the 21st century. The probability of transporting such a victim of these horrific events is common in this profession. The primary responsibility of the transport crew is to their own safety first, and then to provide a safe environment for their patient. Forms of abuse that the CCTP must be aware of while caring for the pediatric population include psychological (emotional) abuse, physical abuse, economic (financial) abuse, sexual abuse, and neglect.

When there are no obvious signs of abuse, such as bruises or broken bones **Figure 23-33**, the patient may have suffered neglect. This is the intentional or unintentional omission of needed care and support, which may present as a child who appears unkempt, appears malnourished, or has recently been diagnosed as having failure to thrive. A key component of the physical assessment at the bedside is the child's behavior. Children younger than 6 years who have experienced neglect usually appear markedly passive to their environment, and children 6 years or older may seem aggressive on initial evaluation.

Signs and Symptoms

Neglect

- Child appears unkempt, malnourished, or has a diagnosis of failure to thrive
- Younger than 6 years: Child is markedly passive to the environment
- Older than 6 years: Child seems aggressive

Transport Management

Abuse and Neglect

- Conduct a thorough assessment.
- Adhere to agency protocol regarding reporting of suspected abuse or neglect.
- Document the events and transport details.

The transport crew should conduct a thorough assessment and gather all necessary transfer documentation and radiographic studies for the receiving hospital. If a detailed assessment cannot be completed based on the response of the pediatric patient, this should be noted in the transfer documentation. As with any patient population, if the provider's assessment and knowledge of age-appropriate behavior do not correlate, and a suspicion of abuse or neglect is present, then the CCTP must adhere to agency protocol regarding the reporting of suspected abuse or neglect. In the case of confirmed abuse, all measures should be taken to preserve evidence. Transfer documentation must reflect findings from the physical exam and statements made by the victim or suspected perpetrator. CCTPs may be called to testify in court regarding such cases, so it is imperative to document the events and transport details with the utmost completeness and clarity.

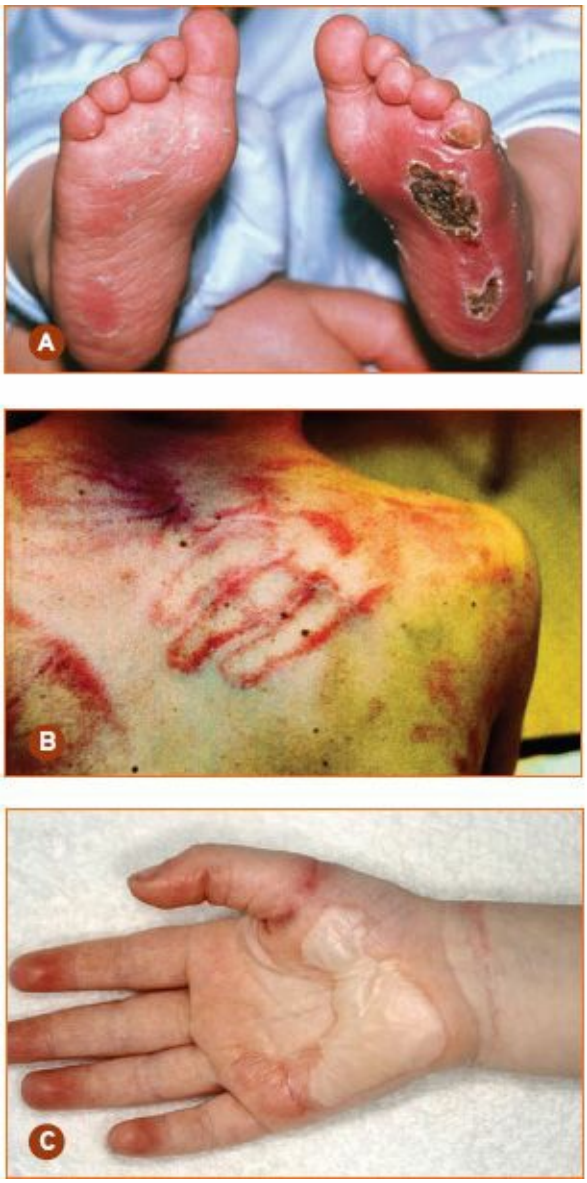

Figure 23-33 Obvious signs of abuse. **A.** Burns like these on the bottom of the feet are highly suggestive of abuse. **B.** Imprints of a hand on the skin suggest assault or other forms of abuse. **C.** Burns on the palm in susceptible patients can be signs of abuse.

Environmental Emergencies

Hypothermia

Hypothermia exists when the patient's body core temperature is 95°F (35°C) or less. It can result from a systemic disease process, prolonged environmental exposure, or when heat production is less than heat loss by convection, conduction, or radiation. The pediatric population is at an increased risk for hypothermia secondary to their relatively larger body surface area, proportionally large head, immature temperature-regulating mechanisms, decreased energy stores, and less body fluid volume and protective fat. Low-birth-weight (premature) infants, newborns, and children involved in trauma are at high risk for hypothermia.

The management of these patients starts by removing them from the cold environment, removing wet clothing, placing under a heat lamp, and providing warm blankets and liquids **Figure 23-34**. As with any patient, the ABCs must be addressed during the initial/primary assessment. Warm humidified oxygen and warmed IV fluids should be administered based on the level of hypothermia. Rapid fluid replacement in this population may in turn cause or increase the state of hypothermia. Regardless of the outside ambient

temperature, the CCTPs should provide additional heat from the vehicles' (rotor wing, fixed wing, or ground) heaters. In the event of severe hypoglycemia, the incidence of cardiopulmonary arrest may occur. Cardiac medication and defibrillation may not be effective when body core temperatures are below 82.4°F (28°C); therefore, CCTPs must adhere to their agency protocols or resuscitation guidelines (Neonatal Resuscitation Program, Pediatric Advanced Life Support).

Figure 23-34 To manage a hypothermic pediatric patient, remove wet clothing, place him or her under a heat lamp, and provide warm blankets and liquids.

Transport Management

Hypothermia

- Remove the child from the cold environment.
- Remove wet clothing.
- Place the child under a heat lamp.
- Provide warm blankets and liquids.
- Address the ABCs.
- Administer warm humidified oxygen and warmed IV fluids based on the level of hypothermia.
- Provide additional heat from the vehicle.
- Follow agency protocols regarding cardiac medication and defibrillation.

Heat Stroke

Heat stroke is classified as a life-threatening emergency in the field with morbidity rates ranging from 17% to 70%. Heat gain results from a mixture of metabolic activity, the environment (high ambient temperature and humidity), and vigorous exercise (exertional heat stroke). This gain is counteracted by several mechanisms, such as conduction, convection, evaporation, and radiation. The pediatric population acclimates more slowly to heat production from exercise than the adult populace. Such variables as a greater skin surface area, decreased sweating capacity, and the inability to shunt heat via the blood from the core to the periphery make the pediatric population more susceptible to this medical emergency. Heat stroke is the result of the body's compensatory heat dissipation system (sweating, radiation, and convection) being overwhelmed by heat production and absorption. Underlying conditions may contribute to this imbalance, which include, but are not limited to, the following: immature thermoregulation of the newborn, burns, and cystic fibrosis.

The classic signs of heat stroke are hyperpyrexia with rectal temperatures of greater than 104°F (40°C); skin that is red, hot, and dry to the touch; severe CNS dysfunction with complaints of headache

and confusion, leading to coma and posturing; tachycardia with hypotension; severe dehydration; nausea and vomiting; hypoglycemia; and polyuria with electrolyte imbalances. The patient may or may not be sweating, depending on the degree of fluid loss.

It is imperative that the management of these patients start in the field by removing the patient from the environment and into an air-conditioned vehicle. On initial contact with the patient, the clothing should be removed or drenched in cool water (conductive heat loss), and the active cooling process should be started per agency protocol. Ice packs can be placed around the neck, axilla, and groin. If time permits during the transport, attempt to fan the patient with misting water until the body temperature reaches 101.3°F (38.5°C) (rectal). IV fluid replacement should be based on the patient's presentation, cardiac status, and laboratory results. Be prepared to administer 0.9% normal saline at a rate of 5 to 20 mL/kg over 20 to 60 minutes depending on the patient's hemodynamic status. If intractable seizures or muscle cramps are noted, a hypertonic solution (3% saline) may be ordered to administer while en route to the receiving facility. The initial dose of 3% saline solution is 5 mL/kg, and additional dosages should be infused over the next 4 to 6 hours. If the patient begins to shiver, diazepam, 0.2 to 0.3 mg/kg IV, may be administered depending on protocol. The patient's cardiac status (arrhythmias) and neurologic status (GCS score) should be closely monitored continuously for any changes while en route to the receiving faculty.

Signs and Symptoms

Heat Stroke

- Rectal temperature greater than 104°F (40°C)
- Skin that is red, hot, and dry to the touch
- Severe CNS dysfunction with complaints of headache and confusion, leading to coma and posturing
- Tachycardia with hypotension
- Severe dehydration
- Nausea and vomiting
- Hypoglycemia
- Polyuria with electrolyte imbalances

Transport Management

Heat Stroke

- Move the patient into an air-conditioned vehicle.
- Remove the child's clothing or drench the child in cool water.
- Start the active cooling process per agency protocol.
- Place ice packs around the neck, axilla, and groin.
- If time permits, fan the child with misting water until the body temperature reaches 101.3°F (38.5°C) (rectal).
- Administer IV fluids, hypertonic solution, or diazepam, if necessary, according to agency protocol and medical orders.
- Monitor the patient's cardiac and neurologic status for changes during transport.

Drowning

Drowning is a top cause of death for the pediatric populations between the ages of 1 and 14 years. Over the past few years, the amount of education has increased to alert the general public about the hazards of drowning in pools and lakes for our pediatric population. However, there is still a lack of awareness about bathtubs and buckets because a child can drown in as little as an inch of standing water.

Figure 23-35 The diving recovery position should be used when treating patients with cold water drowning.

The primary insult is hypoxemia that may or may not be attributed to aspiration. Wet drowning accounts for 85% of incidents. Hypoxemia as a result of aspiration begins the insult to these patients, and is followed by metabolic acidosis, hypothermia, and cardiac compromise. The key to a successful outcome is good resuscitation and a brief submersion. Secure the airway early, provide positive-pressure ventilations, and add PEEP early. Rewarm the patient and work to reverse metabolic acidosis. These patients might be on fluid restriction per the physician or at least half maintenance infusions, and furosemide might be needed. There is a possibility that vasopressors might also be needed. Antibiotics are only needed if a bacterial infection is suspected. Patients can experience a wet drowning incident in fresh or salt water, although the exact etiology does not change the initial treatment. In recent research, it is believed the mammalian dive reflex occurs mostly with sudden submersion in extremely cold water **Figure 23-35**.

Approximately 10% to 15% of drowning incidents are related to dry drowning. Dry drowning occurs when the patient has a laryngospasm that prevents water from entering the lungs. The duration of the laryngospasm determines the extent of the hypoxemia. Death from dry drowning is the result of asphyxiation vs aspiration.

Patients With Special Needs

Children with special health care needs may be even more of a challenge in the transport environment. With all the advances in the care of the critically ill child and in neonatal resuscitation (with respect to babies being born and surviving as early as 24 weeks), the frequency of a CCTP having to take care of a special needs child is increasing. These children are being sent home with more complex equipment, such as ventilators, apnea monitors, nagogastric tubes, gastrostomy tubes or buttons, jejunostomy tubes, and ventriculoatrial or ventricu-loperitoneal shunts. It would be difficult for the CCTP to be familiar with every different illness or congenital disease seen in the pediatric community, so parents and caregivers are the best resource for understanding their child's illness and using the specialized equipment. **Figure 23-36** and **Figure 23-37** show a special needs patient with a tracheostomy tube and a feeding tube, respectively.

Figure 23-36 A special needs patient with a tracheostomy tube.

The CCTP might encounter special needs children either on a transport to the hospital before surgery or on a transport back to a tertiary hospital after surgery. Children with congenital heart disease, for example, might be sent to a large hospital for the first of multiple operations and then sent back home. The CCTP might also encounter these children if equipment malfunctions or as the time nears for the child's next surgery.

If your protocols and the child's condition allow, it might be possible to let the parent or caregiver assist you with care during transport. Sometimes having the parent suction or supply information about the child's illness can calm the parent and the patient, and also decrease anxiety they may feel regarding the child's hospital stay.

Flight Considerations

There are no specific flight considerations for pediatric critical care transport. The same flight considerations presented in other chapters apply with the pediatric patient. A key point to remember in all transports is that children are not small adults. The CCTP should be familiar with age-specific development and deviation from the norm; for example, pediatric patients will quickly decompensate without warning. Also remember that "all that wheezes is not asthma" and that cardiopulmonary resuscitation is usually caused from a respiratory, not a cardiac, etiology.

Figure 23-37 A special needs patient with a feeding tube.

In most circumstances, a parent/caregiver should be offered the opportunity to be transported with the patient, thus putting the pediatric patient at ease with the environment. As with adult patients, never lie to pediatric patients. Use every opportunity to build their trust.

Summary

The emergency care of children is challenging and difficult under the best of circumstances. Well-guided, standardized preparation for the transport of a critically ill or injured child is essential. Working collaboratively with various organizations, such as Emergency Medical Services for Children and pediatric components of emergency medical professional organizations, allows the CCTP to provide appropriate care to this vulnerable population.

Case Study

IT IS 1:00 AM AND THE PARENTS of an 11-year-old boy call EMS because he is "sucking for air."

EMS arrives on the scene 6 minutes later and immediately completes an initial/primary assessment, establishes that he has no known allergies, and begins treatment with an albuterol nebulizer. The boy is a cooperative and responsible child, but the parents have been noncompliant with administering his rescue inhalers and nebulizers. He is alert and cooperative but has audible wheezing with intercostal, subcostal, and substernal retractions with tracheal tugging. The cardiac monitor reveals sinus tachycardia with a rate of 118 beats/min, a blood pressure of 110/62 mm Hg, respirations of 36 breaths/min, and an initial SpO_2 of 84% on room air. En route, IV access is obtained. During that time, the SpO_2 rapidly increases to 94% and his work of breathing begins to decrease.

At 1:18 AM, the patient arrives at the local emergency department (ED) and care is transferred to the ED nurse and ED physician. A physical examination reveals a patent airway, but he has thick secretions that he cannot cough up. Breathing is rapid and forced. He continues to have retractions and an SpO_2 of 95% while on the nebulizer. Diminished breath sounds with expiratory wheezing are auscultated. Pulses are bounding, the skin is pale pink and diaphoretic, and capillary refill is 3 seconds centrally and peripherally. He is cooperative but very fatigued.

At 1:25 AM, he is started on a continuous albuterol/ipratropium nebulizer to a maximum of three doses, and he is given methylprednisolone and magnesium sulfate for management of his asthma. A chest radiograph is ordered. The ED physician calls the pediatric intensivist at the children's hospital for a possible transfer as a result of the child's history of asthma and previous intubations. The children's hospital accepts the patient to their pediatric floor, and you depart in a critical care ground ambulance.

Thirty minutes later, the patient's work of breathing is reported as "improving" and the chest radiograph shows the hyperinflation of the lungs typically seen in children with asthma. You arrive, begin assessment, and obtain a report from ED personnel.

At 2:02 AM, the patient becomes unresponsive and has an SpO_2 of 78%. You and your partner initiate bag-mask ventilation. You immediately prepare your equipment and intubate the child with a 6.5 ET tube.

After successful intubation and ET tube placement, confirmation with visualization of the tube passing the cords, fogging of the ET tube, and $ETCO_2$ monitoring, the child is given adequate pain medication sedation and paralytics, and is placed on a ventilator. His SpO_2 is now 93% and his vital signs are stable. You and your partner start an in-line nebulizer and prepare to move the patient to the stretcher for transport.

During transport, you observe that the child's stomach is distended with air.

At 2:21 AM, the child suddenly deteriorates as his SpO_2 decreases to 81% and his heart rate increases to 150 beats/min. The alarm on the ventilator is displaying "high pressure." The ventilator is disconnected, and manual ventilation with a bag-valve device is initiated.

A few minutes later, the patient's ET tube placement was reconfirmed, he was suctioned, and all equipment was working properly. He remains difficult to ventilate as a result of increased resistance, and the $ETCO_2$ increased to 60 mm Hg. Reassessment now reveals decreased breath sounds on the right side, jugular venous distention, and a decreasing blood pressure.

At 2:30 AM, you perform needle decompression on the patient's right side. There is a rush of air and resistance to bagging decreases. He is then placed back on the ventilator. His vital signs are blood pressure of 112/61 mm Hg and heart rate of 102 beats/min; he is being ventilated at a rate of 12 breaths/min. His SpO_2 is now 98% on an FIO_2 of 60%. He is resting comfortably under adequate sedation and pain medicine, and his condition is greatly improved. The rest of the transport is uneventful. You and your colleagues advise the receiving physician of the changes in the patient's condition during transport. All paperwork, treatments, and medications given are reported to the pediatric intensive care unit nurse with a copy of the transport report to be left with the patient's chart.

1. How was the ET tube size calculated?
2. What is the treatment priority after the patient is intubated and placed on the ventilator?
3. What is the treatment priority after the child deteriorates to an SpO_2 of 81%?
4. What mnemonic can be used initially to help address the acute change in your patient's status?
5. What procedure should be performed when you observe that the child's stomach is distended with air?

Analysis

Endotracheal tube size is calculated with the formula:

$$\frac{\text{Age} + 16}{4}$$

A length-based resuscitation tape, also called the Broselow tape, can also be used. Remember that ET tube size formulas are only guides for ET tube selection. An ET tube that is 0.5 mm smaller and larger must be readily available.

After the child is intubated and placed on the ventilator, the treatment priority is sedation and possibly pain medication. When you observe the patient's stomach distended with air, a nasogastric or orogastric tube should be inserted to decompress the stomach and reduce the risk of aspiration.

When the child deteriorates to an SpO_2 of 81%, the treatment priority is assessment of the ABCs. At this point, the CCTP should take the patient off of the ventilator and manually ventilate the patient with a bag-valve device.

The DOPE acronym is used to help remember how to care for this deteriorating patient. Recall that it stands for *Dislodgement* of the tube, *Obstruction* of the tube, *Pneumothorax*, and *Equipment* failures.

When the crew discovers a pneumothorax, the next treatment priority is needle decompression. In pediatric populations, the child may still have an equal rise/fall of the chest and audible lung sounds on both sides of the chest. Children typically have thin chest walls and lung sounds "echo" to the affected side from the unaffected side. In addition, the inflated lung may still elevate the side of the chest with the collapsed lung. Again, this is related to pliable and compliant chest walls.

Asthmatic children are at a greater risk for pneumothorax because of hyperinflation of the lungs and high airway pressures. Remember, in most cases, the air can get in, but it has difficulty getting out. Particular caution must be taken with children during bag-mask or mechanical ventilation. Slow down your expiration time for these patients. Some children may need I:E times of 1:3 to 1:5. Assess, treat, and *reassess*!

Prep Kit

Ready for Review

- The basic anatomy of the cardiovascular system is the same in children as in adults, but there are physiologic differences, such as differences in normal ranges for pulse rate and blood pressure and children's limited duration of compensatory mechanisms.
- Children's respiratory systems—lungs that continue developing through adolescence, smaller lower airways, smaller number and size of peripheral airways, immature alveoli, and decreased collateral ventilation—put them at higher risk for severe symptoms caused by respiratory diseases and for atelectasis.
- Infants' highly reactive airways make them more vulnerable to environmental allergens, viral respiratory diseases, and hereditary factors.
- Children are more susceptible to brain injuries because their brains are not well compartmentalized, which means there is more room for the brain to move in the skull.
- A normal fontanelle is soft and flat but has a feeling of fullness. The posterior fontanelle closes at 2 months of age, and the anterior fontanelle closes at 16 to 18 months of age.
- Cephalohematoma occurs in 1% to 2% of live births involving mechanical trauma, and is found predominately in the parietal region of the skull. It usually resolves in 6 to 8 weeks and can be associated with linear fractures. The CCTP should note the size and location of the hematoma during initial assessment and during transport. Possible complications are rare but include infection, hyperbilirubinemia, meningitis, and osteomyelitis.
- Caput is soft-tissue swelling that usually resolves within 24 hours.
- Children's bones are more porous than adults' bones, and tend to buckle rather fracture. Epiphyseal-metaphyseal growth plate injuries account for 10% to 15% of fractures in children; with reduction and immobilization, most have excellent outcomes.
- The child's thorax is pliable and able to absorb a significant amount of energy without fracturing. A small or suspected rib fracture may indicate a severe pulmonary contusion, which is more life threatening to the child than the rib fracture.
- Children's ligaments are strong and more resilient than those of adults, making the joints strong and dislocations rare.
- Because of a highly flexible cervical spine, young children tend to have avulsions rather than fractures. They are more prone to head injuries because they have relatively large, heavy heads with weak neck muscles.
- Children have a higher risk of aspiration as a result of an immature cardiac sphincter, are more susceptible to blunt abdominal trauma because they have weaker abdominal muscles, and are susceptible to hypoglycemia as a result of immature liver function.
- Children are more prone to dehydration than adults because they have a higher percentage of body water. Minimum urine outputs are 2 mL/kg/h for infants and 1 mL/kg/h for children, compared with 0.5 mL/kg/h for adults.
- Infants and children exposed to extremes of heat and cold are at higher risk than adults for hypothermia and hyperthermia because their ability to regulate temperature is not fully developed and they have a larger body surface to mass ratio.
- Close monitoring of oxygen and medication consumption is essential with children because they have a higher rate of metabolism and consume more oxygen than adults. The rate of onset of hypercapnia and

hypoxemia is accelerated.

- The CCTP should monitor the pediatric patient closely for hypoglycemia, which can manifest at a rapid onset with an asymptomatic or classic presentation. Treatment depends on the weight and age of the patient. Administration of 50% dextrose is contraindicated in the pediatric population.
- An understanding of normal growth and development, as well as the individual pediatric patient's developmental level, helps guide assessment, safety considerations, and communication techniques.
- Care strategies for psychosocial concerns vary with the age of the child. Speaking at eye level, using first names, and explaining medical procedures with age-appropriate words are techniques that can be used at all age levels. Maintaining a calm and confident manner also helps to reassure both the child and parent.
- CCTPs need to be academically, technically, and emotionally prepared to care for pediatric patients. They must recognize and address the needs of the parents, guardians, or caregivers, as well as those of the patient.
- Pediatric assessment begins with the PAT, which assesses the child's appearance, work of breathing, and circulation.
- After using the PAT to form a general impression of the patient, perform an initial/primary assessment. Any abnormal finding indicates the need for immediate treatment and may require deferral of the next step. Perform a secondary assessment on medical and trauma patients.
- Assess all children for pain. A numeric scale can be used for older children and adolescents; the FLACC or FACES scale can be used for infants and younger children.
- The CCTP can get extensive information for the child's history from the child's parents or caregivers. Scene or situation information may also be useful.
- Children with neural tube defects may have a latex allergy that can be life threatening. All latex products must be removed from care areas when treating these patients.
- Pediatric medication doses often have to be calculated, which increases the possibility of errors; doses of high-alert medications require an independent recheck before they are administered.
- The CCTP should be familiar with pediatric medications used for critical care transport and the different methods of medication delivery. The best option for administering resuscitation medications is a vascular access device.
- Nasal congestion can be life threatening to an infant because infants are obligatory nose breathers. Normal saline spray and a bulb syringe can be used to clear the nasal airways. Positioning the infant with the head up at 30° to 45° also aids in keeping the nasal airways clear. Administration of oxygen via a nasal cannula may also work well.
- Airway differences and other factors, such as infection, trauma, or foreign body airway obstruction, can impair the child's airway patency. Proper choice of blade size, proper positioning, and effective sweeping of the tongue are essential for successful intubation. Assess the corneal reflex to determine if the child has a gag reflex before inserting the oral airway.
- Tools used to identify the work of breathing in children include assessing stridor, snoring, retractions, head bobbing, accessory muscle use, tripoding, nasal flaring, wheezing, and grunting. The CCTP should know the parameters for normal pediatric vital signs but should remember to assess the patient, not the numbers or monitors. Assessing the child's level of consciousness, palpating the child's chest, and auscultating are used to assess breathing adequacy. Measurements used to determine breathing adequacy include SpO_2, $ETCO_2$, and arterial blood gas readings.

- Assessment of a child's cardiovascular system includes observing the child's general appearance and level of consciousness, including assessing the child's fingers and toes for evidence of clubbing; obtaining vital signs; assessing the child's skin, which should be warm, dry, and the appropriate color; and measuring the child's blood pressure. For some disease processes, MAP may be a more important measure in guiding treatment than blood pressure.
- Any trauma or medical condition that causes fluid losses requires IV access for volume replacement. Intraosseous IO insertion is recommended when rapid venous access cannot be obtained. The most common site for IO insertion is the anterior tibia. Contraindications include osteogenesis imperfecta, osteopetrosis, and fractures of the ipsilateral extremity.
- Urine output can be an objective indicator of pediatric circulatory status and the effectiveness of volume replacement. Low urine output indicates poor kidney perfusion.
- Neurologic assessment includes evaluating the child's general appearance, assessing the fontanelles, checking the child's pupil size and response to light, and evaluating muscle tone and reflexes, including the Moro reflex, the stepping reflex, and the Babinski reflex.
- In children who are not yet walking, the normal Babinski reflex is the opposite of normal for adults—flaring toes are normal, and toes pointing downward indicate brain injury. Protective reflexes are lost in ascending order.
- The GCS is the most sensitive indicator of mental status; it is modified when examining infants and children.
- Assessment of the renal system includes evaluation of hydration status and physical assessment, including assessment of the fontanelles in infants, assessment of skin turgor, the presence or absence of tears when crying, and sunken eyes. Daily weights are an objective measurement; acute weight loss may indicate fluid loss.
- Fluid overload is less common in children, but it may occur with congenital heart defects or renal insufficiency. Hypoxia and grunting are early signs of pulmonary edema. Additional signs of fluid overload include weight gain, edema, history of intake greater than output, and pulmonary edema. Early signs of pulmonary edema may be discounted because of subtle presentation. Pulmonary edema is confirmed by a chest radiograph.
- Resuscitation of infants and children must include measures to maintain body temperature because of children's physiologic differences. Measures must be taken to prevent hyperthermia and hypothermia.
- CCTPs who anticipate caring for critically ill or injured children need knowledge and skills specific to caring for infants and children as well as practice in pediatric care and mentoring from professional colleagues who care for pediatric patients on a regular basis.
- Equipment necessary for pediatric care should be available when transporting infants and children. The transport environment should also be latex free because of the high likelihood of latex allergies in special needs children. All equipment and supplies should be secured prior to transport to reduce the possibility of injury in the event of a crash.
- A team approach to interfacility transfer is best. Communication tools such as SBAR help to standardize the exchange of information among providers. The team should have a contingency plan for resuscitating the child if necessary during transport, and the driver or pilot should be prepared to respond if changes in the patient's condition or weather prevent completion of the transport.
- For safe transport, pediatric patients and health care providers must be secured in the vehicle and appropriate protective gear should be used. Interventions needed to stabilize the patient should be performed before transport. CCTPs need to be aware of local, regional, and national protocols for

addressing the increased risks of air medical transport and be prepared to take measures to reduce them.

- Guidelines for transporting parents or caregivers with a child should be in place before a child needs transport. Safe transport of the child is the priority, and each situation must be assessed for the caregiver's comfort level and potential for disruption of care during transport.
- The AAP recommends that self-inflating bags be used for resuscitation of children. CCTPs who will be caring for children should be familiar with their use as well as the use of flow-inflating bags, oxygen hoods, shortened tracheal tubes, and blade options.
- Respiratory illness is a common reason for pediatric transport. Upper airway conditions, lower airway conditions, parenchymal diseases, and abnormal control of ventilation can lead to upper airway failure.
- Respiratory distress is characterized by an increase in the work of breathing. Although the effort to breathe is increased, the child may still have adequate exchange of oxygen and carbon dioxide. The additional effort may also be for compensatory reasons.
- There are no strict guidelines for defining respiratory failure because it depends on the child's baseline respiratory function. Intervention to prevent respiratory or cardiac collapse is paramount. The CCTP should take all measures (per protocol) to maintain and preserve a patent airway and hemodynamic status before transport begins.
- Croup is a common viral infection characterized by a hoarse, "barking seal" cough that is often worse at night. Management ranges from the administration of humidified oxygen to the administration of racemic epinephrine to oral intubation in severe cases of obstruction.
- Epiglottitis is a bacterial infection that most commonly occurs in children aged 3 to 5 years. Symptoms include the four Ds: dysphagia, dysphonia, drooling, and distress. Management is controversial, but there is consensus that a calm environment should be maintained and a definitive airway should be secured prior to transport. Use of racemic epinephrine is contraindicated.
- Foreign body aspiration causes more than 90% of pediatric deaths in children younger than 5 years. Onset may be dramatic with an immediate life threat or with varying severity. Removal of the foreign body should be attempted only by following AHA and AAP guidelines.
- Early recognition of upper airway inflammation and intervention is imperative to lessen morbidity and mortality. Therapeutic measures are the same as for all upper airway obstructions: maintain a calm environment, administer humidified oxygen, provide a position of comfort, and prepare for deterioration of the airway status.
- Asthma is a chronic inflammatory disorder of the lower airways, resulting in a significant number of pediatric transports. Usually when transport is required, traditional treatments have failed and more advanced therapies are required. If a child has a history of requiring intubations for severe asthma, all treatments should be given during rapid transport to the hospital. Management includes oxygen therapy and the administration of a bronchodilator and corticosteroids.
- Bronchiolitis is a viral infection caused by RSV or another virus that primarily affects infants and young children. Symptoms may vary from mild wheezing to severe respiratory distress. Treatments are similar to treatments for asthma, but bronchodilators should be used with caution. Ribavirin, an antiviral drug, should be administered. Diligent assessment and monitoring of the child's work of breathing before and during transport are critical.
- Bronchopulmonary dysplasia is a chronic lung disease that develops in preterm infants who have been treated with oxygen and positive-pressure ventilation. The pathologic progression of the disease and

the healing process are not well understood. Children with BPD are at very high risk of pulmonary morbidity and mortality during the first 2 years of life.

- Pneumonia is a parenchymal lung disease. Infants and children may not tolerate pneumonia as well as older children and adults. Transport treatment includes vigilant assessment of the work of breathing and hydration status. Antibiotic therapy is required and may have been started at the initial facility.
- Near-SIDS is an acute episode of apnea accompanied by choking or gagging, skin color change, and a noted change in muscle tone. Etiologies associated with near-SIDS are gastroesophageal reflux disease, viral lower respiratory tract infections, seizures, sepsis, and meningitis. Near-SIDS patients usually only require supportive care and immediate transfer to a higher level of care for further studies or consultation.
- SIDS is the sudden, unexplainable death of an infant younger than 1 year. If the infant arrests while en route to the receiving facility, follow standing orders or contact medical control to request orders to continue or discontinue resuscitative measures. Be prepared to care for the parent if a parent accompanies the child during transport.
- Pediatric cardiac conditions are common indications for transport. CCTPs will routinely be involved with four classifications of heart disease or conditions, including a known cardiac defect, an unknown or suspected cyanotic defect, a cardiac arrhythmia, or some form of shock.
- Shock may lead to rapid death or may be more progressive. It is categorized as compensated or uncompensated, determined by the child's blood pressure.
- Hypovolemic shock is the most common cause of shock in pediatric populations. It is characterized by inadequate intravascular volume.
- There are four stages of hypovolemic shock: in stage 1, the child appears asymptomatic; in stage 2, the child maximizes compensatory mechanisms; in stage 3, the child is no longer able to compensate and hypotension occurs; in stage 4, death is imminent if the volume loss is not eliminated and aggressive volume replacement is not initiated. Resuscitation is successful when there is a return to normal heart and respiratory rates, normal blood pressure, and improved mental status and skin condition.
- The child with cardiogenic shock presents with traditional signs of shock, pulmonary congestion, and jugular venous distention. Treatment focuses on improving cardiac function with fluid resuscitation, inotropic support, and pharmacologic support.
- Neurogenic shock, anaphylactic shock, and dissociative shock are types of distributive shock. Treatment focuses on stopping vasodilation, returning volume to the intravascular space, and improving tissue perfusion.
- Symptoms of anaphylactic shock include increased general body edema, hypotension, rash, urticaria, anxiety, and warm, flushed skin. A child in anaphylactic shock may also experience bronchospasm and laryngeal edema, which may be life threatening. Management involves removing the allergen, replacing volume, and administering epinephrine.
- In dissociative shock, the hemoglobin molecule is unable to give up oxygen to the tissues. Dissociative shock is rare in the pediatric population. Examples of dissociative shock include CO poisoning and cyanide poisoning.
- There are two phases of septic shock: the warm and the cold phases. If not treated, a patient will progress from the warm to the cold phase. The CCTP should be able to diagnose septic shock based on the American College of Critical Care Medicine criteria. The goal of treatment is to resolve the hypovolemia and improve the perfusion status caused by cardiogenic shock.

- Approximately one of every 100 infants has a congenital heart defect. Cardiac anomalies may not be diagnosed until the neonate is 1 to 8 weeks old. Depending on their severity, cardiac defects may require immediate surgery or supportive care until the child is older and able to tolerate surgical intervention.
- Cardiac anomalies may be cyanotic or acyanotic. Acyanotic cardiac anomalies include VSDs, atrioventricular canal defects, ASDs, aortic stenosis, patent ductus arteriosus, and pulmonary stenosis.
- Aortic stenosis, hypoplastic left heart syndrome, and coarctation of the aorta cause impaired left ventricular output that may be treated by the CCTP.
- Persistent pulmonary hypertension (PPHN) in the newborn is caused by abnormally elevated pulmonary vascular resistance, resulting in hypoxia. Extracorporeal membrane oxygenation is used for short durations for patients with PPHN and congenital diaphragmatic hernia. Venoarterial ECMO is the form used most with neonates. Only a handful of teams in the United States have the expertise to perform ECMO transport.
- Cardiac defects that cause cyanosis include TOF and TGA. TOF is a cardiac anomaly consisting of four defects: ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta. TOF is the most common heart defect seen beyond infancy. TGA is a defect in which the great vessels are reversed.
- A hypercyanotic spell, also called a TET spell, presents with marked cyanosis, irritability, tachypnea, pallor, and even loss of consciousness. Treatment may include supplemental oxygen, morphine, propranolol, and placing the patient in a knee-chest position.
- ECG rhythm interpretation is different for children than for adults. Normal values vary with the child's age. It may be helpful to increase the ECG monitor sweep speed to identify subtle nuances in the components of the ECG.
- Causes of acute renal failure are divided into three categories: prerenal, intrarenal, and postrenal.
- Prerenal causes are the most common in children and are primarily related to dehydration and decreased renal perfusion.
- Intrarenal or parenchymal causes are diverse, but all lead to nephron damage and loss of glomerular function. Hemolytic uremic syndrome is one of the most common causes of intrarenal failure in infants and children younger than 4 years. Acute glomerulonephritis, APSGN, and ATN are also intrarenal causes of renal failure.
- Postrenal or obstructive failure can cause irreversible parenchymal damage if not treated.
- Potentially life-threatening complications of acute renal failure include electrolyte imbalances such as hyponatremia, hypocalcemia, and hyperkalemia; volume losses or pulmonary edema and fluid overload; volume overload; hypertension; and septic shock.
- Trauma is the leading cause of death for children from the age of 6 months to young adulthood. The leading causes of trauma are motor vehicle, pedestrian, and bicycle accidents; submersions; burn; and firearm injuries.
- The two main resources for CCTPs assessing pediatric trauma patients are the GCS, which has been altered for pediatric patients, and the pediatric trauma score.
- Head trauma is the leading cause of morbidity and mortality in children. Injuries to the brain are evaluated as primary or secondary injuries.
- Primary injuries occur at the moment of impact and cause physical and mechanical destruction of brain tissue. Secondary injuries are injured areas of the brain that may remain viable but are vulnerable to

hypoxic, ischemic, and inflammatory responses. If untreated, secondary brain injury leads to irreversible brain damage and death.

- Concussion is the most commonly seen head injury in the pediatric population. The CCTP provides supportive measures during transport; performs and documents a neurologic assessment; and documents the patient's pain level and tolerance of transport.
- Other head injuries that CCTPs may encounter with children are cerebral contusion, epidural hematoma, and subdural hematoma. Subdural hematoma can be caused by child abuse, such as shaken baby syndrome.
- The incidence of spinal cord injuries in children is relatively rare, but mortality related to spinal cord injury in children is more than twice that in adult populations. As with brain injuries, spinal cord injuries may occur with a primary insult and then a secondary insult.
- The most important intervention with spinal cord injuries is proper immobilization. A properly fitting cervical collar and, ideally, a pediatric backboard should be used. If a pediatric backboard is not available, a standard backboard can be used with adaptations to accommodate the child.
- Children may sustain damage to the spinal cord and spinal ligaments without damage to the spinal vertebrae. This damage is called SCIWORA, which stands for spinal cord injury without radiographic abnormalities. SCIWORA is suspected when there are clinical signs or symptoms of spinal cord injury but the cervical spine radiographs are normal.
- Facial trauma, soft-tissue swelling, hanging injuries, and clothesline injuries can cause upper airway obstruction. The patient's tongue can also obstruct the airway. Simple pneumothorax, tension pneumothorax, open pneumothorax, hemothorax, and flail chest may threaten the child's life. Management of these conditions is generally the same for children as for adults. The CCTP should be aware of differences in managing these conditions in children.
- Pericardial tamponade is a hemodynamic emergency. Pericardiocentesis may be challenging in the field. It may be beyond the scope of some CCTPs and it should not be performed in a moving ground or air vehicle.
- Children's bones tend to buckle, rather than fracture, because they are more porous than adults' bones. Children also have stronger and more resilient ligaments than adults, making dislocations rare in pediatric populations.
- The child's cervical spine is highly flexible, and children tend to have avulsions rather than fractures. Because of their large, heavy heads and weak neck muscles, children tend to have rapid deceleration injuries, resulting in hyperflexion and torsion forces.
- Pelvic fractures can cause massive internal hemorrhaging and can lead to profound deterioration of the child. PASG is one option for stabilizing a pelvic fracture for transport.
- A femur fracture can cause significant blood loss in children. Older children and adolescents are most at risk for femur fractures.
- Children will experience similar injury patterns as adults in motor vehicle accidents despite the use of car seats and restraints. In a pedestrian crash, children's injuries are most likely to involve the head and chest. The CCTP must find out what occurred and be alert for these injury patterns.
- Burns are the second most common cause of accidental death in children. The peak incidence of burn injuries occurs in children aged 1 to 5 years. Most burn injuries in children are from scalding liquids. Children have a higher mortality rate than adults from burns.
- The CCTP should remove the burn source, address initial life threats, care for the wound, manage the

child's pain, and monitor the child closely during transport to the burn center.

- CCTPs must adhere to agency protocol regarding reporting suspected child abuse or neglect. In cases of confirmed abuse, CCTPs must preserve evidence. CCTPs may be called on to testify in court, so it is important to document findings from the physical exam, statements made by the victim or suspected perpetrator, and transport details.
- Children are at higher risk for hypothermia than adults. Hypothermia exists when the patient's core body temperature is 95°F (35°C) or less. CCTPs should adhere to agency protocols or resuscitation guidelines for children with hypothermia.
- Heat stroke is a life-threatening emergency with morbidity rates ranging from 17% to 70%. The patient should be moved immediately into an air-conditioned vehicle, and measures should be taken to lower body temperature.
- Drowning is the second leading cause of death for children aged 1 to 14 years. Wet drowning accounts for 85% of incidents. The key to a successful outcome is brief submersion and good resuscitation. Approximately 10% to 15% of drowning incidents are related to dry drowning. Death from dry drowning is the result of asphyxiation vs aspiration.
- The frequency of caring for children with special needs is increasing. Parents and caregivers are the best resource for understanding their child's illness and for using the child's specialized equipment.

Vital Vocabulary

acute glomerulonephritis (AGN) A histopathologic diagnosis associated with edema, hypertension, and hematuria; results from the deposits of circulating immune complexes in the kidney basement membrane, which ultimately causes reduced glomerular filtration.

acute poststreptococcal glomerulonephritis (APSGN) A form of acute glomerulonephritis that occurs following an infection by streptococci.

acute tubular necrosis (ATN) A condition that results in damage to the tissue of the kidneys' tubules.

aortic stenosis Narrowing of the aortic valve.

atrial septal defect (ASD) A hole in the atrial septal wall that allows blood to flow from the left atrium into the right atrium.

atrioventricular canal defect A hole in both the atrial and ventricular septal walls that allows blood to flow from the left side of the heart to the right side of the heart; usually involves defects of both the mitral and tricuspid valves.

Babinski reflex When the toe(s) move upward in response to stimulation to the sole of the foot. Under normal circumstances, the toe(s) move downward.

bronchiolitis A condition seen in children younger than age 2 years, characterized by dyspnea and wheezing.

bronchopulmonary dysplasia (BPD) A chronic lung disease that develops in preterm neonates who have been treated with oxygen and positive-pressure ventilation; infants who survive this have pulmonary hypertension and abnormal pulmonary vascular development.

Brudzinski sign Passive flexion of the legs and thighs when the examiner flexes the patient's neck to the chest. If this causes pain or causes the knees and hips to flex involuntary, the sign is positive.

cerebral contusion A focal brain injury in which brain tissue is bruised and damaged in a defined area.

coarctation of the aorta (CoA) Pinching or narrowing of the aorta that obstructs blood flow from the heart to the systemic circulation.

concussion A transient interruption of normal neurologic function.

croup A childhood viral disease characterized by edema of the upper airways with barking cough, difficult breathing, and stridor; also called laryngotracheobronchitis.

epiglottitis Inflammation of the epiglottis.

extracorporeal membrane oxygenation (ECMO) A supportive intervention which provides oxygenation to a patient by removing the patient's blood to a heart and lung machine that does the work normally done by the lungs and heart. The blood is then transfused back into the patient's circulation.

FLACC scale A pain assessment scale that scores points for five categories, including face, legs, activity, cry, and consolability.

hemolytic uremic syndrome (HUS) A serious condition in which the patient develops acute renal failure, and which also causes anemia and thrombocytopenia; thought to be caused by several bacterial and viral infectious organisms, most often verotoxin-producing strains of *E coli*.

hyperkalemia An increased level of potassium in the blood.

hypocalcemia A low level of calcium in the blood.

hyponatremia A blood serum sodium level that is below 135 mEq/L, and a serum osmolarity level that is less than 280 mOsm/kg.

hypoplastic left heart syndrome (HLHS) Underdevelopment of the aorta, aortic valve, left ventricle, and mitral valve; this defect involves the entire left side of the heart.

intrarenal A type of acute renal failure caused by damage of an actual nephron.

Kernig sign Resistance and pain elicited on extension of the leg at the knee, with the patient in the supine position and the hips flexed perpendicular to the trunk; when pain occurs as a result of this test, the test result is positive.

Moro reflex An infant reflex in which, when an infant is caught off guard, the infant opens his or her arms wide, spreads the fingers, and seems to grab at things.

near–SIDS An acute episode in which an infant experiences apnea accompanied by choking or gagging, skin color change, and a noted change in muscle tone; also called an ALTE (apparent life-threatening event).

patent ductus arteriosus (PDA) A situation in which the ductus arteriosus, which assists in fetal circulation, does not transition as it should after birth to become the ligamentum arteriosum; the result is that the connection between the pulmonary artery and the aorta remains, allowing some oxygenated blood to move back into the heart rather than all of it moving out of the aorta and into the systemic circulation.

Pediatric assessment triangle (PAT) An assessment tool that allows rapid formation of a general impression of the type and level of illness or injury in an infant or child without touching him or her; consists of assessing appearance, work of breathing, and circulation of the skin.

persistent pulmonary hypertension (PPHN) A condition in the newborn caused by an abnormally elevated pulmonary vascular resistance resulting in hypoxia. The typical presentation consists of low APGAR scores, hypoglycemia, or a congenital diaphragmatic hernia.

postrenal A type of acute renal failure caused by downstream obstruction of urine flow from the kidneys,

with initially intact nephrons; commonly caused by a blockage of the urethra by prostate enlargement, renal calculi, or strictures.

prerenal A type of acute renal failure caused by decreased perfusion of an intact nephron; often reversible if the underlying condition can be found and perfusion can be restored to the kidney.

pulmonary stenosis Narrowing of the pulmonary valve.

reactive airway disease (RAD) A term used to describe any condition that causes hyperreactive bronchioles and bronchospasm.

SCIWORA An acronym that stands for spinal cord injury without radiographic abnormalities.

stepping reflex An infant reflex that occurs when the infant is held up in the air and moves his or her legs up and down as if marching.

sudden infant death syndrome The sudden death of an infant younger than 1 year that remains unexplained after a thorough case investigation.

tetralogy of Fallot (TOF) A cardiac anomaly that consists of four defects: a ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta.

transposition of the great arteries (TGA) A defect in which the great vessels are reversed; the aorta is connected to the right ventricle, and the pulmonary artery is connected to the left ventricle.

ventricular septal defect A hole in the septum separating the ventricles, allowing blood from the left ventricle to flow into the right ventricle.

Glossary

3-3-2 rule A method used to predict difficult intubation. A mouth opening of less than three fingers wide, a mandible length of less than three fingers wide, and a distance from hyoid bone to thyroid notch of less than two fingers wide indicate a possibly difficult airway.

abandonment The termination of an established patient-care provider relationship by the care provider without simultaneous transfer of health care responsibility to another care provider of equal or greater competence.

Abbreviated Injury Scale (AIS) A trauma scoring system that ranks injury severity by assigning an individual injury score of 1 to 6 to six body regions, with 1 being a minor injury and 6 being an injury with a high mortality rate; does not account for multisystem injuries.

abdominal compartment syndrome (ACS) A condition that can result from intra-abdominal hypertension, and that includes a range of deleterious effects, including decreased end-organ perfusion; if untreated, it can lead to death.

ablation Removal of a pathway or function by electrocautery or radiofrequency.

ABO-incompatible transfusion reactions A type of transfusion reaction in which the patient possesses antigens to a blood type and receives that blood type.

absolute refractory period The early phase of cardiac repolarization, wherein the heart muscle cannot be stimulated to depolarize.

absorption Acquisition of additional heat, radiation, or other energy from the environment; or, a substance's molecules are moved from the site of entry on the body into the systemic circulation.

accuracy A measure of the likelihood that an average of a set of test values will be the same as individual values in the set.

acetylcholine (ACh) A chemical neurotransmitter in the parasympathetic nervous system.

acetylcholinesterase An enzyme that breaks down acetylcholine at the neuromuscular junction.

acquired immunity The immunity the body develops as part of exposure to an antigen.

acrocyanosis A decrease in the amount of oxygen delivered to the extremities. The hands and feet turn blue because of the lack of oxygen.

acromegaly A syndrome that results from excessive growth hormone secreted by the pituitary gland after the epiphyseal plate has closed; characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate.

activated charcoal A carbon-based liquid with an incredible absorptive ability that is typically administered orally or via nasogastric or orogastric tube to decrease the available quantity of a toxic substance.

activated partial thromboplastin time (aPTT) A value that represents the intrinsic coagulation pathway's clotting ability; also known as partial thromboplastin time (PTT).

active immunity Production of specific antibody in response to an infection or antigen.

acute coronary syndrome (ACS) The term used to describe any group of clinical symptoms consistent with acute myocardial ischemia.

acute gastritis A type of gastritis characterized by a rapid onset of mucosal inflammation, frequently

accompanied by mild to severe upper GI bleeding.

acute glomerulonephritis (AGN) A histopathologic diagnosis associated with edema, hypertension, and hematuria; results from the deposits of circulating immune complexes in the kidney basement membrane, which ultimately causes reduced glomerular filtration.

acute poststreptococcal glomerulonephritis (APSGN) A form of acute glomerulonephritis that occurs following an infection by streptococci.

acute radiation syndrome Radiation poisoning.

acute renal failure (ARF) Decreased renal function in the absence of preexisting renal disease. Classified into three categories: prerenal, intrarenal, and postrenal.

acute tubular necrosis (ATN) A condition that results in damage to the tissue of the tubules of the nephron, preventing proper ion and fluid exchanges in the kidneys.

adaptive immune system The secondary mechanism that protects the host by reacting with and eliminating specific antigens after requiring more time than the innate immune system to mobilize its defense against unknown pathogens.

Addisonian crisis The sudden appearance of symptoms, especially shock, in a patient with chronic adrenal insufficiency; may appear suddenly as a result of an increased period of stress, trauma, surgery, or severe infection; other symptoms include weakness, altered mental status, hyperthermia, and severe pain in the lower back, legs, or abdomen.

Addison's disease A chronic hormonal or endocrine disorder caused by a deficiency of cortisol and/or aldosterone and characterized by weakness, fatigue, hypotension, unexplained weight loss, and darkening of the skin.

adhesions Bands of connective tissue that can distort the normal GI anatomy. They are the result of improper healing or scar tissue growth following surgery.

adrenal insufficiency (AI) Underproduction of cortisol and aldosterone caused by a decreased function of the adrenal cortex; occurs when at least 90% of the adrenal cortex has been damaged.

adsorbtion The process of attracting molecules of a substance to the surface of that substance.

adventitious breath sounds Abnormal breath sounds that are heard in addition to, or in place of, normal sounds.

aerobic metabolism A form of energy production in which mitochondria utilize glucose, amino acids, and fatty acids combined with oxygen and ADP to produce ATP, carbon dioxide, water, and heat.

afferent pathways Ascending pathways that carry sensory impulses toward the central nervous system.

afterload An expression of cardiac work related to the forces that must be overcome to eject blood from the ventricle; the tension or stress that develops in the ventricles during systole.

agonal respirations Slow, shallow, irregular respirations or occasional gasping breaths; results from cerebral anoxia.

Air Medical Physician Association (AMPA) An organization of physicians and air medical professionals that promotes safe patient transport.

alanine aminotransferase (ALT) An intracellular enzyme that is found in large amounts in the liver and in the kidney, skeletal muscle, and heart; formerly known as SGPT.

albumin The most common protein in the body, which acts as a transport protein, is a free radical

scavenger, and serves as the main source of protein-generated oncotic pressure; also a blood product containing this specific protein found in the blood, and prepared by the fractionation of pooled plasma; used for volume replacement in certain conditions.

alcoholic ketoacidosis A type of acidosis characterized by a buildup of ketones in the blood and caused by a large intake of alcohol.

aldosterone One of the two main hormones responsible for adjustments to the final composition of urine; it increases the rate of active resorption of sodium and chloride ions into the blood and decreases the resorption of potassium.

aldosteronism A syndrome of high blood pressure and low blood potassium levels caused by an excess of aldosterone; there are two main types (primary and secondary).

alkaline phosphatase An enzyme that is essential for proper digestion and absorption through the mucous membrane in the gastrointestinal tract; clinically useful for testing liver function and for diagnosing a common bile duct obstruction.

Allen test A technique in which the patient's hand is initially held above the head while the fist is clenched and the radial and ulnar arteries are compressed; the hand is then lowered and the fist is opened, ulnar pressure is released, and radial pressure is maintained; after ulnar pressure is released, color should return to the hand within 6 seconds.

alveolar ventilation (V_A) The volume of air that comes into contact with the alveolar capillary membrane surfaces and participates in the exchange of gases between the lung and blood.

amniotic fluid embolism A rare condition that can occur antepartum and postpartum, in which fetal tissue crosses over the placental barrier into maternal circulation, thereby causing obstruction to the mother's organs with organ failure or respiratory and cardiovascular compromise.

amylase A key enzyme used by the body to metabolize carbohydrates; it is produced primarily by the salivary glands and the pancreas.

amyloidosis A group of diseases that result from abnormal deposits of the protein amyloid in various tissues of the body; can occur in a localized area or may be systemic.

anaerobic metabolism A less efficient form of energy production in which an alternative pathway converts glucose to pyruvic acid with the simultaneous production of ATP and that also results in the production of lactate.

anaphylactic shock A severe hypersensitivity reaction that involves bronchoconstriction and cardiovascular collapse.

anaphylactoid reaction A non–IgE-mediated response that causes the rupture of mast cells and basophils, which then release histamine and other defense mediators.

anatomic dead space (V_D) Space in airway structures such as the trachea, bronchi, and bronchioles that does not participate in gas exchange. It is defined physiologically as ventilation without perfusion.

aneurysm A weakened portion of the wall of an artery where the blood creates a localized dilation or bulge; can involve the wall intact or be classified as dissecting, in which the artery wall ruptures and blood pools between the inner and outer artery wall.

angiodysplasia Deformed submucosal blood vessels in the GI tract that are prone to bleeding.

angiography Radiologic observation of dye injected into the bloodstream for leakage.

anion A negatively charged ion.

anion gap (AG) A summary of the relationship among the three major contributors to the overall electrical charge (Na^+, Cl^-, and HCO_3^-); abnormal AG values may signal disturbances in the overall electrical and acid-base balance of the serum and presence of disease.

anisocoria A condition in which the pupils are not of equal size.

anode The electrode in a pacing circuit that is positively charged when current is flowing.

antegrade conduction Conduction in the normal direction between cardiac structures.

anterior cord syndrome Displacement of bony fragments into the anterior portion of the spinal cord, often as the result of flexion injuries or fractures, that disrupts blood flow in the anterior spinal artery.

antiarrhythmic A type of medication used to treat and prevent cardiac rhythm disorders.

anticholinergic syndrome A syndrome that occurs following excessive exposure to medications such as antihistamines, atropine, and benztropine (Cogentin), or other substances such as Jimson weed, resulting in muscarinic receptor blockade at the neuromuscular junction; characterized by tachycardia, hyperthermia, dilated pupils, warm (or hot) dry skin, ileus, delirium, seizures, psychosis, and urinary retention.

antigen An agent that, when taken into the body, stimulates the formation of specific protective proteins called antibodies.

anxiolysis The reduction of anxiety by the administration of an antianxiety agent.

aortic regurgitation Backward flow of blood through the aortic valve from the aorta into the left ventricle.

aortic stenosis Narrowing of the aortic valve.

APGAR score A scoring system for assessing the status of a newborn that assigns a number value to each of five areas of assessment (the total possible score is 0 to 10).

aphasia Any loss or impairment of language function as a result of brain damage.

apnea Respiratory pause greater than or equal to 20 seconds; the absence of respiration.

apneustic breathing A condition in which lesions in the respiratory center of the brain stem lead to a breathing pattern characterized by prolonged, gasping inspiration, followed by extremely short, ineffective expiration.

arachnoid mater The middle layer of the meninges, which contains blood vessels that give it the appearance of a spider web.

arterial blood gas (ABG) Analysis of the following characteristics of blood: pH, partial pressure of carbon dioxide (in arterial blood), partial pressure of oxygen (in arterial blood), concentration of bicarbonate ion, base excess (indicating whether the patient is acidotic or alkalotic), and oxygen saturation of the hemoglobin molecule.

arterial lines Catheters inserted into the patient's arterial vascular system for the purpose of producing a waveform with pressure measurements; also called an A-line.

arterial oxygen content (CaO_2) The total amount of oxygen in the arterial blood.

arteriovenous malformation (AVM) Abnormally formed blood vessels that have a higher rate of bleeding than average vessels.

ascites A buildup of fluid in the abdominal cavity that can impede lung expansion and put pressure on

other organs.

aspartate aminotransferase (AST) An intracellular enzyme that is found in large amounts in the liver and in skeletal muscles, the brain, red blood cells, and the heart; formerly known as SGOT.

aspartate aminotransferase/alanine aminotransferase (AST/ALT) ratio A ratio used as an indicator of liver damage; this ratio can determine if the elevation is due to a liver injury or injury elsewhere in the body.

assault The act of putting someone in reasonable apprehension of imminent harmful or offensive contact.

assist ratio A setting on the IABP that allows the operator to determine how often the pump inflates the balloon. A 1:1 setting means the balloon inflates with each heartbeat; and 1:2, with every other heartbeat, etc; also called IABP frequency.

assisted systole The pressure waveform that follows the diastolic augmentation peak.

AST:ALT A calculated index that is useful for determining the cause of liver dysfunction.

atmosphere Gases that extend from the earth's surface to space; composed primarily of nitrogen, oxygen, argon, and trace gases.

atresia Complete absence of lumen.

atrial septal defect (ASD) A hole in the atrial septal wall that allows blood to flow from the left atrium into the right atrium.

atrioventricular canal defect A hole in both the atrial and ventricular septal walls that allows blood to flow from the left side of the heart to the right side of the heart; usually involves defects of both the mitral and tricuspid valves.

atrioventricular (AV) valves The valves (mitral and tricuspid) that separate the atria from the ventricles.

auto launch A protocol that launches an aircraft at the time it is placed on standby rather than waiting for the formal launch request. An auto launch is frequently activated when the distance to be covered for the response is greater than 30 nautical miles.

autonomic dysreflexia A potentially life-threatening complication of spinal cord injury that results from the loss of parasympathetic stimulation. It is characterized by a massive, uninhibited, uncompensated cardiovascular response as the result of some stimulation of the sympathetic nervous system below the level of injury. Also called autonomic hyperreflexia.

auto-PEEP The nonintended increase in end alveolar pressure due to air trapping.

axonal transport The movement of organelles and proteins along a nerve cell axon into and out of the cell body.

azotemia A combined elevation of blood urea nitrogen and serum creatine levels often seen in acute renal failure.

azygos system A network of blood vessels that connects the superior and inferior vena cava; it also drains a portion of the esophageal venous blood.

Babinski reflex When the toe(s) move upward in response to stimulation to the sole of the foot. Under normal circumstances, the toe(s) move downward.

bacteriocidal Capable of killing bacteria.

bacteriostatic Capable of inhibiting bacterial growth.

barometric pressure The weight per unit area of all of the molecules of the gases above the point at which the measurement was taken.

barotitis media Inflammation and possible petechial hemorrhage in the middle ear and possible rupture of the eardrum that results from the failure of the middle ear space to ventilate when going from low to high atmospheric pressure; also known as ear block.

barotrauma Injury to tissues, organs, or structures within the body, resulting from rapid or significant changes in environmental air pressure.

basal ganglia Masses of nuclei located deep in the cerebral hemispheres that play a major role in fine motor function.

basal metabolic rate (BMR) The heat energy produced at rest by normal body metabolic reactions, determined mostly by the liver and skeletal muscles.

base excess (BE) A measure of metabolic derangement that is part of the arterial blood gas panel; also known as base deficit (BD) as the value can be either positive (excess) or negative (deficit).

basilar skull fracture A fracture along the base of the skull.

battery Harmful or offensive touching of another without consent.

Battle's sign Migration of blood to the mastoid region, posterior and slightly inferior to the ear, resulting in discoloration; also called retroauricular ecchymosis.

Beck's triad The combination of a narrowed pulse pressure, muffled heart tones, and jugular vein distention associated with cardiac tamponade; usually resulting from penetrating chest trauma.

bicarbonate (HCO_3^-) An ion (HCO_3^-) that is present in the blood; measurement represents the metabolic component of the arterial blood gas panel.

bicarbonate–carbonic acid buffer system The principal extracellular buffer system, which operates primarily in the lungs and kidneys, and by which Co_2 and H_2O are reversibly converted into H_2CO_3 (carbonic acid), which in turn is reversibly converted into H^+ and HCO_3^- (bicarbonate).

bifascicular block The combination of a right bundle branch block and a block of one of the fascicles of the left bundle, the left anterior or left posterior fascicle.

bi-level positive airway pressure (BiPAP) The use of two separate pressures—inspiratory positive airway pressure and expiratory positive airway pressure—to raise the breathing baseline above ambient pressure. The pressure gradient enhances ventilation, and the reduced expiratory pressure makes exhalation easier and increases patient tolerance.

bilirubin A waste product of heme formed during erythrocyte metabolism. It is moved to the small intestine within bile and then converted into urobilinogen, resulting in brown pigmented feces.

bioavailability The amount or percentage of a medication that reaches systemic circulation without being altered following administration.

Biot's (ataxic) breathing Breathing characterized by three patterns: (1) slow and deep, (2) rapid and shallow, and (3) apnea. Causes include meningitis, increased intracranial pressure, and central nervous system dysfunction.

biphasic A term used to describe a wave with negative and positive components; usually used in conjunction with P and T waves.

bipolar lead A conduction lead comprising two electrodes attached at specific body sites with different

polarity used to examine electrical activity by monitoring changes in the electrical potential between them.

bipolar system A closed system consisting of bipolar leads and a module to generate impulses and measure response.

bleb A blister or bladderlike structure that may be filled with fluid.

blood urea nitrogen (BUN) A test used to measure urea, which is a biomarker for adequate kidney function.

blood–brain barrier A network of endothelial cells and astrocytes (neuroglia) in the brain that regulate the transport of nutrients, ions, water, drugs, and waste products to and from the brain through the process of selective permeability.

body packers People who swallow carefully packaged capsules for smuggling purposes.

body stuffers People who hastily swallow illicit substances to avoid impending arrest.

Boyle's law States that the volume of a gas is inversely proportional to the pressure to which it is subjected. Gases trapped in body cavities will expand with increases in altitude and will contract with decreases in altitude.

bradypnea A respiratory rate that is slower than normal.

brain herniation Displacement of a portion of the brain from its correct location within the cranial cavity to a different location.

brain tissue compliance The change in brain volume resulting from a change in pressure.

brain tissue oxygen tension ($P_{br}O_2$) A method of monitoring temperature and oxygenation via placement of a commercial probe into the brain tissue through a bolt; can be done simultaneously with ICP monitoring placement.

breach of duty to act A case in which a health care provider does not conform to the standard of care by providing inappropriate care, failing to act, or acting beyond the scope of practice.

breech A delivery presentation in which the buttocks emerge first.

Broca's area Part of the frontal lobe that is located at the inferior frontal gyrus and that participates in the formulation of words.

bronchiolitis A condition seen in children younger than age 2 years, characterized by dyspnea and wheezing.

bronchopulmonary dysplasia (BPD) A chronic lung disease that develops in preterm neonates who have been treated with oxygen and positive-pressure ventilation; infants who survive this have pulmonary hypertension and abnormal pulmonary vascular development.

bronchovesicular sounds A combination of the tracheal and vesicular breath sounds, heard in places where airways and alveoli are found, the upper part of the sternum and between the scapulae.

Brown-Sequard syndrome Loss of function as a result of penetrating trauma accompanied by hemisection of the spinal cord and complete damage to all spinal tracts on the involved side; characterized by loss of motor function and sensation of light touch, proprioception, and vibration on the ipsilateral side and temperature and pain sense on the contralateral side.

Brudzinski sign Passive flexion of the legs and thighs when the examiner flexes the patient's neck to the chest. If this causes pain or causes the knees and hips to flex involuntary, the sign is positive.

B-type natriuretic peptide (BNP) A polypeptide whose value that is indicative of abnormal ventricular function and congestive heart failure.

buffer Any substance that can alternately bind or release H_+ depending on outside conditions.

BUN:Cr A calculated index that is used to determine the cause of increased levels of blood urea nitrogen and creatinine.

cable The physical wire that connects the electrode to the ECG monitor.

caloric test A method for assessing vestibular function that involves the raising and lowering of the temperature in the external auditory canal; also called Bárány test.

capnography The measurement of exhaled Co_2, which in most cases correlates with the Co_2 levels in arterial blood, can be done with two different types of devices—an electronic monitor that displays a waveform or a colorimetric device that should turn yellow during exhalation, indicating proper tube placement.

capnometry The measurement of exhaled Co_2, performed the same way as capnography, but which provides a light-emitting diode readout of the patient's exhaled Co_2.

caput succedaneum In the newborn, a subcutaneous collection of fluid with poorly defined margins within the scalp, resulting from pressure on the head during delivery.

carboxyhemoglobin (COHb) A measure of the amount of hemoglobin–carbon monoxide complexes in the blood.

cardiac electrophysiology The cardiac specialty that involves evaluation and management of rhythm disturbances.

cardiac index A hemodynamic value that adjusts a patient's cardiac output to take into account his or her total body surface area.

cardiac monitoring The continuous observation of the patient's condition in relation to his or her cardiac rhythm.

cardiac output (CO) The amount of blood pumped by the heart per minute, calculated by multiplying the stroke volume by the heart rate per minute.

cardiogenic shock A condition caused by loss of 40% or more of the functioning myocardium; the heart is no longer able to circulate sufficient blood to maintain adequate oxygen delivery.

cathode The electrode in a pacing circuit that is negatively charged when current is flowing.

cation A positively charged ion.

cauda equina The collection of individual nerve roots into which the spinal cord separates at the L2 vertebra.

caudal Pertaining to or in the direction of the feet.

central cord syndrome A syndrome in which cavities form in the central portions of the spinal cord, usually in the cervical area; may be due to a tumor, genetic origin, or trauma; presents along with hemorrhage or edema to the central cervical segments.

central cyanosis Bluish coloration of the skin due to the presence of deoxygenated hemoglobin in blood vessels near the skin surface.

central diabetes insipidus A result of damage to the posterior part of the pituitary gland, which causes a

lack of the hormone vasopressin, an anti-diuretic hormone, to be produced; because of the lack of anti-diuretic hormone, patients frequently experience polyuria and polydipsia.

central lumen The lumen or port of the IAB catheter used to guide initial catheter insertion and to monitor arterial pressure during operation.

central neurogenic hyperventilation A pattern of very deep, rapid respirations at rates of 40 to 60 breaths/min, caused by a midbrain lesion or dysfunction.

central venous lines IV access catheters that terminate in central circulation, usually just proximal to the right atrium.

central venous pressure (CVP) The pressure in the superior vena cava (average 2 to 6 cm H_2O); reflects the pressure in the venous system when the blood is returned to the right atrium; indicative of a patient's fluid volume status and right-sided heart performance.

cephalad Toward the patient's head.

cephalohematoma A subperiosteal collection of blood; may be accompanied by a linear skull fracture.

cerebral angiography A procedure that uses imaging and a contrast material or dye to view the blood vessels in the brain and is used to find abnormalities.

cerebral aqueduct The narrowest portion of the brain's ventricular system; it provides communication with the fourth ventricle, which lies between the brain stem and the cerebellum.

cerebral blood flow (CBF) The amount of blood flow the brain requires to maintain homeostasis. In a 24-hour period, the brain requires 1,000 L of blood to obtain 71 L of oxygen and 100 g of glucose.

cerebral contusion A focal brain injury in which brain tissue is bruised and damaged in a defined area.

cerebral cortex The outermost layer of the cerebrum.

cerebral function analysis monitor (CFAM) A device that can provide summed, averaged, and analyzed outputs of the general state of brain activity.

cerebral function monitor (CFM) A device that can provide summed and averaged outputs, but not analysis, of the general state of brain activity.

cerebral hemispheres The name for each half of the brain (right or left), each of which contains one of the paired lobes (occipital, parietal, temporal, and frontal).

cerebral metabolic rate for oxygen ($CMRO_2$) A measurement used to determine neuronal demand for oxygen. Neurons with high activity rates require greater amounts of oxygen.

cerebral perfusion pressure (CPP) The pressure gradient across the brain; it provides an estimate of perfusion adequacy: CPP = MAP – ICP.

Charcot's triad Fever, jaundice, and right upper quadrant abdominal pain suggestive of choledocholithiasis.

Charles' law States that when pressure is constant, the volume of a gas is very nearly proportional to its absolute temperature. Thus, the volume is directly proportional to the temperature when it is expressed on an absolute scale where all other factors remain constant.

chelating agents Chemical substances that bind to heavy metals to remove them from the body.

Cheyne-Stokes respiration A cyclic pattern of increased respiratory rate and depth with periods of apnea. Causes include increased intracranial pressure, renal failure, meningitis, drug overdose, or hypoxia secondary to congestive heart failure.

choanal atresia A congenital narrowing or blockage of the nasal airway by membranous or bony tissue.

cholangitis An infective form of biliary tract obstruction in which white blood cell levels rise.

cholecystitis Inflammation of the gallbladder.

choledocholithiasis Gallstones in the biliary tract system, which put the person at high risk for developing a biliary tract obstruction.

cholelithiasis Gallstones in the gallbladder.

cholinergic syndrome Cholinesterase inhibitor toxicity.

cholinesterase An enzyme that hydrolyzes acetylcholine to acetic acid and choline.

chordae tendineae The thin, fibrous strands stretching out from the apexes of some of the papillary muscles of the ventricles, extending upward and attaching to the edges of the AV valves, which help keep the cusps of the valves from turning inside out when pressure builds up in the ventricles.

choroid plexus A cluster of nerve roots at the lateral and the third and fourth ventricles of the brain that produce cerebrospinal fluid.

chronic renal failure (CRF) A gradual decrease in renal function resulting from irreversible damage to the nephrons. It is characterized by a glomerular filtration rate (GFR) of less than 30 mL/min, and will eventually progress to end-stage renal disease.

chronotropic Altering the rate of contraction of the heart.

circle of Willis A system of arteries located at the base of the skull that (in most people) is able to compensate for reduced blood flow from any one of the major contributors to cerebral circulation.

cirrhosis Irreversible structural changes to the liver that impair its proper functioning.

cluster breathing An abnormal respiratory pattern in which a cluster of irregular respirations that vary in depth are followed by a period of apnea at irregular intervals.

coagulation necrosis The death of tissue resulting from a blockage of blood flow to that tissue, in which the blockage is caused by clots preventing blood from reaching the tissue.

coarctation of the aorta (CoA) Pinching or narrowing of the aorta that obstructs blood flow from the heart to the systemic circulation.

cocaine washout syndrome Profound exhaustion with the ability to regain normal mental status and orientation when aroused; common with heavy cocaine users.

cold zone The area surrounding the warm zone at a hazardous materials scene. No environmental hazards should be present in this zone.

colonoscopy Similar to endoscopy, but used for the lower GI tract.

comminuted fracture A type of skull fracture in which the skull is splintered or shattered into many pieces.

Commission on Accreditation of Air Medical Transport Services (CAMTS) An organization dedicated to improving the quality of patient care and safety of the transport environment for both rotor-wing and fixed-wing providers. CAMTS also provides voluntary accreditation of critical care transport agencies.

compartment syndrome A condition that develops when edema and swelling result in increased pressure within soft tissues, causing circulation to be compromised, possibly resulting in tissue necrosis.

compensatory stage A stage of hypoxia in which the physiologic adjustments that occur in the respiratory and circulatory systems are adequate to provide defense against the effects of hypoxia. Factors such as environmental stress and prolonged exercise can potentiate certain effects of hypoxia.

competence Capacity or ability to understand the nature and effects of one's decisions or actions.

complete breech A delivery presentation in which the buttocks present first and the legs are crossed inside the uterus, oriented transversely to the birth canal; in this case, the mother is unable to vaginally deliver.

complete spinal cord injury A complete disruption of all tracts of the spinal cord, with permanent loss of all cord-mediated functions below the level of transaction.

computed tomography (CT) An imaging study in which focused beams examine an area that is then reconstructed by computer to give a high-resolution view; multiple "slices" or views are created; performed on almost every patient with abnormal neurologic findings; also called CAT scanning.

concentration The amount of a substance present in a given volume of fluid.

concentration gradient The natural tendency for substances to flow from an area of higher concentration to an area of lower concentration, within or outside the cell.

concussion A transient interruption of normal neurologic function.

conduction Transfer of heat to a solid object or a liquid by direct contact.

congenital adrenal hyperplasia A disease group in which the adrenal glands do not function properly, and as a result do not produce a sufficient amount of the hormone cortisol.

conjugate movement Movement of both eyes together in the same direction.

consent Voluntary agreement by a patient with sufficient mental capacity to capably choose assessment, treatment, or transport offered by the care provider; a patient not accepting care demonstrates the right to refuse.

contact phenomena injuries Injuries that occur as the direct result of trauma to the head, including local effects such as scalp laceration, skull fracture, hematoma, and intracerebral hemorrhage.

contamination A state in which a certain substance, such as blood, infectious material, or a toxic substance, is present on an item or surface; in the case of radiation, it is important to distinguish between this and irradiation.

continuous positive airway pressure (CPAP) A means of raising the breathing baseline above ambient pressure. The increased pressure across the entire breathing cycle increases the mean airway pressure, stents the airway, and increases the functional residual capacity, thereby improving oxygenation.

contrecoup injury A situation in which an impact occurs on one side of the head, causing the brain to move within the cranial vault and forcibly contact the opposite side of the skull, resulting in damage on that side of the brain; also called transitional injury.

convection The mechanism by which heat (body heat in the context of this chapter) is picked up and carried away by moving air currents.

Coombs' test A test used to identify antibodies that may bind to the red blood cells and cause hemolysis.

corpus callosum A large tract of transverse fibers that provides a communication link between the two cerebral hemispheres.

crackle Breath sound produced as fluid-filled alveoli pop open under increasing inspiratory pressure;

can be fine or coarse.

cranial nerves (CN) The 12 nerves arising directly from the brain that govern many of the senses and the functions of muscles in the eyes, face, and pharynx.

C-reactive protein (CRP) An acute phase protein synthesized in the liver; an indicator of inflammation.

creatine kinase (CK) An enzyme that cleaves the high-energy phosphate from creatine in muscle tissues and transfers it to adenosine diphosphate to yield adenosine triphosphate; measurement is used in the assessment for a myocardial infarction.

creatine A major storehouse of intramuscular high-energy phosphate.

creatinine (Cr) The metabolized form of creatine resulting from muscle metabolism and eliminated through the urine. The rate of creatinine clearance is calculated as follows: [(140 – age) × weight in kilograms], divided by [plasma creatinine level × 72].

crew resource management A system that originated as the result of a NASA workshop in 1979 as a means to improve air safety. It incorporates equipment, procedures, and crew concerns to make the best decision during flight operations, focusing on interpersonal communication, leadership, and decision making.

critical care Constant, complex, detailed health care as provided in various acute life-threatening conditions; the ability to deal with crucial situations rapidly and with precision using various advanced machines and devices for treating and monitoring the patient's condition.

critical care patient Any patient who experiences an actual or potential life-threatening illness or injury that requires continual monitoring and care by a specially trained physician, registered nurse, or paramedic.

critical care transport The transport of a patient from an emergency department, critical care unit, or incident scene during which the patient receives the same level of care as was provided in the hospital or originating facility.

critical care transport professional (CCTP) A health care professional who has successfully completed a recognized critical care program and meets the minimum qualifications set forth by the employing transport program.

critical stage The stage of acute hypoxia in which there is almost complete mental and physical incapacitation, resulting in rapid loss of consciousness, seizures, respiratory arrest, and death.

Crohn's disease An inflammation of the GI tract in which all layers of the mucosa may be affected. It results in scattered ulcerations and fibroses throughout the large and small intestines.

cross-tolerance A form of drug tolerance in which patients who take a particular medication for an extended period can build up a tolerance to other medications in the same class.

croup A childhood viral disease characterized by edema of the upper airways with barking cough, difficult breathing, and stridor; also called laryngotracheobronchitis.

cryoprecipitate A blood product created from plasma and in which clotting factors, especially factor VIII, are concentrated; used to treat patients with coagulation disorders.

cumulative effect An effect that occurs when several successive doses of a medication are administered or when absorption of a medication occurs faster than excretion or metabolism.

current The movement of electrons through an electrical circuit over time, measured in amperes.

Cushing's syndrome A condition caused by an excess of cortisol production by the adrenal glands or by

excessive use of cortisol or other similar steroid (glucocorticoid) hormones.

Cushing's triad A cascade of events provoked when intracranial pressure rises to the level of the arterial pressure, vasoconstriction occurs in an effort to shift fluid volumes in the cranium, and the ensuing brain displacement puts pressure on the medulla oblongata by pushing it into the foramen magnum, resulting in disturbances in breathing, heart rate, and blood pressure.

cytokines Chemical messengers that enhance cell growth, promote cell activation, direct cellular traffic, stimulate macrophage function, and destroy antigens; interleukins are a type of cytokine.

daily safety briefing A meeting held at the beginning of each critical care transport shift, in which the daily plan, crew member duties, equipment and aircraft issues, weather expectations, and emergency situations are reviewed.

Dalton's law States that the total pressure of a gas mixture is the sum of the individual or partial pressures of the gases in the mixture; also referred to as the law of partial pressure.

damage In a legal context, damage must result from a breach of duty for a health care provider to be found negligent. Usually, the injury is physical.

dampened waveform A hemodynamic pressure waveform that appears to have lost crisp deflections.

D-dimer test A test of hypercoagulability that detects a fragment from the fibrinolysis process; the test can be used to help diagnose and monitor diseases and conditions related to inappropriate clotting; for example, it can be used to test for deep venous thrombosis.

decompression sickness A condition resulting from exposure to low barometric pressure, causing inert gases normally dissolved in body fluids and tissue to come out of physical solution and form bubbles.

decontamination Use of chemical, physical, or other means to remove, inactivate, or eradicate harmful microorganisms from persons, surfaces, or objects.

deep frostbite A type of frostbite in which the affected part looks white, yellow-white, or mottled blue-white and is hard, cold, and without sensation.

deep partial-thickness burn A burn in which the skin is blistered but not charred and is painful to the touch, usually the result of steam, oil, or flames and involving the deeper layers of the dermis.

delayed hemolytic transfusion reactions A type of transfusion reaction that does not occur until 3 to 7 days after transfusion.

delayed traumatic intracranial hemorrhage (DTICH) Hemorrhage that occurs within the first 3 to 10 days following an injury to the occipital-parietal region via a coup-contrecoup mechanism.

delta wave The slurring of the upstroke of the first part of the QRS complex that occurs in Wolff-Parkinson-White syndrome.

depolarization The process of discharging resting cardiac muscle fibers by an electrical impulse that causes them to contract.

depolarizing paralytics Medications that cause neuromuscular blockade by binding and briefly activating receptor sites at the neuromuscular junction, preventing further activation of these sites and causing chemical paralysis.

depressed skull fracture A type of skull fracture in which a portion of the skull is depressed; the scalp and/or dura may or may not be torn.

dextrocardia A congenital cause of right axis deviation, in which the heart develops in a right-facing

position, creating a mirror image of the normal left-facing heart.

diabetic ketoacidosis (DKA) A form of acidosis in uncontrolled diabetes in which certain acids accumulate when insulin is not available.

diaphragma sellae An extension of the dura mater that forms a roof over the sella turica, which contains the pituitary gland.

diaphragmatic hernia Passage of loops of bowel with or without other abdominal organs, through the diaphragm muscle; occurs as the bowel from the abdomen "herniates" upward through the diaphragm into the chest (thoracic) cavity.

diastatic stellate fracture A fracture involving injury to a bone with separation of an epiphysis; prevalent in abused children.

diastole The relaxation phase of the heart cycle, in which the ventricles are dilated and filling with blood.

diastolic augmentation The increase in aortic pressure during diastole that IAB inflation produces, improving coronary and peripheral perfusion, and that may be thought of as a "second systole."

diastolic augmentation waveforms The waveforms caused by IAB inflation during diastole.

diastolic blood pressure (DBP) The trough or resting pressure in the arterial system that occurs during ventricular diastole.

dicrotic notch The brief increase in aortic pressure reflected in a notching of the wave; caused by the sudden closure and spring back of the aortic valve leaflets; signals the start of diastole.

diencephalon Portion of the cerebrum consisting of the thalamus, the hypothalamus, the subthalamus, and the epithalamus.

differential diagnosis A list of all possible diagnoses, aside from the projected diagnosis, that could be causing a patient's symptoms.

diffuse axonal injury (DAI) A deep-brain injury in which shearing forces damage the integrity of the axon at the node of Ranvier, which consequently alters the axoplasmic flow.

digoxin A cardiac glycoside that produces positive inotropic and negative chronotropic activity in the heart and is primarily indicated in the treatment of chronic heart failure and to control the ventricular rate in atrial tachyarrhythmias.

dilation Opening of the cervix to a maximum of 10 cm, at which point it is considered complete.

dilation and curettage (D&C) A surgical procedure in which the cervix is opened and the uterus scraped of tissue.

diplopia Double vision.

direct bilirubin Conjugated bilirubin; the result of bilirubin's conjugation in the liver, which is ultimately excreted in the bile.

discordant A term that describes T waves that are in the opposite direction from the terminal portion of the QRS complex in bundle branch blocks.

disseminated intravascular coagulation (DIC) A complex condition arising from different causes that activate coagulation mechanisms, resulting in obstructed blood flow as a result of microclots; in fibrinolysis, the attempt by the body to reopen the microcirculation. Bleeding and thrombosis and, potentially, organ dysfunction result.

distal intestinal obstruction Partial or complete obstruction of the distal small bowel (ileum) or large

intestine.

distributive shock A condition that occurs when there is widespread dilation of the resistance vessels, the capacitance vessels, or both.

disturbance stage A stage of hypoxia in which physiologic responses are inadequate to compensate for the oxygen deficiency, and hypoxia is evident.

diverticula Small pouches of tissue that develop as outcroppings of the large intestine, typically in the descending colon and sigmoid colon.

diverticulitis Inflammation of diverticula.

diverticulosis Development of diverticula that may then become inflamed or bleed.

do not resuscitate (DNR) order A type of advance directive that describes which life-sustaining procedures should be performed in case of a sudden deterioration in a patient's medical condition.

doll's eye test An oculocephalic reflex test that is performed on the unconscious patient by rapidly rotating the head from side to side and observing the eye movement.

dorsal Toward the back surface of an object; posterior.

drag The resistance of an airplane to forward motion, directly opposed to thrust.

dromotropic Influencing the conduction rate within the heart.

drug antagonism Medications that bind with a receptor site and prevent activation of these receptors by other medications, without causing receptor activation or related clinical effects.

drug interaction The alteration of the action of a particular medication when combined with another medication.

dual-chamber pacemaker An artificial pacemaker with two leads (one in the atrium and one in the ventricle) so electromechanical synchrony can be achieved.

DUMBELS Mnemonic for symptoms of anticholinesterase inhibitor toxicity: Diaphoresis/diarrhea, Urination, Miosis, Bradycardia/bronchospasm/bronchorrhea, Emesis, Lacrimation, and Salivation.

dura mater The outer membrane of the meninges.

dural venous sinuses Endothelial-lined spaces between the periosteal and meningeal layers of the dura mater.

duration of action How long the medication concentration can be expected to remain above the minimum level needed to provide the intended action.

duty to act A legal obligation of public and certain other ambulance services to respond to a call for help in their jurisdiction. When the duty to act applies varies from state to state; it can be when a CCTP initiates treatment or when the dispatch center confirms that a transport vehicle is being sent.

dysbarism A condition resulting from the effects (excluding hypoxia) of a pressure differential between the ambient barometric pressure and the pressure of gases within the body.

dysconjugate movement Lack of symmetric movement between the two visual axes.

eclampsia The condition that exists once a patient with preeclampsia develops seizures; warning signs of the transition include severe headache, scotomata, hyperreflexia, epigastric pain, and anxiety; the condition causes serious maternal complications.

ectopic pregnancy A pregnancy in which the ovum implants somewhere other than the uterine

endometrium.

Edinger-Westphal nucleus Part of the midbrain that is responsible for mediating the autonomic reflex centers for pupillary accommodation to light.

effective performance time The amount of time an individual is able to perform useful duties in an environment of inadequate oxygen; also known as expected performance time.

efferent pathways Descending pathways that carry motor impulses away from the central nervous system.

ejection fraction The portion of the blood ejected from the ventricle during systole.

electrical alternans An ECG pattern in which the QRS vector changes with each heartbeat. This pattern is pathognomonic of cardiac tamponade.

electrode In the context of a 12-lead ECG, an electrical sensor placed on the chest to record the bioelectrical activity of the heart. In the context of a pacemaker, a conductor in contact with cardiac tissue at the end of a pacing lead; it delivers impulses to that tissue.

electroencephalography (EEG) A procedure that records the electrical activity of the brain by measuring brain waves.

emancipation A legal status in which a person who is younger than the legal age in a given state is legally considered an adult; he or she gives up the right to maintenance and support from a parent, and the parent relinquishes the right to control the child.

embolic stroke Occurs when a blood clot, known as an embolus, forms in one part of the body and travels through the bloodstream to the brain or neck.

emergency locator transmitter (ELT) A device that activates upon the crash of an aircraft and broadcasts a signal that rescuers can use to locate the downed aircraft.

Emergency Medical Treatment and Active Labor Act (EMTALA) A federal law passed by Congress in 1986, with a primary focus of preventing hospitals from transferring patients to other facilities because they are unable to pay for services. Initially, EMTALA was a portion of the Consolidated Budget Reconciliation Act of 1985 (COBRA).

endocardial (transvenous) leads Pacemaker leads guided by angiography and attached to the endocardium.

endocrine hypertension Significant high blood pressure caused by a hormonal disorder; often related to excess hormone produced by a tumor.

endometrium The inner mucous membrane of the uterus.

endoscopy The method of choice for visualization of the GI tract; it allows for observation, diagnosis, and treatment of an insult to the GI tract.

end-stage renal disease (ESRD) A loss of proper kidney functioning, with renal replacement therapy becoming a requirement for survival.

enhanced elimination A process that replaces or augments the body's normal method of eliminating, modifying, or breaking down toxic substances.

enteroclysis Infusion of barium contrast dye into the GI tract to observe for obstruction.

enzymes Proteins that act as catalysts for biochemical reactions within the body.

epicardial leads Pacemaker leads attached to the epicardium (outer surface of the myocardium);

placement and troubleshooting are done in the hospital and require surgery and anesthesia.

epidemiology The study of disease distribution within populations and the factors that determine that distribution.

epidural hematoma (EDH) An injury resulting in the accumulation of blood between the inner periosteum and the dura mater; also called extradural hematoma.

epiglottitis Inflammation of the epiglottis.

epithalamus An area of the cerebrum that is located in the dorsal portion of the diencephalon and contains the pineal gland.

epitope The specific portion of the antigen that is recognized by the antibody or B cell.

eschar The leathery covering of a burn injury, formed after the burned tissues dry out.

escharotomy A surgical incision in an eschar to lessen constriction; sometimes necessary (although rarely performed in a prehospital setting) to prevent edema from building up, impairing capillary filling, and causing ischemia.

esophageal atresia A congenital defect in which the esophagus ends in a blind pouch, often associated with other anomalies such as tracheoesophageal fistula.

esophageal detection device (EDD) A bulb or syringe that is attached to the proximal end of the ET tube; a device used to confirm proper ET tube placement.

esophageal varix Swelling of esophageal veins into the lumen of the esophagus.

etiology The cause of a disease.

eupnea Normal breathing at a rate of 12 to 20 breaths/min in the adult patient.

evaporation The conversion of a liquid to a gas.

exertional hyponatremia A low sodium level as a result of prolonged exertion in hot environments coupled with excessive hypotonic fluid intake that leads to nausea, vomiting, and, in severe cases, mental status changes and seizures.

expiratory reserve volume (ERV) The air that can be expelled from the lungs after a normal exhalation.

external fetal monitoring Electronic heart monitoring of the fetus while in utero, performed via electrodes on the pregnant woman's abdomen.

extinction A test of sensation discrimination in which the CCTP simultaneously touches opposite, corresponding areas of the body, and asks the patient where the touch is felt; it is intended to identify sensory inattention.

extracorporeal membrane oxygenation (ECMO) A supportive intervention which provides oxygenation to a patient by removing the patient's blood to a heart and lung machine that does the work normally done by the lungs and heart. The blood is then transfused back into the patient's circulation.

extradural space A potential space between the cranial bones and the periosteal layer of the dura that becomes a real space only when blood from torn vessels pushes the periosteum from the cranium and accumulates; also called epidural space.

face-to-face intubation Performing intubation at the same level as the patient's face; used when the standard position is not possible. In this position, the laryngoscope is held in the provider's right hand and the ET tube in the left.

false imprisonment Intentional and unjustifiable detention of a patient.

falx cerebelli A fold of dura mater that forms the division between the two lateral lobes of the cerebellum.

falx cerebri A double fold of dura mater that divides the cerebrum into right and left hemispheres by descending vertically into the longitudinal fissure that extends from the frontal lobe to the occipital lobe.

fasciotomy A surgical incision into an area of fascia, for example to relieve pressure between two compartments; not usually performed in a prehospital setting.

FAST An ultrasound examination directed at identifying the presence of free intraperitoneal or pericardial fluids, performed by transducing four distinct areas of the abdomen; stands for Focused Assessment with Sonography for Trauma.

fecal-oral route The route of transmitting infectious organisms from one individual to another; commonly, enteric bacteria or viruses are shed in the feces, spread via contamination of food or water sources, and ingested by other individuals.

Federal Aviation Administration (FAA) A US governmental agency within the Department of Transportation that regulates and oversees civil aviation within the United States; established and enforces the Title 14 CFR that govern aircraft operation within the United States.

Fick principle A method of indirectly determining cardiac output, in which the amount of oxygen uptake of blood as it passes through the lungs is equal to the oxygen concentration difference between mixed venous and arterial blood; the formula uses assumed values for oxygen consumption derived from basal metabolic studies on healthy subjects, which may or may not be valid in critically ill patients.

Fick's law States that the net diffusion rate of a gas across a fluid membrane is proportional to the difference in partial pressure, proportional to the area of the membrane, and inversely proportional to the thickness of the membrane.

first-order elimination The plasma concentration of a medication or substance is proportional to its rate of elimination.

first-pass effect Medications absorbed from the intestine that are partially inactivated as they pass through the hepatic circulation into the liver before entering the systemic circulation; also called first-pass metabolism.

fissures Deep grooves between adjacent gyri of the brain.

fixed-wing aircraft Airplanes; these are capable of transporting critically ill and injured patients a distance of 150 miles or greater.

FLACC scale A pain assessment scale that scores points for five categories, including face, legs, activity, cry, and consolability.

flat fracture The least common type of depressed skull fracture, in which the depressed segment does not have any connection with the cranial vault.

flexion-extension injury A spinal cord injury that results from forward movement of the head, typically as the result of rapid deceleration, or from a direct blow to the occiput.

flicker vertigo An imbalance in brain cell activity caused by exposure to low-frequency flickering or flashing light. Light flickering from 4 to 20 times per second can precipitate reactions, including nausea, migraines, unconsciousness, and seizures.

flight following The practice of maintaining constant contact with other local traffic and air traffic controllers.

flight surgeon A physician who specializes in flight medicine and has been trained extensively in various aspects of aviation and the effects of flight on the human body; also specializes in working with pilots and flight crew members.

flow-cycled ventilator A positive-pressure ventilator that ends inspiration when a predetermined flow rate is achieved.

flow rate The speed of the gas at which the tidal volume is delivered.

focal ischemic stroke Occurs when an area of marginally perfused tissue, the ischemic penumbra, surrounds a core of ischemic cells, and the cells will eventually die without medical intervention.

fomite An inanimate object that is capable of transmitting infectious organisms from one individual to another.

footling breech A delivery presentation in which both feet extend into the birth canal; this is the only malpresentation in which field delivery may be considered.

foramen magnum The opening at the base of the skull through which the bundle of nerve fibers constituting the spinal cord exits.

foramen of Luschka An opening at the base of the fourth ventricle that leads to the subarachnoid space and is essential for the normal flow of cerebrospinal fluid; part of the brain's ventricular system.

foramen of Magendie An opening at the base of the fourth ventricle that leads to the subarachnoid space and is essential for the normal flow of cerebrospinal fluid; part of the brain's ventricular system.

foramen of Monro An opening in the skull that connects the two lateral ventricles with the third ventricle, a central cavity; part of the brain's ventricular system.

Foster–Kennedy syndrome A tumor or abscess at the base of the frontal lobe that impacts the olfactory nerve.

fraction of inspired oxygen (F_{IO_2}) Percentage of inhaled oxygen expressed as a decimal. For example, 40% oxygen = F_{IO_2} of 0.40.

frank breech A delivery presentation in which the buttocks present first, both of the infant's hips are flexed, and the feet are near the fetus' head.

Frank-Starling curve States that the force of the cardiac muscle contraction is proportional to the amount of stretch placed on the muscle fibers (meaning that the more the heart is stretched by the incoming blood, the more forcefully the ventricles contract and the more blood that is ejected); demonstrates how changes in ventricular preload lead to changes in stroke volume.

Frank-Starling law A law of physiology that states that the greater the myocardium is stretched, the greater the force of contraction.

fresh-frozen plasma (FFP) A blood product in which uncoagulated plasma has been separated from the red blood cells; primarily composed of water, proteins, salts, metabolites, and clotting factors.

frontal lobe The largest of the four lobes of the brain; it lies underneath the frontal bone of the skull and is separated posteriorly from the parietal lobe by the central fissure and inferiorly from the temporal lobe by the lateral fissure; responsible for a variety of cognitive and motor functions.

frostbite Localized damage to tissues resulting from prolonged exposure to extreme cold.

full-thickness burn A burn that extends through the epidermis and dermis into the subcutaneous tissues beneath, in which skin is pale, painless, leathery, and charred; also called a third-degree burn.

fulminant hepatic failure A sudden and significant insult to the liver characterized by encephalopathy and a mortality rate of up to 90%.

functional residual capacity (FRC) The amount of air remaining in the lungs after normal expiration; the sum of residual volume and expiratory reserve volume.

functioning adenoma A type of pituitary lesion in which overproduction of hormones occurs.

fundus The optic disk, macula, and blood vessels on the back wall of the internal eyeball.

Galveston formula A formula used to calculate fluid resuscitation for children, which takes into consideration the BSA burned and the TBSA of the child, with half of the amount given in the first 8 hours after injury and the second half over the next 16 hours.

gas lumen The lumen or port of the IAB catheter that carries helium between the IAB and the pump console to inflate and deflate the balloon.

gastritis Inflammation of the gastric mucosa that occurs when the equilibrium of offensive and defensive mechanisms for the lining is altered.

gastroschisis A centrally located, full-thickness abdominal wall defect.

Gay-Lussac's law States that the pressure of a gas when volume is maintained constant is directly proportional to the absolute temperature for a constant amount of gas. Simply stated, as pressure increases, volume increases.

gestation Period of time elapsed from conception to birth. For humans, the full period is normally 40 weeks.

gigantism A syndrome that results from excessive growth hormone, secreted by the pituitary gland before the epiphyseal plate has closed; characterized by the growth of bones, muscles, and many internal organs at an abnormally fast rate.

Glasgow Coma Scale (GCS) An evaluation tool used to determine level of consciousness, which evaluates and assigns point values (scores) for eye opening, verbal response, and motor response, which are then totaled; effective in helping predict patient outcomes.

global ischemic stroke Results when severe hypotension or cardiac arrest produces a transient drop in blood flow to all areas of the brain.

glomerular filtration rate (GFR) A benchmark for comparison of nephron function, based on the amount of fluid filtered by the glomerulus per minute.

gluconeogenesis Glucose formation.

glycogenolysis The breakdown of glycogen to glucose.

glycosuria The presence of glucose in the urine.

Graham's law States that the rate at which gases diffuse is related inversely to the square root of their densities.

gravida The number of pregnancies a woman has had, including those not carried to term.

gravitational forces Force changes that occur with acceleration and deceleration.

gyri Convolutions on the surface of the cerebrum that functionally increase the cortical surface area.

half-life (T1/2) The time period required to eliminate one half of the plasma concentration. During the second "half-life," an additional 25% of the original plasma concentration is eliminated. After three half-lives, one-eighth of the original plasma concentration remains.

halo test A test for leaking CSF that is accomplished by collecting and assessing fluid that drains from the nose, mouth, or ears; a "halo" consisting of a dark red circle surrounded by a lighter yellowish one is a positive halo sign.

hapten A small-molecular-weight nonprotein molecule that is capable of reacting with a specific antibody but cannot elicit the formation of antibodies unless bound to a carrier protein; also called a partial or incomplete antigen.

hard landing An excessively firm contact with the ground, potentially resulting in injury or aircraft damage.

Hashimoto's disease A condition that occurs when the immune system attacks the patient's thyroid gland. The leading cause of hypothyroidism; also known as chronic lymphocytic thyroiditis.

health care–associated pneumonia (HCAP) A pneumonia that occurs in nonhospitalized patients who have contact with health care facilities or personnel.

Health Insurance Portability and Accountability Act (HIPAA) A law enacted in 1996, providing for criminal sanctions and civil penalties for releasing a patient's protected health information (PHI) in a way not authorized by the patient.

heat cramps Acute and involuntary muscle pains, usually in the lower extremities, the abdomen, or both, that occur because of profuse sweating and subsequent sodium loss in sweat.

heat exhaustion A clinical syndrome characterized by volume depletion and heat stress that is thought to be a milder form of heat illness and on a continuum leading to heat stroke.

heat stroke The least common and most deadly heat illness, caused by a severe disturbance in thermoregulation, usually characterized by a core body temperature of more than 104°F (40°C) and altered mental status.

heat syncope An orthostatic or near-syncopal episode that typically occurs in nonacclimated people who may be under heat stress.

Helicobacter pylori A bacterium that causes most peptic ulcers.

helicopter emergency medical service (HEMS) Use of a rotor-wing aircraft to deliver air medical service, for which the goals are to rapidly transport CCTPs to a patient, stabilize the patient's condition, and rapidly transport that patient to a tertiary care center.

helicopter shopping The practice of making sequential calls to numerous air medical providers in an attempt to find a service that will accept a mission request that has been declined by other services based on safety factors such as poor weather, limited landing zone availability, exceptional distances, or other factors.

HELLP syndrome A hemolytic disorder that occurs during the latter stages of gestation, usually after the 20th week, and whose clinical findings include hemolytic anemia, elevated liver enzyme levels, and a low platelet count; patients will present with blurred vision, abdominal pain, headache, and edema.

hematemesis Coffee-ground emesis containing partially digested blood.

hematochezia Stool streaked with bright red blood, originating from the lower GI tract.

hematocrit The percentage of formed elements (that is, cells) in a venous blood sample.

hematuria The presence of red blood cells in the urine.

hemiblocks Blocks of one of the fascicles of the left bundle branch, the left anterior or left posterior fascicle.

hemoconcentration Decreased fluid in the blood, which means that concentrations of other blood components increase.

hemodialysis (HD) Use of vascular access through a fistula or AV shunt to access the blood directly. Solute separation occurs across an artificial semi-permeable membrane within the dialysis machine.

hemoglobin (Hgb) The protein responsible for carrying oxygen to the body's cells and, to a lesser extent, carbon dioxide back to the lungs.

hemoglobinuria The presence of hemoglobin in the urine.

hemolysis A situation in which red blood cells are destroyed, resulting in the release of hemoglobin and red blood cell remnants into the bloodstream; sometimes follows massive blood transfusions or blood transfusion reactions.

hemolytic transfusion reaction A type of transfusion reaction caused by ABO or Rh incompatibility, intradonor incompatibility, improper crossmatching, or improper blood storage.

hemolytic uremic syndrome (HUS) A serious condition in which the patient develops acute renal failure, and which also causes anemia and thrombocytopenia; thought to be caused by several bacterial and viral infectious organisms, most often verotoxin-producing strains of *E coli*.

hemoperfusion A treatment in which a patient's blood is filtered outside the body through a substance that removes toxic substances from it; a method of removing toxic substances from the blood.

hemorrhagic conversion After the brain tissue surrounding the stroke has died, renewed blood flow to the region, for example as triggered by medication, is no longer held in place by the tissue, resulting in hemorrhage.

Henry's law States that the amount of gas dissolved in solution is directly proportional to the pressure of the gas over the solution.

hepatic encephalopathy Encephalopathy secondary to hepatic disease.

hepatitis Inflammation of liver cells that can impede proper functioning of the liver and lead to chronic conditions such as cirrhosis.

hepatitis C virus (HCV) The virus that is the most common cause of cirrhosis and is especially pathogenic in causing hepatitis.

hepatoiminodiacetic acid (HIDA) scan Administration of a radiologically labeled chemical specific for bile incorporation to a patient; the path taken by the marker is observed through radiography to ascertain whether an obstruction is present.

hepatojugular reflex A reflex tested in assessment in which midabdominal pressure is applied while observing for jugular venous distention; if noted, the test result is positive and indicates volume overload.

hepatotoxicity Capable of damaging the liver.

hernia A protrusion of an organ from its tissue lining.

hexaxial system The system developed to describe the coronal plane that is created by the limb leads (I, II, III, aVR, aVL, and aVF).

high-altitude cerebral edema (HACE) An altitude illness in which there is a change in mental status and/or ataxia in a person with acute mountain sickness or the presence of mental status changes and ataxia in a person without acute mountain sickness.

high-altitude pulmonary edema (HAPE) An altitude illness characterized by dyspnea at rest, cough, severe weakness, and drowsiness that may eventually lead to central cyanosis, audible rales or wheezing, tachypnea, and tachycardia.

high-level disinfection Treatment used on inanimate objects to kill all microorganisms but which does *not* kill bacterial spores.

hippus phenomenon A pattern of pupil response to light in which there is rapid constriction of the pupil followed by dilation; can be normal or signify compression of cranial nerve III.

Hirschsprung's disease A congenital lack of ganglion nerve cells in a portion of the distal intestines leading to poor intestinal peristalsis, constipation, and, if not diagnosed and treated, potentially death.

histotoxic hypoxia Hypoxia caused by the inability of the tissues to use oxygen, usually as a result of poisoning by toxins such as carbon monoxide and cyanide.

homeostasis Stability in the body's internal environment.

hospital-acquired pneumonia (HAP) Pneumonia that occurs in a hospitalized patient within 48 hours or more after admission to the hospital that was not apparent at the time of admission.

hot loading Loading a patient into a helicopter while the helicopter is running.

hot zone The area immediately surrounding the chemical source at a hazmat scene.

human leukocyte antigen (HLA) An antigen present on the cell membrane surface of circulating platelets, white blood cells, and most tissue cells.

humidity The degree of moisture in the air, expressed as a percentage.

hydroureteronephrosis Dilation and obstruction of a ureter.

hypemic hypoxia Hypoxia caused by a decrease in the oxygen-carrying capacity of the blood due to a reduced amount of hemoglobin in the blood or a reduced number of red blood cells; also known as anemic hypoxia.

hypercalcemia An increased level of calcium in the blood.

hypercapnia Greater than normal amounts of carbon dioxide in the blood.

hyperchloremia An abnormally high level of chloride in the blood.

hyperchloremic acidosis A form of metabolic acidosis in which low bicarbonate (base) concentration occurs along with an increase in chloride concentration.

hyperdynamic state A condition that occurs as the first stage of distributive shock and is characterized primarily by high cardiac output and low peripheral vascular resistance; also known as warm shock.

hyperemic An increase in blood flow into a tissue or organ; congested with blood.

hyperkalemia An abnormally high level of potassium in the blood.

hyperosmolar hyperglycemic nonketotic syndrome (HHNS) A metabolic derangement that occurs principally in patients with type 2 diabetes, and is characterized by hyperglycemia, hyperosmolarity, and absence of significant ketosis.

hyperpnea A breath that is deeper than normal; can lead to low levels of Co_2.

hyperreflexia A condition of overactive reflexes that can involve excessive twitching or spasms.

hyperresonance An abnormal respiratory sound that is exaggerated or increased beyond normal and low in pitch.

hypersensitivity Occurs when a patient reacts with exaggerated or inappropriate allergic symptoms after coming into contact with a substance the body perceives as harmful.

hyperthyroidism A condition caused by an increased production of T3 (triiodothyronine) and T4 (thyroxine) from the thyroid gland, resulting in an increase in the body's organ function, and characterized by an increase in body temperature, gradual weight loss, increased and/or irregular heart rate, sweating, and irritability.

hypertrophy An increase in the size of the cells as the result of synthesis of more subcellular components, leading to an increase in tissue and organ size.

hypoalbuminemia An abnormally low level of albumin in the blood.

hypocalcemia A low level of calcium in the blood.

hypochloremia An abnormally low level of chloride in the blood.

hypodynamic state A condition that occurs as the second stage of distributive shock and is characterized primarily by a subnormal temperature, a low white blood cell count, profound hypotension and hypoperfusion, and a sudden drop in cardiac output; also known as cold shock.

hypokalemia An abnormally low level of potassium in the blood.

hyponatremia An abnormally low level of sodium in the blood.

hypoplastic left heart syndrome (HLHS) Underdevelopment of the aorta, aortic valve, left ventricle, and mitral valve; this defect involves the entire left side of the heart.

hypopnea A shallow breath; can lead to increased Co_2 levels and decreased oxygen levels.

hypothalamic-pituitary axis An interrelationship between the hypothalamus and pituitary gland in which a releasing or an inhibiting factor is sent from the hypothalamus to the pituitary, resulting in an increase or a decrease in metabolism and other functions throughout the body.

hypothalamo-hypophyseal portal system The venules between the capillaries in the hypothalamus and pituitary gland by which the hypothalamus sends releasing or inhibiting factors to the pituitary gland, thereby increasing or decreasing metabolism.

hypothalamus The most inferior portion of the diencephalon; it is responsible for control of many body functions, including heart rate, digestion, sexual development, temperature regulation, emotion, hunger, thirst, and regulation of the sleep cycle.

hypothermia A condition in which the core body temperature decreases to less than 95°F (35°C).

hypothyroidism A condition caused by a deficiency of T3 (triiodothyronine) and T4 (thyroxine) from the thyroid gland, resulting in a slowing of the body's organ function, and characterized by a decrease in body temperature, gradual weight gain, and increased risk for acute myocardial infarction and cerebrovascular accident.

hypotonia Low or poor (floppy) muscle tone.

hypovolemic shock A condition that occurs when the circulating blood volume is inadequate for delivering adequate oxygen and nutrients to the body.

hypoxia A state of oxygen deficiency in the body, which is sufficient to cause an impairment of function.

Hypoxia is caused by the reduction in partial pressure of oxygen, inadequate oxygen transport, or the inability of the tissues to use oxygen.

hypoxic hypoxia Hypoxia caused by a decrease in the amount of oxygen in the blood due to a reduction in oxygen pressure in the lungs, a reduced gas exchange area, exposure to high altitude, or lung disease.

hypoxic ischemic encephalopathy (HIE) Damage to cells in the central nervous system (the brain and spinal cord) from inadequate oxygen.

I time The time frame for the delivery of the tidal volume.

I:E ratio An expression for comparing the length of expiration to inspiration. The normal ratio is 1:2. This means that expiration is twice as long as inspiration. It is not measured in seconds.

iatrogenic Any adverse physical condition that results from medical treatment.

iatrogenic response An adverse condition inadvertently induced in a patient by the treatment given.

idiosyncrasy An abnormal (and usually unexplained) reaction by a person to a medication to which most other people do not react.

ileus A lack of movement of GI contents in the absence of an obstruction.

immediate hemolytic transfusion reactions A type of transfusion reaction that usually occurs soon (between 1 and 2 hours) after the transfusion of incompatible red blood cells.

immunocompromised Unable to mount a normal immune response as the result of disease (such as AIDS) or chemotherapy treatment.

immunodeficiency An abnormal condition in which some part of the body's immune system is inadequate, and consequently resistance to infectious disease is decreased.

impedance Resistance to the flow of current along an electrical pathway, measured in ohms.

imperforate anus A congenital condition where the anal opening is either absent or displaced.

implantable cardioverter-defibrillator (ICD) A small, battery-powered electrical impulse generator that is implanted in patients at risk for sudden cardiac death as the result of ventricular fibrillation or pulseless ventricular tachycardia.

implantable pulse generator (IPG) The largest implanted element in a pacemaking system, containing the battery and control circuitry.

implied consent Assumption on behalf of a person unable to give consent that he or she would have consented.

inborn error of metabolism A class of genetic diseases mostly due to defects of single genes that code for enzymes that facilitate conversion of various substances into others leading to accumulation of substances which are toxic or interfere with normal function.

incomplete breech A delivery presentation in which the buttocks present first and one foot extends into the birth canal.

incomplete spinal cord injury A disruption of the tracts of the spinal cord in which the patient retains some degree of cord-mediated function.

incorporation In the radiologic context, a process in which radioactive materials enter the body during radiation exposure, causing ongoing internal exposure and creating devastating individual patient toxicity.

incubator An enclosed, clear plastic, heated bed that keeps the infant warm.

indicator conditions Rare or unusual diseases associated with an immunocompromised state. Also called AIDS-related diseases.

indifferent stage The stage of altitude hypoxia in which the body is able to compensate for the hypoxia induced by low barometric pressures.

indirect bilirubin A by-product of the metabolism of red blood cells that is unconjugated and, therefore, not water soluble.

inflammatory bowel disease (IBD) Term covering two colon inflammation pathologies: ulcerative colitis and Crohn's disease.

informed (express) consent A patient's voluntary agreement to be treated after being told about the nature of the disease, the risks and benefits of the proposed treatment, alternative treatments, and the choice of no treatment at all.

inhibition The presence of one medication that decreases the effect of another medication.

Injury Severity Score (ISS) A trauma scoring system that adds the squares of the three highest abbreviated injury scale scores to create a score between 1 and 75 that accounts for multiple injuries, with 1 being a minor injury and 75 being an injury with a high mortality rate.

innate immune system The primary antigen and immunogennonspecific defense mechanism that protects the host by eliminating microbes to prevent infection and other antigens in an attempt to prevent allergic reactions.

innate immunity Immunity to diseases inherent in the genetic makeup of an individual.

inotropic Affecting the force with which muscle tissue contracts, especially cardiac muscle.

inspiratory capacity (IC) The maximum amount of air that can be inspired; the sum of inspiratory reserve volume and tidal volume.

inspiratory reserve volume (IRV) The amount of air that can be inhaled after a tidal volume is inhaled.

instrument flight rules (IFR) A mode of flight used when adverse weather conditions exist, visibility is poor, or cloud cover is low. The pilot may not be able to see outside the aircraft, must rely on instruments, and must be in constant contact with an air traffic controller who assists in maintaining proper separation from other air traffic.

instrument meteorological conditions (IMC) Weather conditions (eg, cloudiness or low visibility) in which a pilot must fly under instrument flight rules, depending on instruments to guide the aircraft.

insulin resistance A condition in which the pancreas produces enough insulin but the body cannot effectively use it.

interference A direct biochemical interaction between two drugs.

intermediate-level disinfection Treatment used on inanimate objects to kill *M tuberculosis*, vegetative bacteria, and most viruses and fungi, but which does *not* kill bacterial spores.

internal capsule A massive bundle of efferent and afferent fibers connecting the various subdivisions of the brain and spinal cord.

International Civil Aviation Organization (ICAO) An agency of the United Nations that defines standards for international air navigation and, as part of its role in developing safe practices, requires crew resource management.

international normalized ratio (INR) A comparative rating of a patient's prothrombin time to help standardize the prothrombin time when planning treatment.

intervertebral foramen A space in the middle of the vertebra that allows the exit of a peripheral nerve root and spinal vein as well as the entrance of a spinal artery on both sides at each vertebral junction.

intra-aortic balloon pump (IABP) therapy A procedure involving a balloon inserted into the aorta and connected to a pump via a catheter, helping to increase the blood flow to the coronary arteries during diastole (inflation) and decrease afterload of blood from the left ventricle (deflation).

intra-atrial conduction delay Delayed conduction within one of the atria, often associated with left or right atrial enlargement.

intra-atrial pathways The anterior or Bachman bundle, middle bundle, and posterior internodal system, through which the electrical impulse passes after the SA node; represented by the P wave on the ECG; also called intranodal pathways.

intracerebral hemorrhage Direct bleeding into the brain parenchyma.

intracranial pressure (ICP) The pressure exerted by brain tissue, intracranial vascular contents, and cerebrospinal fluid in the closed, nondistensible cranial cavity.

intracranial temperature (ICT) Core brain temperature or homeostatic mean gradient temperature of 38.4°C.

intrarenal A type of acute renal failure caused by damage of an actual nephron.

intussusception An event where one part of the intestine folds into another part of the intestines, leading to a blockage.

invasive hemodynamic monitoring A term describing methods for assessing the physiologic condition of the three principle components of the cardiovascular system: heart, vascular network, and fluid volume; mainly assesses the capability of a patient's heart to pump the requisite amount of blood to the body, but also can assess compliance, tone, resistance of the vascular network, and fluid status; includes a variety of pressure values and other measurements.

invasive ventilation Application of mechanical ventilation through an artificial airway such as a tracheostomy or ET tube.

involuntary (autonomic) nervous system The sympathetic and parasympathetic branches of the nervous system, whose fibers connect the structures of the CNS with smooth muscle, cardiac muscle, and glands.

ionic bond A type of chemical bond formed between oppositely charged ions.

ionized calcium Calcium that is not bound or chelated (also called free calcium); its value is useful in assessing for renal failure, nephrotic syndrome, acid-base derangements, and decreases or elevations in chelating compounds.

irradiation Exposure to radiation; it is important to distinguish between this and contamination because health care providers and emergency responders are not placed at any risk by patients who have been exposed but are not contaminated.

ischemic stroke Occurs when an artery to the brain has been blocked by a thrombus, embolus, trauma, or vasospasm (often due to drugs).

isobaric pressurization system A system in which the aircraft cabin is pressurized and the cabin altitude is maintained at a constant pressure even as ambient pressure decreases. This type of pressurization is

found in most cargo planes and passenger aircraft.

isoelectric When referring to a wave, the wave is neither positive nor negative.

isovolumetric contraction The early stage of ventricular contraction during which ventricular blood volume is unchanging because all valves are closed (the semilunar valves have not yet opened).

isovolumetric relaxation The early stage of ventricular relaxation during which ventricular blood volume is unchanging because all valves are closed (the AV valves have not yet opened).

Jackson-Pratt drain A surgical drain used to remove fluid buildup from the wound site during the postoperative healing process.

jejunostomy tube (J tube) A feeding tube placed through the abdominal wall into the jejunum.

joule A measurement of energy.

jugular venous bulb oximetry A technique in which a sampling catheter is placed in the internal jugular vein and directed upward so that its tip rests in the jugular venous bulb at the base of the brain; samples of blood can then be drawn to measure mixed venous oxygen saturation (SVO_2).

JumpSTART triage A sorting system for pediatric patients younger than 8 years or weighing less than 100 lb. There is a minor adaptation for infants because they cannot ambulate on their own.

Kehr's sign Left shoulder pain that may indicate a ruptured spleen. Right shoulder pain may indicate trauma to the liver.

Kernig sign Resistance and pain elicited on extension of the leg at the knee, with the patient in the supine position and the hips flexed perpendicular to the trunk; when pain occurs as a result of this test, the test result is positive.

ketone bodies Organic products of fat catabolism—specifically, acetoacidic acid, acetone, and beta-hydroxybutyric acid.

ketonuria The presence of ketone bodies in the urine.

Kussmaul's respiration A fast and deep respiratory pattern without any periods of apnea. The rate and depth are greater than the normal rate expected; breathing is labored, with periods of deep breaths punctuated by sighs.

lactate The form of lactic acid that is physiologically present in the body.

lactate dehydrogenase (LDH) An enzyme that catalyzes the metabolism of pyruvate (the end product of glycolysis) to lactate in the absence of a functioning citric acid cycle.

lactic acidosis A form of acidosis caused by an excess accumulation or impaired excretion of lactate, leading to an elevated anion gap; can result from exposure to various toxic substances, inadequate tissue perfusion in various shock states, dysfunction of certain organs, nutritional deficiency, infection, malignancy, diabetes, or hereditary metabolic disorders.

lead In the context of the 12-lead ECG, the designated position of the electrode, or the name of the electrode placement. In the context of a pacemaker, an insulated wire that carries signals in a pacemaking system between the implantable pulse generator and the heart tissue.

Le Fort criteria A categorization of facial fractures involving the maxilla that are differentiated based on the location of fracture lines and the extent of mobility of facial structures on physical examination.

left anterior fascicle The portion of the electrical conduction system responsible for innervating the anterior and superior areas of the left ventricle. It is a single-stranded cord terminating in the Purkinje

cells.

left posterior fascicle The portion of the electrical conduction system responsible for innervating the posterior and inferior areas of the left ventricle. It is a widely distributed, fanlike structure terminating in the Purkinje cells.

left ventricular stroke work index A calculation of the contractility of the left ventricle indexed to the patient's body surface area; same as stroke volume index.

left ventricular end-diastolic pressure The pressure exerted on the left ventricle at the end of diastole; the normal value is 4 to 12 mm Hg and is measured by using a pulmonary artery catheter.

leukocytosis An abnormally high number of white blood cells.

leukotrienes A class of biologically active compounds that occur naturally in leukocytes and that produce allergic and inflammatory reactions.

Lhermitte phenomenon A condition in which forward flexion of the neck produces an electric shock feeling, usually running down the back.

lift The upward force created by the wings moving through the air, which sustains the airplane in flight.

ligament of Treitz A small ligament supporting the small intestine at the junction between the duodenum and jejunum. It serves as the dividing point between the upper and lower GI tract.

limb leads The ECG lead electrodes attached to the limbs that form the hexaxial system, dividing the heart along a coronal plane into the anterior and posterior segments.

limbic lobe (rhinencephalon) Part of the temporal lobe that is the seat of emotions and instincts.

linear skull fracture A type of skull fracture characterized by a single fracture line.

linear stellate fracture A fracture with multiple linear fractures radiating from the site of impact.

lipase A pancreatic hormone that metabolizes lipids.

lipid disorders A group of disorders that cause a change in the production or use of cholesterol and that also may cause a change in the way cholesterol is circulated or processed in the body.

liquefactive necrosis Tissue death caused by bacterial or fungal infections in which cellular destruction has occurred, leaving a lesion filled only with pus and the liquid remains of the tissue.

lithotripsy Use of external vibrations to break up gallstones.

liver function test (LFT) A test for liver damage that measures enzymes that normally appear in liver cells but may spill out into the vasculature with parenchymal damage.

long QT syndrome A prolonged QT interval on the ECG primarily caused by a congenital disorder and that under certain conditions tends to deteriorate into ventricular tachyarrhythmias and can lead to syncope or sudden cardiac death; the patient loses consciousness, often without warning.

long-term variability A pattern of changes in the baseline fetal heart rate occurring within 30-second intervals rather than from beat to beat; due to the parasympathetic-sympathetic interplay in the fetal heart rate.

low-level disinfection Treatment used on inanimate objects to kill most bacteria, some viruses, and some fungi, but which does *not* kill *M tuberculosis* and does *not* kill bacterial spores.

lumbar puncture A procedure in which a needle is inserted into the lumbar portion of the back and into the subarachnoid space to obtain spinal fluid for testing or to administer drugs.

Lund and Browder chart A detailed version of the rule of nines chart that takes into consideration the changes in body surface area brought on by growth.

magnetic resonance imaging (MRI) A noninvasive diagnostic imaging technique used to visualize the internal structure and function of the body, which works by using a powerful magnet to align water molecules present in body compartments; an image is obtained from this alignment and the speed at which molecules alter or release.

major burn A classification from the American Burn Association that includes: (1) partial-thickness burns involving more than 25% of BSA in adults or 20% of BSA in children younger than 10 years and adults older than 50 years; (2) full-thickness burns involving more than 10% of BSA; (3) burns involving the face, eyes, ears, hands, feet, or perineum that may result in functional or cosmetic impairment; (4) burns caused by caustic chemical agents; (5) high-voltage electrical injury; (6) burns complicated by inhalation injury or major trauma; and (7) burns sustained by high-risk patients.

malignant hyperthermia A condition that can result from certain anesthesia medications (notably succinylcholine) and is characterized by muscle spasms, rigidity, acidosis, hyperthermia, tachycardia, tachypnea, myoglobinuria, rhabdomyolysis, and hyperkalemia.

Mallampati classification A system for predicting the relative difficulty of intubation based on the amount of oropharyngeal structures visible in an upright, seated patient who is fully able to open his or her mouth.

Mallory-Weiss syndrome Longitudinal laceration of the esophagus, often following severe vomiting.

malrotation A congenital anomaly of rotation of the midgut, in which the small bowel is found predominantly on the right side of the abdomen.

mass A tumor, aneurysm, or abscess.

mean airway pressure The amount of positive pressure in the airway, averaged over the inspiratory and expiratory phases of the breathing cycle.

mean arterial pressure (MAP) The average (or mean) of the systolic and diastolic blood pressures (SBP and DBP); MAP = DBP + 1/3(SBP – DBP).

mean electrical axis The sum of all electrical impulses.

mechanical ventilation The application of a device that provides varying degrees of ventilatory support.

mechanism of action The way in which a medication produces the intended response.

meconium A dark green fecal material that accumulates in the fetal intestines and is discharged around the time of birth.

medical control The oversight designed to ensure that actions taken by providers on behalf of patients are appropriate; divided into direct medical control, available in real time via radio, and indirect medical control such as standing orders and protocols.

medical direction Supervision of medical care, provided online (telephone or radio) or off-line (protocols, standing orders, education, and quality improvement).

medulla oblongata The lowermost portion of the brain stem.

melena Black, tarry stool containing partially digested blood, with bleeding originating from the upper GI tract.

metabolic acidosis A pathologic condition (blood pH < 7.35) resulting from the accumulation of acids in

the body caused by any number of systems in the body, including the gastrointestinal system, or major organ failure.

metabolic alkalosis A pathologic condition (blood pH > 7.45) resulting from the accumulation of bases in the body caused by any number of systems in the body, including the gastrointestinal system, or major organ failure.

metabolic syndrome A group of symptoms that together may lead to coronary artery disease, stroke, and type 2 diabetes; usually related to predisposition to a lipid disorder.

methamphetamine washout syndrome Excessive sleep, hunger, and depression as a result of excessive amphetamine use.

microcirculation Circulation that occurs in the microvasculature, the body's smallest vessels (arterioles, capillaries, and venules).

midbrain A small area of the brain stem extending between the diencephalon, the pons, and the third ventricle.

mild hypothermia A condition in which the core body temperature is between 90°F and 95°F (32.2°C and 35°C); at this stage, the body usually compensates with increased thermogenesis and interrupted thermolysis.

mild TBI Concussion; a traumatically induced physiologic disruption of brain function that occurs without structural damage.

Mini-Mental State Examination A simple, easily applied test of higher cognitive functions.

Minnesota esophagogastric tamponade tube A tube that is placed to stop bleeding of esophageal varices. It is similar to the Sengstaken-Blakemore tube, but has a built-in suction catheter.

minor burn A classification from the American Burn Association that includes: (1) partial-thickness burns involving less than 15% of BSA in adults or 10% of BSA in children and older adults; and (2) full-thickness burns involving less than 2% BSA that do not present a serious threat of functional or cosmetic risk to the eyes, ears, face, hands, feet, or perineum.

minute volume Total volume of air breathed in and out in 1 minute. It is calculated by multiplying the respiratory rate per minute by the tidal volume.

mittelschmerz pelvic pain Abdominal pain occurring midway between menstrual periods, at the time of ovulation and from the ovulation site.

mixed acidosis A pathologic condition in which there is a low pH (< 7.35), an elevated PCO_2 level (> 45 mm Hg), and a low bicarbonate level (< 23 mmol/L), which occurs when there is both a respiratory and a metabolic cause present at the same time.

mixed alkalosis A pathologic condition in which there is an elevated pH (> 7.45), a low PCO_2 level (< 35 mm Hg), and an elevated bicarbonate level (> 29 mmol/L), which occurs when there is both a respiratory and a metabolic cause present at the same time.

mixed central venous oxygen saturation ($ScvO_2$) The percentage of oxygen bound to hemoglobin in blood returning to the right side of the heart from the head and upper body, representative of oxygen extraction by the head and upper extremities.

mixed venous oxygen saturation (SvO_2) The percentage of oxygen bound to hemoglobin in blood returning to the right side of the heart, representative of global oxygen extraction.

mobile intensive care units Ambulances or helicopters that are used only for maintaining specialized or intensive care treatment; used primarily for interfacility transports.

mode The particular way in which a spontaneous or mechanical breath is delivered.

moderate burn A classification from the American Burn Association that includes: (1) partial-thickness burns of 15% to 25% of BSA in adults or over 10% to 20% of BSA in children and older adults; and (2) full-thickness burns involving 2% to 10% of BSA that do not present a serious threat to functional or cosmetic impairment of the eyes, ears, face, hands, feet, or perineum.

Monro–Kellie doctrine A theory developed by two Scottish anatomists, who stated that the central nervous system is enclosed in a rigid compartment along with cerebrospinal fluid, whose total volume tends to remain constant; an increase in any component—whether brain, blood, or CSF—will cause an increase in pressure and decrease the volume of one of the other elements.

morbidity The number of nonfatally injured or disabled people. Usually expressed as a rate, meaning the number of nonfatal injuries in a certain population in a given time period divided by the size of the population.

Moro reflex An infant reflex in which, when an infant is caught off guard, the infant opens his or her arms wide, spreads the fingers, and seems to grab at things.

mortality Deaths caused by injury and disease; usually expressed as a rate, meaning the number of deaths in a certain population in a given time period divided by the size of the population.

motor area Part of the frontal lobe that contains pyramidal cells that control voluntary motor function on the opposite side of the body.

mucosa The outermost layer of the alimentary canal. It consists of three sublayers: surface epithelium, lamina propria, and muscularis mucosae.

multiple organ dysfunction syndrome (MODS) Altered organ function in acutely ill patients, which is diagnosed when two or more organs stop functioning.

Murphy's sign Pain when pressure is applied to the right upper quadrant of the abdomen in a specific manner; helps detect gallbladder problems.

muscularis externa The third tissue layer of the alimentary canal. It contains two levels in most places: the circular layer and the longitudinal layer.

myocardial oxygen consumption (MVO_2) The volume of oxygen that the heart muscle consumes; an expression of the level of oxygen demand in the heart.

myoglobin An oxygen-carrying heme protein present in high concentrations in the cytoplasm of cardiac and skeletal muscles.

myoglobinuria The presence of myoglobin, a respiratory pigment of muscle tissue, in the urine.

myxedema coma A rare, life-threatening condition that can occur in patients who have severe, untreated hypothyroidism, and which is characterized by altered mental status and lethargy, failure of the thermoregulatory system, and a precipitating event; may be accompanied by auditory and visual hallucinations, seizures, or unresponsiveness.

National Transportation Safety Board (NTSB) An independent federal agency that promotes transportation safety, including aviation, railroad, highway, maritime, pipeline, and hazardous materials safety; investigates transportation crashes to identify the cause and make safety recommendations.

NBG code A code of five letters used to categorize pacemakers by their functions and capabilities, developed by a joint effort of North American and British electrophysiology groups.

near–SIDS An acute episode in which an infant experiences apnea accompanied by choking or gagging, skin color change, and a noted change in muscle tone; also called an ALTE (apparent life-threatening event).

necrotizing fasciitis A limb- or life-threatening infection of the soft tissue that affects the subcutaneous tissues, fat, and fascia.

negative-pressure ventilator A mechanical ventilator that operates using pressure that is less than ambient (atmospheric) pressure.

negligence Failure to provide the quality of care (as defined by applicable standards) usually expected with conditions requiring that care; negligence is established when the plaintiff proves four elements: duty to act, breach of the duty, injury to the patient, and the breach was the direct cause of the injury.

neonate An infant during the first 28 days after birth.

neurocranium The part of the skull that encloses and protects the brain.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, leading to widespread dilation; seen in spinal cord injuries.

neuroleptic malignant syndrome (NMS) A potentially fatal reaction to antipsychotic, antischizophrenic, and antiemetic medications, characterized by patient hyperthermia, profound muscle rigidity, metabolic acidosis, and altered mental status.

neutrophils One of the types of leukocytes (white blood cells); these numerous phagocytic microphages usually are the first of the mobile phagocytic cells to arrive at an area of injury or infection.

newborn An infant within the first few hours after birth.

nicotinic receptors Cholinergic receptors that bind with the neurotransmitter acetylcholine.

nitrogen narcosis A state resembling alcohol intoxication produced by nitrogen gas dissolved in the blood at high ambient pressure.

nondepolarizing agents Medications designed to cause temporary paralysis by binding in a competitive but nonstimulatory manner to part of the ACh receptor; they do not cause fasciculations.

nonfunctioning adenoma A type of pituitary lesion in which the tumor does not secrete any hormones.

noninvasive ventilation Application of mechanical ventilation through a mask, mouthpiece, or other interfaces other than an artificial airway.

normal pressure hydrocephalus (NPH) An accumulation of CSF that causes the ventricles of the brain to enlarge. The enlarged ventricles of a patient with this condition may not cause increased intracranial pressure.

normal range A range of values encompassing the results that 95% of healthy people would have for the particular test.

nosocomial Infections acquired during hospitalization or a nursing home stay.

nuchal rigidity Marked resistance to head movement in any direction that is suggestive of meningeal irritation.

obstructive diseases Diseases that result in difficulty with moving air out of the lungs, such as asthma, COPD, cystic fibrosis, and bronchioectasis.

occipital lobe The lobe of the brain that occupies the most posterior portion of the cerebrum; it is the primary receptive area for vision, specifically the interpretation of visual stimuli.

off-line medical control Medical direction given through a set of protocols, policies, and/or standards.

Ohm's law The principle given by the equation V = IR, which states that applied voltage is equal to the current times the resistance of the circuit.

oligohydramnios Decreased volume of amniotic fluid during a pregnancy; a risk factor associated with abnormalities of the urinary tract, postmaturity (birth after a prolonged pregnancy), and intrauterine growth retardation.

omphalocele Herniation of abdominal contents into the base of the umbilical cord.

online medical control A type of medical direction in which the care provider is in direct contact with a physician, usually via two-way radio or telephone.

onset of action The time needed for the concentration of the medication at the target tissue to reach the minimum effective level.

operational control The person who has the ultimate authority to initiate, conduct, and terminate the EMS mission; in an air medical program, usually the chief pilot or operational manager.

opioid syndrome Toxicity that develops following illicit use and abuse of opioids.

opioids The class of chemicals that includes naturally derived opiates and newer artificial medications with the same properties.

opsonize To make bacterial cells more susceptible to the action of phagocytosis by the action of binding an antibody to the pathogen's cell membrane.

optic disk The most prominent structure visible in the eye; it represents the termination of the optic nerve.

osmolality The amount of dissolved substance in 1 kg of water.

osmolarity The amount of dissolved substance in 1 L of water.

osmosis The diffusion of water across membranes.

osmotic pressure The pressure created in a space divided by a semipermeable membrane owing to differences in concentrations of solutes found in the solutions on either side of the membrane.

ostomy A surgically created opening through which feces can be voided in the absence of some or all of the large intestine or rectum.

ovarian cyst A fluid buildup within an outcropping of tissue from the ovary. If such a cyst is ruptured, significant bleeding can occur.

ovarian torsion Twisting of an ovary about its ligaments, resulting in ischemia and possibly necrosis.

overtriage Considering a patient to be in more serious condition than he or she actually is.

oxygen consumption ($\dot{V}O_2$) The amount of oxygen used by the cells and tissues.

oxygen delivery (DO_2) The amount of oxygen delivered to the tissues each minute.

oxygen extraction fraction (OEF) The fraction of oxygen extracted from the blood as it passes by to maintain normal oxygen delivery and, consequently, normal brain functions.

oxygen extraction ratio (ERO_2) The relationship between oxygen consumption and oxygen delivery, or the cells' ability to utilize oxygen.

oxygen hood A tent placed over the head of an infant for the purpose of delivering supplemental oxygen.

oxygen paradox A condition that results when a hypoxic person rapidly breathes in 100% oxygen; he or she may experience sudden dizziness, which is quickly resolved followed by complete restoration of function. The condition is possibly due to the sudden constriction of dilated arteries in the brain.

pacemaker syndrome The occurrence of symptoms relating to the loss of atrioventricular synchrony in ventricularly paced hearts or symptoms caused by inadequate timing and ventricular contractions in paced hearts.

pacing circuit The conduction pathway along which the pacing impulse flows; formed by a power source, one or two lead-electrode pairs, and body tissue.

pacing impulse The electrical impulse sent to the heart to stimulate the heart to beat.

packed red blood cells (PRBCs) A blood product that retains all of the characteristics of whole blood with the exception of the extraction of approximately 250 mL of platelet-rich plasma from each unit of whole blood.

palpable purpura Larger areas of bleeding under the skin (greater than 3 mm).

pancreatitis Inflammation of the pancreas leading to tissue destruction, improper functioning of the pancreas, and chronic disease.

panel Groups of related tests that are performed as a single unit; also called profile.

papillary muscles A type of muscle in the ventricle from which the chordae tendineae extend and attach to the cusps of the AV valves.

paracentesis A "tapping" of the abdomen with a needle to draw off ascites.

parietal lobe The lobe of the brain situated directly posterior to the frontal lobe on the other side of the central fissure; it is largely responsible for sensory functions.

parity The number of pregnancies a woman has had that were carried to more than 28 weeks' gestation.

Parkland formula A formula that recommends giving 4 mL of lactated Ringer's solution or normal saline for each kilogram of body weight, multiplied by the percentage of body surface area burned; sometimes used to calculate fluid needs during lengthy transport times.

paroxysmal nocturnal dyspnea Severe shortness of breath occurring at night after several hours of recumbency, during which fluid pools in the lungs; the person is forced to sit up to breathe; caused by left-sided heart failure or decompensation of chronic obstructive pulmonary disease.

paroxysmal supraventricular tachycardia A supraventricular tachycardia that starts and ends abruptly.

partial pressure of oxygen (arterial) (Pa_{O_2}) The amount of the total pressure in the blood contributed by oxygen; a value measured when analyzing arterial blood gas level.

partial pressure of oxygen (P_{O_2}) A measurement of the amount of oxygen dissolved in the blood.

partial-thickness burn A burn that involves the epidermis and part of the dermis, characterized by pain and blistering; also called a second-degree burn.

partial thromboplastin time (PTT) A value that represents the intrinsic coagulation pathway's clotting ability; also known as activated partial thromboplastin time (aPTT).

passive immunity Short-lived immunity acquired from placental transfer, antibodies in the mother's milk, or antiserum administered IV.

passive leg raising (PLR) A technique used to assess fluid responsiveness in patients with suspected volume depletion, performed by raising both of the patient's legs to a 45° angle and then taking the blood pressure; improvement in blood pressure suggests that the patient will benefit from fluid administration.

patent ductus arteriosus (PDA) A situation in which the ductus arteriosus, which assists in fetal circulation, does not transition as it should after birth to become the ligamentum arteriosum; the result is that the connection between the pulmonary artery and the aorta remains, allowing some oxygenated blood to move back into the heart rather than all of it moving out of the aorta and into the systemic circulation.

pathogens The microorganisms responsible for activating the immune system and that cause disease; includes viruses, parasites, fungi, and bacteria.

pathologic edema Systemic swelling, which may have several causes, including preeclampsia.

peak airway pressure The amount of positive pressure generated by the ventilator to deliver the tidal volume.

Pediatric assessment triangle (PAT) An assessment tool that allows rapid formation of a general impression of the type and level of illness or injury in an infant or child without touching him or her; consists of assessing appearance, work of breathing, and circulation of the skin.

pelvic inflammatory disease (PID) An infection of the female upper organs of reproduction, specifically the uterus, ovaries, and fallopian tubes.

penile fracture A rupture of one of the blood-containing sacs in the penis, resulting in deformity and possible loss of function.

peptic ulcer An erosion of the mucosal lining of the GI tract.

percutaneous endoscopic gastrostomy (PEG) tube A feeding tube that is placed through the abdominal wall into the stomach.

perfusionists Highly trained technicians who are intimately familiar with the operation of intra-aortic balloon pumps and adult and pediatric extracorporeal membrane oxygenation machines and who may assist during any medical situation, including critical care transports, in which it is necessary to support or temporarily replace a patient's circulatory or respiratory function.

pericardial tamponade Impairment of diastolic filling of the right ventricle as a result of significant amounts of fluid in the pericardial sac surrounding the heart, leading to a decrease in the cardiac output.

pericardiocentesis A procedure in which a needle or angiocath is introduced into the pericardial sac to relieve cardiac tamponade.

pericarditis An inflammatory process involving the pericardium.

peripheral blood smear A glass slide containing a drop of blood; analysis allows the lab to microscopically examine the structure of the blood cells.

peristalsis A general term applicable to any concerted and directional movement in the body such as the movements that push food or urine through the body.

peritoneal dialysis Use of a catheter to introduce dialysate solution into the abdomen using the peritoneum as a natural semipermeable membrane to separate solutes.

persistent pulmonary hypertension (PPHN) The persistence of elevated pressures in pulmonary

vasculature after birth, associated with failure to transition from fetal circulation to postpartum or normal newborn circulation. The typical presentation consists of hypoxia, low APGAR scores, hypoglycemia, or a congenital diaphragmatic hernia.

petechial lesions Small areas of bleeding under the skin (pinpoint).

pharmacodynamics The branch of pharmacology that studies reactions between medications and living structures, including the processes of body responses to pharmacologic, biochemical, physiologic, and therapeutic effects.

pharmacokinetics The study of the metabolism and action of medications with the particular emphasis on the time required for absorption, duration of action, distribution in the body, and method of excretion.

pheochromocytoma A catecholamine-producing benign tumor of chromaffin cells located in the center of the adrenal gland, which can occur either sporadically or chronically as a result of genetic risk factors; causes stimulation of alpha-adrenergic and beta-adrenergic receptors, resulting in hypertension, increased cardiac contractility, glycogenolysis, gluconeogenesis, intestinal relaxation, and increased heart rate.

phlebostatic axis An imaginary point located at the fourth intercostal space, mid-chest level, which serves as an external landmark for the right atrium.

phosphate buffer system The buffer system that functions in the renal tubules and intracellular fluids to convert strong acids or bases into weak acids or bases so that there is only a minimal effect on overall pH.

phosphodiesterase An enzyme that helps break phosphodiester bonds, creating smaller nucleotides.

physiologic zone The zone that extends from sea level to 10,000′ and is the area of the atmosphere to which humans are well adapted. The barometric pressure is sufficient in this zone to facilitate adequate oxygenation. The changes in pressure encountered with rapid ascents or descents within this zone can produce ear or sinus trapped-gas problems.

physiologically deficient zone The zone that extends from 10,000′ to 50,000′. Noticeable physiologic deficits occur above 10,000′. A decrease in barometric pressure results in oxygen deficiency, causing hypoxic hypoxia. In this zone, the manifestation of trapped and evolved gases occurs. The use of pressurized aircraft and/or supplemental oxygen is necessary in this zone.

pia mater The innermost layer of the meninges, which rests directly on the brain or spinal cord.

Pierre Robin syndrome A condition present at birth marked by a very small lower jaw (micrognathia). The tongue tends to fall back and downward (glossoptosis) and there is a cleft soft palate.

ping-pong ball fracture A pediatric greenstick fracture of the skull.

plasma protein fraction A blood product that contains 83% albumin and 17% globulins.

platelet (Plt) count A measurement of the number of platelets in the blood, which is useful for assessing a patient's coagulation status.

pleural friction rub The result of an inflammation that causes the pleura to thicken, decreasing the pleural space and allowing the surfaces of the pleura to rub together.

plexus A cluster of nerve roots that permits peripheral nerve roots to function as a group.

P mitrale A double-humped, M-shaped P wave that is 120 milliseconds wide or greater with the tops of the humps 40 milliseconds apart or greater; found in limb leads I, II, and III; represents left atrial enlargement.

pneumomediastinum The collection of air within the mediastinum (the space within the chest that contains the heart, major blood vessels, vagus nerve, trachea, and esophagus; located between the two lungs).

pneumoperitoneum The collection of air within the peritoneum (the membrane in the abdomen encasing the liver, spleen, diaphragm, stomach, and transverse colon).

point-of-care (POC) testing Laboratory testing that is performed at the point of care, for example, the bedside, so that results can be quickly obtained and considered while decisions are being made about patient care.

polydipsia Excessive thirst, resulting in excessive intake of fluid.

polyhydramnios An excessive amount of amniotic fluid. May cause preterm labor.

polyphagia Excessive desire to eat, resulting in overconsumption of food.

polyuria Frequent and plentiful urination.

pons Part of the brain stem located between the midbrain and the medulla oblongata; it relays information to and from the brain and spinal cord along fiber tracts.

poor R-wave progression An abnormal R-wave pattern; one of the factors that may signify anterior infarction.

portal hypertension An increase in vascular resistance through the hepatic portal system. It can cause high venous pressure in gastric and esophageal veins, leading to varices, among other problems.

positive end-expiratory pressure (PEEP) The amount of pressure above ambient pressure present in the airway at the end of the respiratory cycle.

positive-pressure ventilator A mechanical ventilator that operates using pressure that is greater than ambient pressure.

posterior cord syndrome Extension injury that produces dysfunction of the dorsal columns, presenting as decreased sensation to light touch, proprioception, and vibration.

postrenal A type of acute renal failure caused by downstream obstruction of urine flow from the kidneys, with initially intact nephrons; commonly caused by a blockage of the urethra by prostate enlargement, renal calculi, or strictures.

potentiation The effect of increasing the potency or effectiveness of a drug or other treatment; may occur by administering two medications concurrently, where one increases the effect of the other.

P pulmonale A tall P wave that is 2.5 mm high or greater, found in leads II and III; indicates right atrial enlargement.

PR interval The interval of time that occupies the space between the beginning of the P wave and the beginning of the QRS complex.

precision A measure of how a value is likely to be the same every time a test is performed.

precordial leads Another term used to describe the chest leads in an ECG.

preeclampsia A condition of late pregnancy that involves gradual onset of hypertension, headache, visual changes, and swelling of the hands and feet; also called toxemia of pregnancy.

prefrontal area Part of the frontal lobe that provides control of thought, concentration, depth and ability to think abstractly, memory, and autonomic nervous system response, concomitant to emotional change.

pregnancy-induced hypertension (PIH) The occurrence of hypertension in a pregnant woman, usually after 20 weeks' gestation, defined as a blood pressure of 140/90 mm Hg or greater in a woman with a previously normal blood pressure, or a rise of 30 mm Hg systolic and/or 15 mm Hg diastolic in a woman with baseline hypertension; can lead to preeclampsia if uncontrolled.

preload The amount of blood that flows into the ventricle passively from the atria; related to the overall volume status of the patient; measured by right atrial pressure or central venous pressure and wedge pressure.

premature Underdeveloped; refers to infants born before 36 weeks from the first day of the last menstrual period.

premotor area Part of the frontal lobe that is adjacent to the motor area and helps coordinate certain movements.

prerenal A type of acute renal failure caused by decreased perfusion of an intact nephron; often reversible if the underlying condition can be found and perfusion can be restored to the kidney.

pressure ulcer A sore on the skin arising from prolonged pressure, classified in four stages, with stage 4 being the most severe with tissue necrosis and muscle and bone involvement. All stages are painful and prone to infection; commonly seen in patients confined to a bed.

pressure ventilator A type of positive-pressure ventilator that ends the delivery of the tidal volume based on a predetermined pressure; therefore, the volume is variable.

preterm labor Labor occurring before 36 weeks' gestation, leading to early birth.

priapism Prolonged, painful erection of the penis.

primary aldosteronism A type of aldosteronism usually caused by a tumor of a single adrenal gland that overproduces aldosterone; also known as Conn's syndrome.

primary amyloidosis The most common form of amyloidosis, affecting the heart, kidneys, tongue, nerves, and intestines; classified as apolipoprotein.

primary apnea The initial response to asphyxia at birth, characterized by increased respiratory rate and a slight decrease in heart rate with increased blood pressure; responds to stimulation and oxygen therapy.

primary decontamination A form of decontamination that usually occurs at a scene or outside a health care facility or transport vehicle to protect rescuers and health care providers from exposure to a toxic substance during patient care and transport.

primary MODS Multiple organ dysfunction syndrome that results from a direct insult such as trauma.

primary spinal cord injury Spinal cord injury that occurs at the moment of impact.

prodromal Referring to the early signs and symptoms that occur before a disease or condition, such as a toxic exposure, fully appears, for example, dizziness before fainting.

projected diagnosis An assumed decision on the medical condition of a patient from preliminary investigation; assists in the provision of initial treatment and projection of further diagnostic testing requirements.

prophylaxis Treatment of disease before it occurs (ie, to prevent the disease).

proprioception The ability to perceive the position and movement of one's own body or limbs.

proprioceptive Referring to information that comes from receptors located in the skin, muscles, tendons,

and joints; this information helps a person know the position of his or her body.

protected health information (PHI) Individually identifiable information (such as name, social security number, and date of birth), health information (such as laboratory results and medical history), and demographic information (such as address and telephone number) that is protected by HIPAA.

proteinuria Protein levels detected in the urine.

prothrombin time (PT) A value that represents the extrinsic coagulation pathway's clotting ability by taking into account various clotting factors, fibrinogen, the prothrombin ratio, and the international normalized ratio.

proximal intestinal obstruction Obstruction at or above the level of the jejunum.

proximate (direct) cause The reason an injury occurred; the final element that must be proven for a health care provider to be found negligent.

pseudo-Cushing's state A condition in which a person has higher cortisol levels from a cause other than actual Cushing's syndrome; these causes include depression, alcoholism, malnutrition, and panic attack.

ptosis Drooping of an eyelid.

pulmonary artery catheter (PAC) A catheter with a balloon near its tip that is passed through a vein into the right side of the heart, through the right ventricle, and into the pulmonary artery; records the pressure transmitted back from the left atrium; also referred to as a Swan-Ganz catheter.

pulmonary artery pressure The pressure measured in the pulmonary artery, usually displayed with a pressure waveform and digital systolic, diastolic, and mean values.

pulmonary capillary wedge pressure (PCWP) The mean pressure measured while occluding the pulmonary artery with a balloon-tipped catheter proximal to the site of measurement; reflects left atrial pressure (also called pulmonary artery wedge pressure and pulmonary artery occlusion pressure).

pulmonary overpressurization syndrome (POPS) Also called "burst lung," this diving emergency can occur during ascent and can cause pneumothorax, mediastinal and subcutaneous emphysema, alveolar hemorrhage, and the lethal arterial gas embolism.

pulmonary stenosis Narrowing of the pulmonary valve.

pulmonary vascular resistance (PVR) The resistance or impedance to ejection of the right ventricle of the heart.

pulse CO-oximetry A noninvasive screening and monitoring method for methemoglobinemia and carbon monoxide exposure.

pulse pressure The difference between systolic and diastolic blood pressures.

pyelonephritis An infection of the kidney, typically the result of a urinary tract infection that traveled up the ureter.

QRS complex Deflections in the ECG produced by ventricular depolarization.

quiescent A latent state as in a dormant virus or bacterium, in which an infected patient will exhibit little to no symptoms.

raccoon eyes Orbital fractures and hemorrhage into the surrounding tissue; also called periorbital ecchymosis.

radiation Emission of heat from an object into surrounding, colder air.

rapid decompression Occurs when a large leak or hole develops in a pressurized aircraft; can result in hypoxia and injury to people inside the aircraft and catastrophic failure of the aircraft.

reactive airway disease (RAD) A term used to describe any condition that causes hyperreactive bronchioles and bronchospasm.

reactive gastritis A chronic mucosal edema that results from recurring contact of the mucosa with antagonistic substances such as bile, pancreatic juice, or NSAIDs.

reciprocal changes An ECG pattern in which a lead shows a pattern that is the opposite of the one shown in the lead located 180° from the other; for example, the electrode over the area of infarction records ST-segment elevation, whereas the electrode over the lead that is 180° away records ST-segment depression.

red blood cell (RBC) count A measure of the total number of erythrocytes in the blood.

referencing The process of ensuring that the hemodynamic pressure transducer is at the level of the left atrium.

refractory period A short period immediately after depolarization in which the myocytes are not yet repolarized and are unable to fire or conduct an impulse.

refractory stage A stage in shock in which there is persistently low mean arterial blood pressure despite vasopressor therapy and adequate fluid resuscitation.

relative contraindication A condition that makes a particular treatment or procedure somewhat inadvisable but does not completely rule it out.

relative refractory period The period in the cell-firing cycle at which it is possible but difficult to restimulate the cell to fire another impulse.

renal tubular acidosis (RTA) A form of metabolic acidosis caused by dysfunction of the kidneys or renal system; H^+ cannot be excreted into the urine, even in the presence of overwhelming acidosis. Presents without an elevated anion gap; characterized into Type 1, 2, or 4.

repogle A double-lumen tube used for gastric decompression in infants with gastrointestinal issues; for an infant, usually an 8F size is used and is connected to low intermittent wall suction to collect gastric secretions.

repolarization A state in which the cell becomes more negative, moving away from equilibrium with the extracellular fluid; this is an active process.

residual volume (RV) The amount of air remaining in the lungs after the expiratory reserve volume is exhaled.

resonance Normal lung sound heard with percussion.

respiratory acidosis A pathologic condition (blood pH < 7.35) resulting from the accumulation of acids in the body caused by a breathing problem or insufficient function of the respiratory system.

respiratory alkalosis A pathologic condition (blood pH > 7.45) resulting from the accumulation of bases in the body caused by a breathing problem or insufficient function of the respiratory system.

respiratory depression A low respiratory rate (< 12 breaths/min in adults) for a prolonged period of time; also called hypoventilation.

respiratory failure A situation in which the respiratory system fails to meet the body's metabolic needs. If not reversed, it leads to respiratory or cardiopulmonary arrest.

respiratory insufficiency The inability of the respiratory system to keep up with the metabolic demands of the body.

respiratory syncytial virus (RSV) A labile paramyxovirus that produces its characteristic fusion of human cells in a tissue culture known as the syncytial effect; can affect both upper and lower respiratory tracts but is more prevalent with the lower, causing pneumonias and bronchiolitis.

restrictive diseases Diseases that result in difficulty moving air in to the lungs such as occupational lung diseases, idiopathic pulmonary fibrosis, pneumonia, atelectasis, chest wall deformities and injuries, and neuromuscular diseases that affect breathing.

reticular activating system (RAS) A diffuse system that extends from the lower brain stem to the cerebral cortex; it controls the sleep-wakefulness cycle, consciousness, the ability to direct attention to a specific task, and the perception of sensory input that might alter behavior.

reticular formation (RF) A set of neurons that extends from the upper level of the spinal cord, through the medulla, pons, and midbrain, and into the thalamus and cerebral cortex. It has both excitatory and some inhibitory capabilities, and can enhance, suppress, or modify impulse transmission.

retrograde intubation A technique in which a wire is placed through the trachea and into the mouth with a needle via the cricoid membrane. The ET tube is then placed over the wire and guided into the trachea.

reverse Trendelenburg Supine position with head higher than feet.

revised trauma score A trauma scoring system that rates injury severity by comparing the Glasgow Coma Scale score, the systolic blood pressure, and the respiratory rate and assigning a score between 1 and 13 based on these three values; in some cases the parameters are weighted, resulting in a score of between 1.0 and 7.8408.

Rh factors Antigens found on the cell membrane of red blood cells.

rhabdomyolysis The destruction of muscle tissue leading to a release of potassium and myoglobin, which then accumulate in the blood and urine and impair filtration; occurs most often with crush injuries, electrical burns, or large full-thickness burns. The urine becomes pink, dark red, or rust colored.

rhonchi Rattling vibrations produced as air flows through mucus or around obstruction in the larger airways.

rickettsial diseases Diseases transmitted via tick bite; the three major diseases in this class include Rocky Mountain spotted fever, ehrlichiosis, and anaplasmosis.

right ventricular pressure The pressure in the right ventricle that consists of systolic, diastolic, and mean pressures; important during insertion and use of a PAC.

right ventricular stroke work index A calculation of contractility of the right ventricle indexed to the patient's body surface area.

rotational force An injury-producing force in which the head moves around its center of gravity.

rotation–flexion injury A spinal cord injury to C1-C2, the only area of the spine that allows for significant rotation, in which rotation with abrupt flexion produces a stable dislocation in the cervical spine. In the thoracolumbar spine, rotation-flexion forces typically cause fracture rather than dislocation.

rotor-wing aircraft Helicopters; these are used to transport critically ill and injured patients in rural settings and can travel distances of up to 150 miles.

rubrospinal tract Part of the midbrain that controls the tone of flexor muscles.

rule of 3s A means of prioritizing the basic physiologic needs for survival: The average person can survive 3 minutes without oxygen, 3 hours without shelter, 3 days without water, and 3 weeks without food.

rule of nines A system that assigns percentages to sections of the body, allowing calculation of the amount of skin surface involved in the burn area.

scintigraphy An imaging technology that is similar to angiography, except that the red blood cells themselves are radiologically labeled to allow greater specificity.

SCIWORA An acronym that stands for spinal cord injury without radiographic abnormalities.

scope of practice The body of knowledge, skills, and therapies that health care providers can legally apply in patient care, based on training, certification, medical direction, and applicable law.

secondary aldosteronism A type of aldosteronism that occurs as a result of reduced renal blood flow, which stimulates hypersecretion of aldosterone; can be caused by obstructive renal artery disease, renal vasoconstriction, and edematous disorders.

secondary amyloidosis A form of amyloidosis that occurs as a result of another illness, and which primarily affects the kidneys, spleen, liver, and lymph nodes; classified as amyloid A protein.

secondary apnea The response if asphyxia at birth continues, characterized by a period of gasping respirations, falling heart rate, and falling blood pressure; does not respond to stimulation unless resuscitation is initiated immediately.

secondary decontamination A form of decontamination that is directed at minimizing patient absorption or injury from a toxic substance; occurs after initial decontamination has occurred outside a health care facility or transport vehicle.

secondary MODS Multiple organ dysfunction syndrome that is a slower, more progressive insult to organs and frequently results from the sepsis cascade.

secondary spinal cord injury Spinal cord injury in which multiple factors permit a progression of the primary spinal cord injury; the ensuing cascade of inflammatory responses may result in further deterioration.

Seldinger technique The most common technique for inserting a central venous line; involves inserting a needle with a syringe, then inserting a guide wire into the needle. Once the guide wire is in place, the needle is removed, an incision is made, and a catheter is inserted over the guide wire; the guide wire is then removed.

semilunar valves The valves (aortic and pulmonic) that are the exits from the left and right ventricles into the aorta and the pulmonary artery, respectively.

Sengstaken-Blakemore tube A tube with an inflatable balloon at its end that is inserted into the GI tract and inflated to tamponade bleeding.

sensitivity The ability of a certain test to indicate whether a person has a certain disease; also, a ventilator control that regulates the amount of negative pressure required by the patient to initiate or "trigger" a breath.

sepsis Systemic response to infection manifested by two or more symptoms noted with SIRS.

septic shock A form of shock that occurs in septicemia when endotoxins or exotoxins are released from certain bacteria in the bloodstream, resulting in a persistently low mean arterial blood pressure

despite adequate fluid resuscitation.

seroconversion Development of antibodies, measured in the serum, in response to an infection or vaccine.

serosa A protective layer of connective tissue over most of the alimentary canal; also called the visceral peritoneum.

serotonin syndrome An unusual response to serotonin-altering medications causing hyperserotoninergic symptoms.

severe acute respiratory syndrome (SARS) A highly contagious, potentially life-threatening lower respiratory tract illness that usually starts with flu-like symptoms, including fever, headache, and muscle aches, followed within 2 to 7 days by a dry cough and pneumonia.

severe hypothermia A condition in which the core body temperature drops to less than 90°F (32.2°C).

severe sepsis A type of sepsis with associated acute organ failure; hypoperfusion or hypertension is present.

shoulder dystocia A condition in which the infant's shoulders are too large to travel through the birth canal without additional clinical maneuvering of the infant.

shunt Perfusion without ventilation.

side effects Reactions that can manifest as signs or symptoms that are not desired but are expected based on how the medication works.

single-chamber demand pacemaker A pacemaker with the pacing lead placed in only one chamber of the heart, in which the generator stimulus is inhibited by a signal derived from the heart's depolarization, thus minimizing the risk of pacemaker-induced fibrillation.

SLUDGEM Acronym for Salivation, Lacrimation, Urination, Diarrhea, Gastroenteritis, Emesis, and Miosis, which are symptoms of anticholinesterase inhibitor toxicity.

somatogravic illusion An error in perception that occurs with acceleration, as the otolith organs are displaced rearward, similar to when a person is looking up. This perception of a nose-up altitude may cause the pilot to push the nose of the aircraft down inappropriately at night or in unlit terrain.

space equivalent zone The zone that begins at 50,000′. In this zone, 100% oxygen is not sufficient to prevent hypoxia without the use of a pressurized aircraft or suit. Unprotected personnel may experience boiling of body fluids at a level above 66,500′.

spatial disorientation An error in perception that may result from a person's inability to determine his or her position, altitude, and motion in relation to the surface of the earth or to a significant fixed object during flight.

specialty care transport (SCT) The term used by the Centers for Medicare and Medicaid Services to define ground transportation and medically necessary supplies and services for critically ill and injured patients.

specific gravity The chemical property of a fluid that relates its density to the density of water.

specificity The ability of a certain test to indicate whether a person does not have a certain disease.

spinal shock The temporary local neurologic condition that occurs immediately after spinal trauma; it is characterized by swelling and edema of the spinal cord and can lead to a physiologic transection, mechanically disrupting all nerve conduction distal to the injury.

SpO_2 The noninvasive pulse oximetry measurement of oxyhemoglobin saturation by means of a beam of light applied to a superficial capillary bed such as the digits or ear lobe.

spontaneous abortion Expulsion of the fetus that occurs naturally; also called miscarriage.

stagnant hypoxia Hypoxia caused by a malfunction of the circulatory system resulting in a decrease in blood flow.

standby The situation in which an HEMS provider is notified of a potentially life-threatening emergency call and makes preparations to respond to the call. During standby, the flight crew checks weather data, obtains landing coordinates, and conducts a preflight inspection of the aircraft.

START triage A patient sorting process that stands for simple triage and rapid treatment and uses a limited assessment of the patient's ability to walk, respiratory status, hemodynamic status, and neurologic status.

steady state A point in drug administration at which the rate of administration (frequency and dose) is equal to the rate of elimination, resulting in a constant plasma medication level.

ST-elevation myocardial infarction (STEMI) A myocardial infarction that shows ST-segment elevation on the ECG; patients with STEMI have a high probability of coronary thrombus occlusion.

stepping reflex An infant reflex that occurs when the infant is held up in the air and moves his or her legs up and down as if marching.

stereognosis The ability to sense an object's form through touch.

sterile cockpit The time when unnecessary communication that could distract the pilot is banned in the cockpit—usually during takeoffs, landings, and any other critical phase of flight at the discretion of the pilot in command.

Stevens-Johnson syndrome A milder form of toxic epidermal necrolysis, in which epidermal detachment involves less than 10% of the total body surface area; causes sloughing of the skin, mucous membranes, and cells lining the respiratory system.

strain pattern An ECG pattern that involves ST-segment changes and flipped, asymmetric T waves associated with right or left ventricular hypertrophy.

stress-related erosive syndrome A condition in which small, diffuse peptic ulcers appear in critically ill patients in the intensive care unit, including Cushing's ulcers from head injuries and Curling's ulcers from severe burns.

stridor High-pitched sound representing air moving past fluid or mechanical obstruction within or immediately above the glottic opening.

stroke Results from a disruption of blood flow to the brain that results in neurologic deficit persisting for more than 24 hours.

stroke volume (SV) The amount of blood ejected by the ventricles during each contraction; varies between 60 and 130 mL/beat, with the average being 70 mL.

stroke volume index A calculation of contractility of the left ventricle indexed to the patient's body surface area; same as the left ventricular stroke work index.

ST segment The section of the ECG complex from the end of the QRS complex to the beginning of the T wave; represents the period of inactivity between ventricular depolarization and repolarization; mechanically, represents the time that the myocardium is maintaining contraction.

subarachnoid hemorrhage (SAH) Bleeding between the arachnoid mater and dura mater of the brain.

subdermal burn A severe, life-threatening burn involving the deep structures of muscle, bone, larger blood vessels, and nerves; also called a fourth-degree burn.

subdural hematoma (SDH) Bleeding that accumulates between the dura mater and arachnoid mater.

subdural space The dura-arachnoid junction; this potential space may develop into a real one if a blow to the head causes a loss of blood into the cranial meninges.

submucosa The layer of connective tissue below the mucosa. Blood vessels, lymph, and nerves reside here.

subthalamus An area of the cerebrum that is located below the thalamus and is closely related to the basal ganglia in function.

sudden infant death syndrome The sudden death of an infant younger than 1 year that remains unexplained after a thorough case investigation.

sudden sniffing death syndrome Occurs when a surge of catecholamines on a sensitized myocardium causes ventricular fibrillation or ventricular tachycardia; can occur when a person is startled while huffing hydrocarbons.

sulci Grooves between adjacent gyri.

summation effect The process whereby multiple medications can produce a response that the individual medications alone do not produce.

superficial burn A burn involving only the epidermis, producing very red, painful skin; also called a first-degree burn.

superficial frostbite A type of frostbite characterized by altered sensation (numbness, tingling, or burning) and white, waxy skin that is firm to palpation, but the underlying tissues remain soft.

superficial partial-thickness burn A burn involving the epidermis and part of the dermis, but the deeper layers of the dermis are not involved; also called a second-degree burn.

supine hypotensive syndrome Low blood pressure resulting from compression of the inferior vena cava by the weight of the pregnant uterus when the mother is supine.

surfactant A substance formed in the lungs that helps keep the small air sacs or alveoli from collapsing and sticking together; a low level in a premature baby contributes to respiratory distress syndrome.

sympathomimetic Medication that mimics the body's sympathetic nervous system response (fight or flight response); includes epinephrine and norepinephrine.

sympathomimetic syndrome A syndrome that involves overstimulation of the adrenergic nervous system, resulting in tachycardia, hypertension, agitation, seizures, hyperthermia, dilated pupils, and diaphoresis.

synergism An interaction of two or more medications that results in an effect that is greater than the sum of their effects if taken independently.

systemic inflammatory response syndrome (SIRS) A widespread inflammatory process associated with infectious and noninfectious causes, without end-organ damage.

systemic vascular resistance (SVR) The resistance or impedance to ejection of the left ventricle of the heart.

systole The contraction phase of the heart cycle when the ventricles pump blood out of the heart through

the aorta and the pulmonary artery into the systemic and pulmonary circulatory systems.

systolic blood pressure (SBP) Peak pressure in the arterial system that occurs during ventricular ejection or systole.

T wave The upright, flat, or inverted wave following the QRS complex of the ECG, representing ventricular repolarization.

tachyphylaxis A condition in which the patient rapidly becomes tolerant to a medication.

tachypnea An abnormally fast respiratory rate.

tectospinal tract Part of the midbrain that controls reflex motor movements in response to visual and auditory stimuli.

temporal lobe The lobe of the brain that is located beneath the temporal bone of the cranium; its primary functions relate to hearing, speech, behavior, and memory.

tentorium cerebelli A fold of the dura mater that separates the occipital lobes of the cerebrum from the cerebellum and brain stem, thereby dividing the brain into upper and lower compartments.

term Used to describe an infant delivered at 37 to 42 weeks of gestation.

term newborn Used to describe an infant born between 37 and 42 weeks' gestation.

termination of action The amount of time after the medication's concentration falls below the minimum effective level until it is eliminated from the body.

testicular torsion Twisting of a testicle about the spermatic cord to the point of ischemia and possibly necrosis.

tetralogy of Fallot (TOF) A cardiac anomaly that consists of four defects: a ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta.

thalamus The largest portion of the diencephalons; it acts as a relay station for motor and sensory activity; basic neuronal activity; and memory, thought, emotion, and complex behavior.

therapeutic index The ratio of a drug's lethal dose for 50% (LD_{50}) of the population to its effective dose for 50% (ED_{50}) of the population; a medication's margin of safety.

thermal burn A burn caused by heat, contact with hot objects, ignited liquids, steam, or hot liquids.

thermistor The apparatus used for quickly determining very small changes in temperature.

thermogenesis The production of heat in the body.

thermolysis The liberation of heat from the body.

thermoregulation The process by which the body maintains temperature through a combination of heat gain by metabolic processes and muscular movement and heat loss through respiration, evaporation, conduction, convection, and perspiration.

third spacing A loss of fluids from the intravascular space into the tissues caused by an increase in intravascular pressures and/or increased permeability of the cell membranes. Physical stressors of flight such as temperature, vibration, and changes in gravitational force can cause or aggravate this condition.

thrombocytopenia An abnormally low level of platelets.

thrombotic stroke Occurs when the blood supply to part of the brain is disrupted by a thrombus, or blood clot.

thromboxane A type of substance that causes blood vessels and bronchial smooth muscles to constrict, and promotes blood coagulation by causing platelets to collect.

thrust The force exerted by the aircraft engine, which pushes air backward with the objective of causing a reaction of the airplane in the forward direction.

thyrotoxicosis An excess of thyroid hormones resulting in a hypermetabolic crisis, including tachycardia over 140 beats/min; hyperthermia (sometimes greater than 103.9°F); coma with agitation, nausea, vomiting, diarrhea, and unexplained jaundice; and pulmonary edema; marked by an elevated thyroxine level; also called thyroid storm.

tidal volume (V_T) The volume of air moved into and out of the lungs with each respiratory cycle.

time-cycled ventilator A type of positive-pressure ventilator in which the ventilator ends inspiration after a selected inspiratory time has been achieved.

time of useful consciousness The time between a person's sudden deprivation of oxygen at a given altitude to the point at which deliberate function is lost. With the loss of effective performance during flight, a person is no longer capable of taking proper corrective or protective actions.

timing In the context of IABP therapy, a method for coordinating the IAB inflation-deflation cycle with the cardiac cycle (inflation during diastole and deflation synchronous with systole).

Title 14 Code of Federal Regulations (CFR) Part 135 Established by the FAA, this guideline governs the operations of all commuter or on-demand commercial operations.

Title 14 Code of Federal Regulations (CFR) Part 91 Established by the FAA, this guideline governs the operation of all aircraft within the United States, including the waters within 3 nautical miles of the US coast.

tocolytics A group of medications used to suppress preterm labor.

tolerance Physiologic adaptation to the effects of a drug such that increasingly larger doses of the drug are required to achieve the same effect.

TORCH screen A set of lab values taken to detect congenital infections, including toxoplasma IgG and IgM (1:1,024), rubella titers, urine cytomegalovirus titer, viral culture (for herpes), and culture of scrapings from any vesicular lesions.

torsade de pointes An undulating sinusoidal rhythm in which the axis of the QRS complexes changes from positive to negative and back in a haphazard manner.

tort A wrongful act that gives rise to a civil suit.

total lung capacity (TLC) The maximal amount of air that can fill the lungs; the sum of tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume.

total parenteral nutrition (TPN) The IV administration of all necessary nutrients in a patient whose GI tract does not function.

total protein The total quantity of protein in a blood sample.

toxic epidermal necrolysis syndrome A severe skin reaction to certain medications, environmental allergies, and other unknown toxins, in which epidermal detachment is greater than 30%.

toxidrome A group of symptoms, or syndrome, associated with toxicity of a given substance.

tracheal breath sounds Breath sounds heard by placing the stethoscope diaphragm over the trachea or over the sternum; also called bronchial breath sounds.

tracheal deviation The late sign of a tension pneumothorax in which the trachea is tugged to one side of the neck, usually opposite the side of the pneumothorax.

transcranial Doppler (TCD) ultrasound A noninvasive method of assessing the state of intracranial perfusion and monitoring of cerebral blood flow velocity through thinner areas of the skull; used in patients following rupture of an intracranial aneurysm to assess for vasospasm, used to identify intracranial lesions following a stroke, and used for the detection of cerebral blood flow changes associated with increased ICP.

transfusion reaction A reaction resulting from an endogenous or exogenous factor related to transfused blood.

transient ischemic attack (TIA) A temporary disruption in the blood flow to the brain that lasts less than 24 hours with temporary side effects.

transient tachypnea of the newborn Transient respiratory distress, lasting a few hours, in the newborn and which is secondary to retained fetal lung fluid.

transillumination The act of using a light source placed within the trachea to visualize through the thin tissue that covers the trachea.

transjugular intrahepatic portosystemic shunt The placement of a shunt in the abdomen that bypasses much of the hepatic portal system, intended to decease portal hypertension and its effects.

translational force An injury-producing force in which the head's center of gravity moves along a linear path.

transposition of the great arteries (TGA) A defect in which the great vessels are reversed; the aorta is connected to the right ventricle, and the pulmonary artery is connected to the left ventricle.

trauma injury severity score A calculated scoring system that uses the results of the injury severity score, the revised trauma score, and the patient's age to determine survivability rate; rarely used in the transport setting.

trauma score A score from 1 to 16 that takes into account the Glasgow Coma Scale score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill, and relates to the likelihood of patient survival; not accurate for patients with severe head injuries.

traumatic asphyxia A condition resulting from severe, sudden crushing injury to the chest and abdomen, forcing blood backward out of the right side of the heart; engorging the veins of the chest, neck, and head; and giving the chest, neck, and head an extremely cyanotic appearance.

trifascicular block The combination of bifascicular block (right bundle branch block with a block in the left anterior fascicle or left posterior fascicle) that occurs with a first-degree heart block (prolonged PR interval).

triple-lumen catheter A type of catheter consisting of three distinct continuous tubes that allow for pressure monitoring, blood sampling, and fluid and drug administration.

troponin A key protein involved in muscle contraction that is present in the serum only after cellular necrosis releases the cellular contents of cardiac muscle (such as after myocardial infarction).

tropopause The space between the troposphere and the stratosphere. It rises to 60,000′ at the equator owing to heated air masses that expand and sinks to about 30,000′ at the poles owing to contracting cold air masses.

troposphere A portion of the earth's atmosphere that extends from the surface of the earth to 5 to 10 miles

high depending on the relation to the equator and the poles. This layer is characterized by the presence of water vapors, a constant decrease in temperature with increasing altitude, and large-scale vertical currents.

true anaphylaxis An anaphylactic reaction that results when the allergen binds to IgE on the cell membranes of basophils and when mast cells stimulate the release of histamine from the cell.

true fracture The most common type of closed skull fracture, in which the depressed segment has contact with the cranial vault.

T-tube A T-shaped tube used to drain bile from the gallbladder.

tumor necrosis factor (TNF) A protein mediator released primarily by macrophages and T lymphocytes that help regulate the immune response.

turbid Cloudy or opaque.

turgor The elasticity of the skin.

two-point discrimination A test of sensation discrimination that measures the shortest distance at which the sides of two separate points of a compass or calipers can be distinguished from one another.

tympany A loud, high-pitched, abnormal lung sound.

type 1 diabetes The type of diabetic disease that usually starts in childhood and requires daily injections of supplemental synthetic insulin to control blood glucose; sometimes called juvenile or juvenile-onset diabetes.

type 2 diabetes The type of diabetic disease that usually starts later in life and often can be controlled through diet and oral medications; sometimes called adult-onset diabetes.

type A gastritis A form of gastritis in which the intrinsic factor secreted by mucosal parietal cells is attacked by autoantibodies, ultimately resulting in pernicious anemia.

type B gastritis A form of gastritis caused by *Helicobacter pylori* and in which the degree of inflammation varies in severity.

Type I spatial disorientation The pilot is unaware of becoming disoriented.

Type II spatial disorientation The pilot realizes that a problem exists but does not recognize it as disorientation.

Type III spatial disorientation A sudden incapacitating form of loss of positional awareness.

type-and-crossmatch The test to determine compatibility between patient serum and donor red blood cells prior to transfusion.

ulcerative colitis An inflammation of the rectal mucosal and submucosal tissues.

ultrasound An imaging technique that uses sound, which is transmitted through an area of the body, then denser material reflects waves back to a transducer that produces an image; typically used for obstetrics, gynecology, and abdominal diagnostics.

unassisted systole Pressure waveform reflecting what would normally occur without IABP assistance.

uncal herniation The most common type of brain herniation, in which a portion of the temporal lobe is displaced, resulting in compression of cranial nerve III, the midbrain, and the posterior cerebral artery.

uncus The medially curved anterior part of the hippocampal gyrus.

undertriage Considering a patient to be in less serious condition than he or she actually is.

unipolar lead A lead in which one of the electrodes is placed in the heart and the other lead is placed in an area of zero potential.

unipolar system A type of pacemaker system in which contact between the pacemaker itself and the body tissue actually forms the ground lead for the implantable pulse generator.

universal donors Persons who have type O blood.

universal gas law States how a hypothetical gas should act if there are no variables affecting it, such as temperature or pressure. Also known as the ideal gas law.

universal recipients Persons who have type AB blood.

urinalysis (UA) Laboratory tests performed on a patient's urine.

urinary tract infection (UTI) A common type of infection of the urinary tract that can progress to major conditions if not treated.

vacuum caput In a newborn, an accumulation of fluid at the site where a vacuum extractor was used to assist in delivering the newborn.

vasospastic disease Vascular constriction or spasm.

Vaughan-Williams classification scheme Classification system for antiarrhythmic medications.

vector An organism that carries a disease-causing microorganism from one organism to another.

ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch A state of inadequate ventilation, perfusion, or both, in which there is inadequate gas exchange.

ventilator-associated pneumonia (VAP) A type of hospital-acquired pneumonia that occurs in ventilated patients and that appears more than 48 hours after endotracheal intubation.

ventral Toward the abdomen; anterior.

ventricular-assist device (VAD) Sometimes an alternative to heart transplantation, this mechanical pump is surgically implanted and helps maintain a heart that can no longer function properly. It has primarily been used to support patients who are waiting for a heart transplant.

ventricular septal defect A hole in the septum separating the ventricles, allowing blood from the left ventricle to flow into the right ventricle.

vertebral body The anterior weight-bearing structure within the spine.

vertex A fetal position in which the head is the lowest part of the fetus, resulting in the head presenting first during delivery; this is the normal delivery presentation.

vertical compression Forces transmitted through vertebral bodies and directed either inferiorly through the skull or superiorly through the pelvis or feet (eg, from a direct blow to the parietal region of the skull or rapid deceleration from a fall through the feet, legs, and pelvis).

vesicular breath sounds Softer, muffled sounds in which the expiratory phase is barely audible.

vestibular Describes organs of equilibrium located in the inner ear.

viremia The presence of viruses in the blood.

virulence Physical or biochemical properties of a disease agent that determine its pathogenicity.

viscerocranium The bones making up the facial skeleton.

visual flight rules (VFR) A mode of flight used when weather conditions are good, meaning there is generally very good visibility and minimal cloud cover; the pilot is responsible for maintaining separation from other aircraft.

vital capacity (V_c) The maximal amount of air that can be exhaled following a maximal inspiration; the sum of tidal volume, inspiratory reserve volume, and expiratory reserve volume; approximately 80% total lung capacity.

volatile Easily changed from liquid to gas form.

voltage The force that causes current to flow in a circuit, measured in volts; also called *amplitude* in a pacing system.

volume ventilator A type of positive-pressure ventilator in which the breath ends when the predetermined tidal volume is achieved.

voluntary (somatic) nervous system The nervous system fibers that connect the structures of the CNS with skeletal muscles and the integument.

volvulus Twisting of the stomach or intestine, which often has the effect of cutting off its blood supply.

$\dot{V}/\dot{Q}$ ratio The relationship between alveolar ventilation and alveolar capillary perfusion. The normal value is 0.8.

warm zone Area surrounding the hot zone at a hazmat incident.

water ditching Crashing into water.

water intoxication A condition that occurs when the normal balance of electrolytes in the body is pushed outside safe limits by the overconsumption of water.

weather decline A situation in which an air medical provider is requested, but the pilot and the flight team determine that the weather does not meet established FAA guidelines and therefore decline to make the flight.

weight The downward force due to the weight (gravity) of the airplane and its load; directly opposed to lift.

Wernicke's area Part of the temporal lobe that is responsible for comprehension of both written and spoken words.

West Nile virus (WNV) An arthropod-borne flavivirus that is spread to birds and humans by mosquitoes, which may be characterized by sudden onset of fever with malaise, anorexia, nausea, vomiting, eye pain, headache, myalgia, rash, lymphadenopathy, fatigue, and arthralgias.

wheeze A high-pitched musical sound caused by airflow through a narrowed or constricted airway.

white blood cell (WBC) count A measure of the total number of leukocytes in the blood.

whole-bowel irrigation (WBI) A gastric decontamination method that involves the patient consuming large quantities of a nonabsorbable, electrolyte-balanced liquid that propels stomach and intestinal contents through the digestive system.

wide complex tachycardia A cardiac rhythm of greater than 100 beats/min with a QRS duration of 120 milliseconds or greater; can be of ventricular or supraventricular origin.

Wolff-Parkinson-White (WPW) syndrome A syndrome characterized by short PR intervals, delta waves, nonspecific ST-T wave changes, and paroxysmal episodes of tachycardia caused by the presence of an accessory pathway.

zeroing A process of calibrating a pressure transducer to eliminate extraneous atmospheric and hydrostatic pressures from the data being measured.

zero-order elimination Medications or chemicals are eliminated from the body at a constant rate, regardless of plasma concentration.

Zollinger-Ellison syndrome A condition in which a tumor in the GI tract secretes large amounts of acids.

zone of coagulation The center of a burn, usually the deepest and most severe area.

zone of erythema The outermost area of a burn, representing the least severe burned area, usually an area of first-degree burn.

zone of stasis The area found just outside the zone of coagulation, representing a burned area that is less severe.
