The procedures and protocols in this book are based on the most current recommendations of responsible medical sources. The American Academy of Orthopaedic Surgeons; the American College of Emergency Physicians; University of Maryland, Baltimore County; and the publisher, however, make no guarantee as to, and assume no responsibility for, the correctness, sufficiency, or completeness of such information or recommendations. Other or additional safety measures may be required under particular circumstances.

This textbook is intended solely as a guide to the appropriate procedures to be employed when rendering emergency care to the sick and injured. It is not intended as a statement of the standards of care required in any particular situation, because circumstances and the patient‘s physical condition can vary widely from one emergency to another. Nor is it intended that this textbook shall in any way advise emergency personnel concerning legal authority to perform the activities or procedures discussed. Such local determination should be made only with the aid of legal counsel.

The patients and providers described in the case studies throughout this textbook are fictitious.

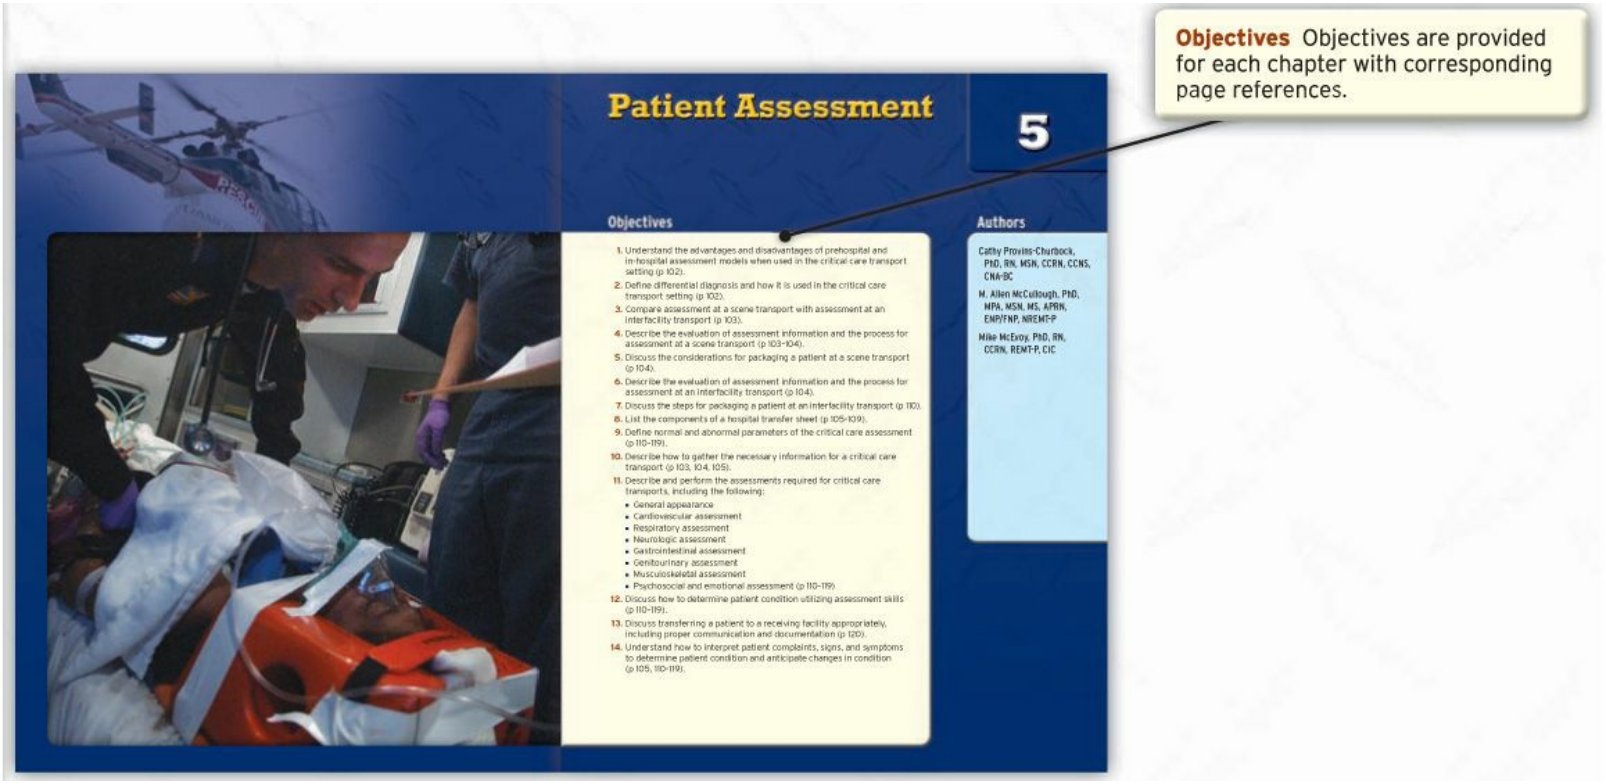
Resource Preview

Welcome to the new gold standard in critical care transport training. Published in conjunction with the American Academy of Orthopaedic Surgeons (AAOS) and the American College of Emergency Physicians (ACEP), *Critical Care Transport* offers cutting-edge content relevant to any health care provider training in critical care transport.

This book meets the curricula of major critical care training programs, including University of Maryland, Baltimore County (UMBC). It covers both ground and flight transport, and meets the objectives of critical care transport certification exams such as the Certified Flight Paramedic (FP-C) exam administered by the Board for Critical Care Transport Paramedic Certification.

Chapter Resources

A multitude of dynamic features have been incorporated to enhance learning of this advanced subject matter. The following pages show the features that help students learn—from skill drills to in-depth case studies to summary boxes.



CHAPTER 10 Trauma 241

possibility of unstable cervical spine and cord injury must always be considered. For scene calls, selective spinal immobilization criteria have become standard. If a patient has a cervical collar in place at a sending facility and the sending physician is unwilling to clear the cervical spine, the CCTP must consider full reimmobilization prior to transport. Patients with neck injury should always be considered difficult airway patients. Securing the airway with endotracheal intubation should be considered prior to most transports. Deterioration of the patient's airway in the back of a transport vehicle with limited space and personnel can be disastrous. Special airway considerations in the presence of neck injury include bleeding into the airway field, expanding hematomas, and tracheal disruption.

For neck trauma resulting in hoarseness accompanied by skin lacerations, ecchymosis, tenderness, subcutaneous emphysema, and/or stridor, an immediate otolaryngology consult is recommended. This may be the reason for transport to a larger hospital. Humidified oxygen, inhaled corticosteroids, and/or nebulized epinephrine may be ordered. Wounds may need to be dressed with occlusive dressings. If the wound is to the lower neck or clavicular area, vascular access may need to be achieved in the lower extremity as the result of compromised drainage from the arms.

Laryngotracheal Injuries

Laryngotracheal injuries represent less than 1% of all traumatic injuries. Most are in the area of the cervical trachea. Direct blunt trauma is the most common. Examples include a steering wheel to the extended throat, hanging, strangulation, and "clothesline" injury during sports such as mountain biking or snowmobiling. Penetrating laryngotracheal injuries are 10% of all penetrating neck injuries. Bubbling from a neck wound and subcutaneous air, along with dysphonia, dyspnea, stridor, visible wounds, and swelling, are all signs of laryngotracheal injury. These injuries can appear stable for a time, followed by rapid and catastrophic deterioration.

The most severe cases are laryngotracheal disruptions. It is vital that paralytics and muscle relaxants not be used. The only support for the trachea may be the supporting musculature. If the patient is paralyzed, the trachea may retract into the chest, making it impossible to ventilate the patient. If the trachea is visible through the neck wall, the endotracheal tube should simply be passed through the neck into the trachea.

Signs and Symptoms

Laryngotracheal Injury

- Bubbling from a neck wound
- Subcutaneous air
- Dysphonia
- Dyspnea
- Stridor
- Visible wounds
- Swelling

Transport Management

Laryngotracheal Injury

- Airway management with careful endotracheal intubation
- Occlusive dressing for open neck wounds
- Spinal precautions
- Transport to a trauma center

Thyroid Injuries

The thyroid gland is very vascular, and direct trauma to the front of the neck can cause hematomas of sufficient size to impinge on the airway. If surgical airway management is required, the location may need to be inferior to the usual site and inferior to the thyroid gland.

There are multiple case reports of thyrotoxicosis (thyroid storm, an excess of thyroid hormones) after trauma, including strangulation and direct blows to the anterior neck, shock (hypotension), or surgical procedures involving the thyroid. Thyroid storm has a 20% to 30% mortality rate. Thyroid storm causes a hypermetabolic crisis, including tachycardia over 140 beats/min, hyperthermia (sometimes with a temperature >103.9°F), coma with agitation, nausea, vomiting, diarrhea, and unexplained jaundice and pulmonary edema. Definitive diagnosis usually includes an elevated thyroxine level (normal level, 5.1 to 12.5 µg/dL). Treatment may include a beta-blocker such as an esmolol drip, sedation, and cooling for transport.

Signs and Symptoms

Thyrotoxicosis (Thyroid Storm)

- Tachycardia greater than 140 beats/min
- Hyperthermia (sometimes a temperature >103.9°F)
- Coma with agitation
- Nausea
- Vomiting
- Diarrhea
- Unexplained jaundice and pulmonary edema
- Elevated thyroxine level

Differential Diagnosis

Thyrotoxicosis (Thyroid Storm)

- Head injury
- Sepsis
- Toxic ingestion

Transport Management

Thyrotoxicosis (Thyroid Storm)

- Administer a beta-blocker (eg, an esmolol drip).
- Administer a sedative.
- Implement cooling measures.

Vascular Neck Injuries

Injury to the carotid, subclavian, and vertebral arteries and external and internal jugular veins can produce rapid exsanguination, hematoma formation, or embolization of air. Vascular neck injury accounts for one fourth of all penetrating

Signs and Symptoms Summarize signs and symptoms of conditions discussed in the chapter.

Differential Diagnosis List potential differential diagnoses of conditions discussed in the chapter.

Transport Management Summarize the transport-specific management of conditions discussed in the chapter.

Special Populations Discuss the specific needs and transport considerations of special populations, including pediatric patients, geriatric patients, and special needs patients.

1) nautical mile = 1.5 miles). For this reason, many services choose to send patients by fixed-wing aircraft, if available, for flights exceeding 100 nautical miles. Some air medical helicopter programs do not charge for their services and are instead funded by taxes or donations. Other air medical services offer a membership program that allows people to pay an annual subscriber fee for their household; this fee covers the cost of any air medical transport during that period.

Special Populations

Any high-risk complication of pregnancy, childbirth, or miscarriage qualifies as criteria for air medical transport.

Determining Air Medical Transport Suitability

When you are considering whether to use air medical transport, the requesting EMS provider or physician must avoid three critical errors:

- Requesting air medical transport for a patient when a more suitable means of transport is clearly indicated
- Requesting air medical transport when the patient could arrive at the receiving facility more quickly by ground transport
- Requesting air medical transport for a patient when cardiac arrest is ongoing or imminent

In most situations, air medical transport compares unfavorably to ground transport on the basis of safety, cost, and availability. On average, air medical transport costs at least four to five times more than ground transport over the same distance. In terms of availability, one air medical aircraft may serve a population of 500,000, whereas 20 or more ambulances may be available to serve the same population. Given this disparity, providers who are requesting air medical transport need to determine whether they will be needlessly tying up resources that could be better utilized elsewhere.

One other consideration to take into account when determining ground vs air transportation is the level of care that can be given. In some states, the highest level of ground provider is a paramedic. When considering flight programs, registered nurses are usually the highest level of provider, thus allowing the higher level of care such as balloon pumps, certain critical medications, and IV infusions of nonparamedic approved medications.

Thirty nautical miles (34.5 miles) or 30-minute transport is considered to be the minimum for which air medical transport is quicker than ground transport. (The industry-wide average for miles transported per flight is 61 miles.) However, factors such as traffic, construction, and weather have to be considered when making this determination. Some patients who require extended extrication time or have limited accessibility may benefit from air medical transport. Other patients may benefit from the advanced caregiving skills of the flight team, including their ability to perform rapid-sequence intubation, place chest tubes, or administer blood.

Other Justifications for Air Transport

A helicopter may sometimes be requested because the ground EMS unit is overwhelmed by the severity of the patient's injuries and needs the expertise of the flight crew. Air medical programs are frequently called to scenes where the ground EMS units have waited on the helicopter to perform advanced procedures such as rapid-sequence intubation. This situation is not strictly limited to ground EMS units, but is frequently observed in smaller hospitals as well. The medical flight team from the helicopter is often well respected in the medical community and is viewed as a "safety net" that can be relied upon when the provider on the ground requests assistance. As a member of the flight crew, you should be fast, proficient, and skilled in your area of expertise. By being proficient and skilled, you can ensure that your team is maintaining a limited on-scene time, which helps reduce the overall flight time to higher levels of care.

Transport of Patients in Cardiac Arrest

It seems counterintuitive to not utilize air medical transport for a patient who is in cardiac arrest or on the precipice of arrest. Cardiac arrest represents one of the most serious medical situations and would, in theory, stand to benefit the most by air medical transport. Nevertheless, most air medical providers do not routinely transport patients in active cardiac arrest for the following reasons.

First, it is against federal air regulations for passengers or crew onboard an aircraft to not be restrained in seatbelts during takeoffs and landings or as requested by the pilot. Providing effective CPR in the aircraft often requires the medical crew to be unbuckled.

Second, CPR is often futile, with fewer than 5% to 8% of all patients who receive CPR being resuscitated. Use of air medical transport for a patient in cardiac arrest is, therefore, generally viewed as a poor use of resources.

Last, to provide effective resuscitation, CPR generally requires a minimum of three providers: one provider performing chest compressions, one managing the airway, and one providing pharmacologic therapy. Rotor-wing aircraft typically carry only two medical providers, thus limiting the effectiveness of resuscitation. Although a patient in cardiac arrest should not be placed in the aircraft and flown, the CCTP must realize that occasionally a patient may arrest in flight and should be prepared to deal with this situation.

Triage of Air Medical Transport Patients

Intuitively, the use of air medical transport makes sense. It expedites transport of critical patients to appropriate facilities. However, numerous studies have concluded that air medical transport tends to be overused. This section discusses considerations when triaging critical care patients.

Overtriage in the Field

A retrospective review of pediatric trauma patients transported by helicopter reveals a trend toward overtriage, in which a patient is considered to be in more serious condition than he or she actually is. For example, a study in central Ohio found that nearly 70% of pediatric trauma patients transported by air were discharged from the emergency department. Similarly, a study at Children's National Medical Center in Washington, DC, found that 85% of pediatric trauma patients sent

Vocabulary Terms are easily identified and defined within the text. A comprehensive vocabulary list follows each chapter.

to the hospital by air were actually overtriaged and did not require air medical transport. A study that reviewed pediatric trauma patients flown to hospitals in Los Angeles, CA, found that 33% were overtriaged and were discharged home from the emergency department. However, many of these cases involved appropriate use of air transport: 37% of these patients had multiple injuries, 14% were intubated in the emergency department, 18% were admitted to the intensive care unit, and 4% were taken directly to the operating room. To curtail the trend toward overtriage, some are advocating for better triage training for prehospital personnel.

An estimated 10% or lower of all patients (pediatric and adult) sent to hospitals require multiple interventions. By contrast, more than 90% of the patients transported by rotor-wing or fixed-wing aircraft require multiple interventions. The patient acuteness (ie, the seriousness of the patient's condition) is much higher in the air medical industry because of the triage by experienced providers prior to the initiation of air medical transport.

Undertriage in the Field

Although many believe air medical transport is overused, there is some benefit to overtriage. **Undertriage** in the field, in which a patient is considered to be in less serious condition than he or she actually is, is a problem as well.

Some trauma physicians state that an overtriage rate of 25% is acceptable to ensure that those patients who most desperately need care are not overlooked. A recent literature review, however, indicates that this number can be as low as 10% and still encompass most outliers. Most trauma surgeons agree that a discharge rate from the emergency department of less than 10% is an indication of undertriage and suggests that patients who would most benefit from quick transport and trauma team activation are not being appropriately triaged.

Air Medical Use Criteria

Table 3-2 lists guidelines for determining whether use of air medical transport from one facility to another is appropriate. When you are making this determination, it is important to identify those patients who will not benefit from air medical transport. Table 3-3 identifies some of the absolute and relative contraindications to air medical transport.

Current **helicopter emergency medical service (HEMS)** criteria use both mechanism of injury and physiologic parameters to determine which patients might benefit most from transport in helicopters. Strictly basing the need for air medical transport on the mechanism of injury is no longer a clinically accepted practice because it has resulted in needless trauma team activations and emergent transports of stable patients. In contrast, new models that use both mechanism of injury and physiologic parameters to triage patients have been found to be effective at including appropriate patients and excluding patients who do not require trauma activation.

HEMS providers should have frequent discussions with the local trauma team about which criteria are used to triage patients. In addition, a formal system to track the "time to discharge" on all patients flown should be implemented. Air medical services whose overtriage rates exceed accepted limits should create opportunities to educate local providers about triage criteria.

Controversies

Controversy exists concerning specialty referral centers refusing transfers from outlying emergency departments unless their particular air medical service is used—even when ground transport would be perfectly acceptable. This practice needs to be addressed in the industry.

TABLE 3-3 Patient Characteristics That Warrant Air Medical Transport

Burns ≥ 10% total body surface area (second degree or greater)
Burns resulting from an explosion with severe respiratory distress or altered level of consciousness (patient not alert)
Burns with sustained unconsciousness
CO inhalation or HazMat exposures with sustained unconsciousness
Postresuscitation from near drowning
Diving accident with suspected neck injury
SCUBA accidents
Electrocution or lightning strike with sustained unconsciousness
Long fall (from heights exceeding 6') with sustained unconsciousness
Stab, gunshot wound, or other penetrating trauma to the torso or head with sustained unconsciousness
Childbirth or miscarriage with high-risk obstetric complication: • Viable premature infant (≤ 20 weeks' gestation) • Viable multiple births (≤ 20 weeks' gestation) • Maternal bleeding disorder • Maternal use of blood thinners
Traffic or transportation crashes with patient pinned and sustained unconsciousness
Traffic or transportation crashes with sustained unconsciousness and high mechanism: • All-terrain vehicles • Automobile vs bicycle or motorcycle • Ejection • Personal watercraft • Rollover crash • Vehicle off bridge/height
Need for advanced life support or specialized care not available by ground services
Time-critical illness or injury: • Stroke or acute coronary syndrome with potential for interventional care • Amputated limb with potential for reattachment

Controversies

Organ donation is a major concern in a critical care unit, but should not be relevant to critical care transport. CCTPs care for critically ill patients as though they are expected to survive. The patient's status as an organ donor should have no impact on care.

Controversies Highlight issues that may be under debate in the critical care community.

Skill Drills Provide written step-by-step explanations and visual summaries of important skills and procedures.

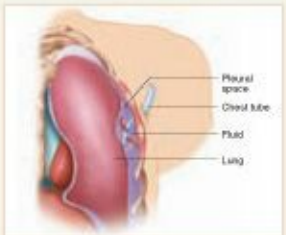


Figure 10-21 A chest tube is inserted through the side of the chest into the pleural space.

- Kelly clamps (curved and straight)
- Sterile occlusive dressing
- Suturing material
- 2% Chlorhexidine
- A local anesthetic if the patient is awake
- A fluid collection device with a one-way valve that allows air, fluid, or pus to flow out of the chest. If not available, an indwelling catheter bag with a one-way valve may be used
- Tape
- Mechanical suction device (not always used)

Indications include:

- Pneumothorax
- Hemopneumothorax
- Empyema

Complications include:

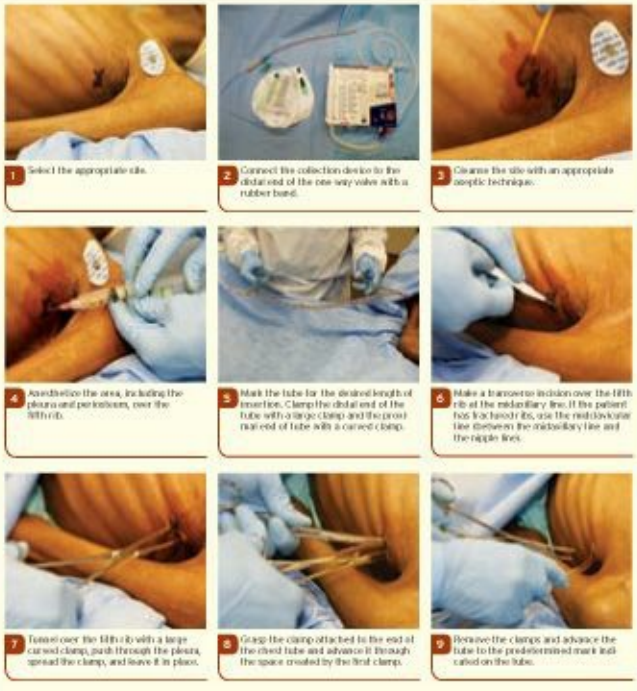
- Recurrent pneumothorax
- Accidental removal
- Broken collection chamber
- Parenchymal injury
- Laceration of intercostal vessels
- Creation of a hemothorax or bleeding
- Misplacement below the diaphragm
- Infection

Skill Drill 10-2 shows the clinical procedure for inserting a chest tube, which is described below:

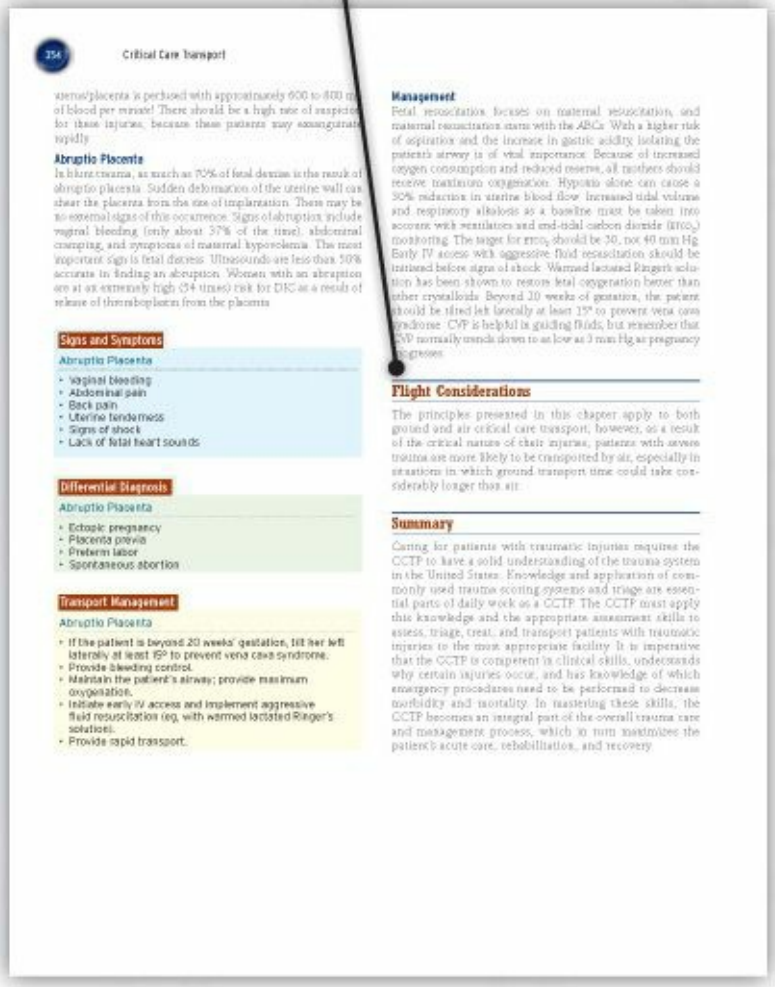
1. Select the appropriate site: midaxillary over the fifth rib (Step 1).
2. Connect the indwelling catheter bag or the collection device to the distal end of the one-way valve with a rubber band (Step 2). Be certain that the arrow on the valve is facing away from the patient.
3. Cleanse the site with an appropriate aseptic technique (Step 3).
4. Anesthetize the area, including the pleura and periosteum, over the fifth rib (Step 4), if the patient is conscious and time permits. If possible, place the patient in a 30° reverse Trendelenburg (head up) position so blood drains to the low end of the lung.
5. Mark the tube for the desired length of insertion (Step 5).
6. Clamp the distal end of the tube with a large clamp (such as a Kelly clamp) and the proximal end of the tube with a curved clamp.
7. Make a transverse incision over the fifth rib in the midaxillary line (Step 6). If the patient has fractured ribs, use the midclavicular line (between the midaxillary line and the nipple line).
8. Tunnel over the fifth rib with a large curved clamp, push through the pleura, spread the clamp, and leave it in place (Step 7).
9. Grasp the clamp attached to the end of the chest tube and advance it through the space created by the first clamp, directing it posteriorly and downward toward the diaphragm (Step 8).
10. Remove the clamps and advance the tube to the predetermined mark indicated on the tube, or least 5 cm beyond the last hole (Step 9).
11. Connect the collection device (Step 10).
12. Remove the distal clamp (Step 11).
13. Suture the tube in place and close the wound (Step 12).
14. Note the depth of the tube at the skin (marked on the tube) and mark with a felt-tip pen.
15. Cover the insertion site with an occlusive dressing and reinforce all connections with tape (Step 13).
16. Upon arrival at the receiving facility, obtain a chest radiograph to confirm placement.
17. Document the procedure, including the size of the chest tube inserted, the amount of return of air/fluid after insertion of the tube, and any changes in patient condition (including oxygen saturation).

Skill Drill 10-2

Chest Tube Insertion



Flight Considerations Summarize flight considerations for emergencies discussed in the chapter.



uterus/placenta is perfused with approximately 600 to 800 mL of blood per minute! There should be a high rate of suspicion for these injuries, because these patients may exsanguinate rapidly.

Abruptio Placenta

In blunt trauma, as much as 70% of fetal demise is the result of abruptio placenta. Sudden deformation of the uterine wall can shear the placenta from the site of implantation. There may be no external signs of this occurrence. Signs of abruption include vaginal bleeding (only about 37% of the time), abdominal cramping, and symptoms of maternal hypovolemia. The most important sign is fetal distress. Ultrasounds are less than 50% accurate in finding an abruption. Women with an abruption are at an extremely high (54 times) risk for DIC as a result of release of thromboplastin from the placenta.

Signs and Symptoms

Abruptio Placenta

- Vaginal bleeding
- Abdominal pain
- Back pain
- Uterine tenderness
- Signs of shock
- Lack of fetal heart sounds

Differential Diagnosis

Abruptio Placenta

- Ectopic pregnancy
- Placenta previa
- Preterm labor
- Spontaneous abortion

Transport Management

Abruptio Placenta

- If the patient is beyond 20 weeks' gestation, tilt her left laterally at least 15° to prevent vena cava syndrome.
- Provide bleeding control.
- Maintain the patient's airway; provide maximum oxygenation.
- Initiate early IV access and implement aggressive fluid resuscitation (eg, with warmed lactated Ringer's solution).
- Provide rapid transport.

Management

Fetal resuscitation focuses on maternal resuscitation, and maternal resuscitation starts with the ABCs. With a higher risk of aspiration and the increase in gastric acidity isolating the patient's airway is of vital importance. Because of increased oxygen consumption and reduced reserve, all mothers should receive maximum oxygenation. Hypoxia alone can cause a 30% reduction in uterine blood flow. Increased tidal volume and respiratory alkalosis as a baseline must be taken into account with ventilators and end-tidal carbon dioxide ($ETCO_2$) monitoring. The target for $ETCO_2$ should be 30, not 40 mm Hg. Early IV access with aggressive fluid resuscitation should be initiated before signs of shock. Warmed lactated Ringer's solution has been shown to restore fetal oxygenation better than other crystalloids. Beyond 20 weeks of gestation, the patient should be tilted left laterally at least 15° to prevent vena cava syndrome. CVP is helpful in guiding fluids, but remember that CVP normally trends down to as low as 3 mm Hg as pregnancy progresses.

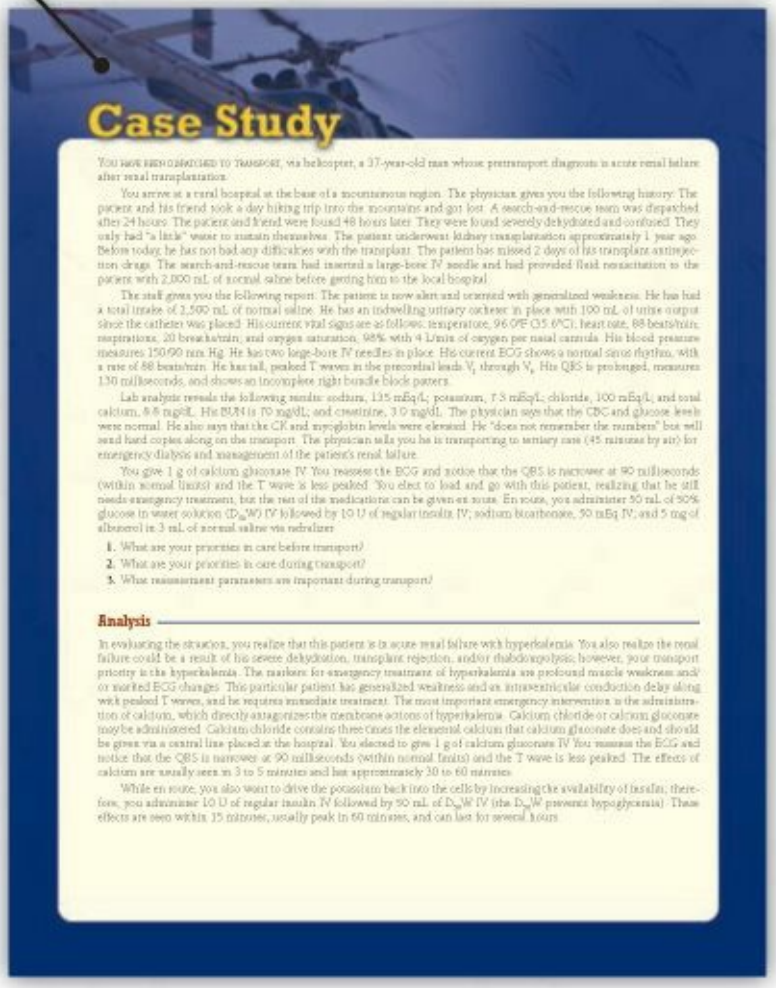
Flight Considerations

The principles presented in this chapter apply to both ground and air critical care transport; however, as a result of the critical nature of their injuries, patients with severe trauma are more likely to be transported by air, especially in situations in which ground transport time could take considerably longer than air.

Summary

Caring for patients with traumatic injuries requires the CCTP to have a solid understanding of the trauma system in the United States. Knowledge and application of commonly used trauma scoring systems and triage are essential parts of daily work as a CCTP. The CCTP must apply this knowledge and the appropriate assessment skills to assess, triage, treat, and transport patients with traumatic injuries to the most appropriate facility. It is imperative that the CCTP is competent in clinical skills, understands why certain injuries occur, and has knowledge of which emergency procedures need to be performed to decrease morbidity and mortality. In mastering these skills, the CCTP becomes an integral part of the overall trauma care and management process, which in turn maximizes the patient's acute care, rehabilitation, and recovery.

Case Study An in-depth, comprehensive scenario at the end of each chapter allows students to synthesize and apply what they've learned. Concludes with an analysis that discusses learning points.



Case Study

YOU HAVE BEEN DISPATCHED TO TRANSPORT, via helicopter, a 37-year-old man whose pretransport diagnosis is acute renal failure after renal transplantation.

You arrive at a rural hospital at the base of a mountainous region. The physician gives you the following history: The patient and his friend took a day hiking trip into the mountains and got lost. A search-and-rescue team was dispatched after 24 hours. The patient and friend were found 48 hours later. They were found severely dehydrated and confused. They only had "a little" water to sustain themselves. The patient underwent kidney transplantation approximately 1 year ago. Before today, he has not had any difficulties with the transplant. The patient has missed 2 days of his transplant antirejection drugs. The search-and-rescue team had inserted a large-bore IV needle and had provided fluid resuscitation to the patient with 2,000 mL of normal saline before getting him to the local hospital.

The staff gives you the following report. The patient is now alert and oriented with generalized weakness. He has had a total intake of 2,500 mL of normal saline. He has an indwelling urinary catheter in place with 100 mL of urine output since the catheter was placed. His current vital signs are as follows: temperature, 96.0°F (35.6°C); heart rate, 88 beats/min; respirations, 20 breaths/min; and oxygen saturation, 98% with 4 L/min of oxygen per nasal cannula. His blood pressure measures 150/90 mm Hg. He has two large-bore IV needles in place. His current ECG shows a normal sinus rhythm, with a rate of 88 beats/min. He has tall, peaked T waves in the precordial leads V_2 through V_4. His QRS is prolonged, measures 130 milliseconds, and shows an incomplete right bundle block pattern.

Lab analysis reveals the following results: sodium, 135 mEq/L; potassium, 7.5 mEq/L; chloride, 100 mEq/L; and total calcium, 8.8 mg/dL. His BUN is 70 mg/dL; and creatinine, 3.0 mg/dL. The physician says that the CBC and glucose levels were normal. He also says that the CK and myoglobin levels were elevated. He "does not remember the numbers" but will send hard copies along on the transport. The physician tells you he is transporting to tertiary care (45 minutes by air) for emergency dialysis and management of the patient's renal failure.

You give 1 g of calcium gluconate IV. You reassess the ECG and notice that the QRS is narrower at 90 milliseconds (within normal limits) and the T wave is less peaked. You elect to load and go with this patient, realizing that he still needs emergency treatment, but the rest of the medications can be given en route. En route, you administer 50 mL of 50% glucose in water solution ($D_{50}W$) IV followed by 10 U of regular insulin IV; sodium bicarbonate, 50 mEq IV; and 5 mg of albuterol in 3 mL of normal saline via nebulizer.

1. What are your priorities in care before transport?
2. What are your priorities in care during transport?
3. What reassessment parameters are important during transport?

Analysis

In evaluating the situation, you realize that this patient is in acute renal failure with hyperkalemia. You also realize the renal failure could be a result of his severe dehydration, transplant rejection, and/or rhabdomyolysis; however, your transport priority is the hyperkalemia. The markers for emergency treatment of hyperkalemia are profound muscle weakness and/or marked ECG changes. This particular patient has generalized weakness and an intraventricular conduction delay along with peaked T waves, and he requires immediate treatment. The most important emergency intervention is the administration of calcium, which directly antagonizes the membrane actions of hyperkalemia. Calcium chloride or calcium gluconate may be administered. Calcium chloride contains three times the elemental calcium that calcium gluconate does and should be given via a central line placed at the hospital. You elected to give 1 g of calcium gluconate IV. You reassess the ECG and notice that the QRS is narrower at 90 milliseconds (within normal limits) and the T wave is less peaked. The effects of calcium are usually seen in 3 to 5 minutes and last approximately 30 to 60 minutes.

While en route, you also want to drive the potassium back into the cells by increasing the availability of insulin; therefore, you administer 10 U of regular insulin IV followed by 50 mL of $D_{50}W$ IV (the $D_{50}W$ prevents hypoglycemia). These effects are seen within 15 minutes, usually peak in 60 minutes, and can last for several hours.

Ready for Review Summarize chapter content in a comprehensive bulleted list.

Prep Kit

Ready for Review

- All cells require energy a continuous supply of oxygen, and nutrients. From those nutrients, mitochondria manufacture energy in the form of adenosine triphosphate (ATP). This process is called cellular respiration.
- Cellular respiration has three parts: glycolysis, the citric acid cycle, and the electron transport chain (oxidative phosphorylation). Unlike the other two parts of cellular respiration, which require oxygen, glycolysis also can occur in an anaerobic environment. But this solo attempt to support cellular respiration causes a reduction in ATP and an increase in lactic acid, which can result in cell damage, impaired function of tissue, and a cascade of injurious effects.
- To get oxygen to the body's cells, the respiratory system must allow oxygen and carbon dioxide exchange across the alveolar-capillary membrane. Once this transfer occurs, arterial blood transports oxygen to the tissues (the oxygen is dissolved in plasma [3%] or is bound to hemoglobin [97%]).
- Various factors can affect the delivery of oxygen-rich blood to the tissues, including blood volume, viscosity and arterial elasticity. However, the primary determinants of transport are blood pressure (it must be stable) and cardiac output (it must be adequate).
- Under normal conditions, only 25% of the oxygen delivered to the tissues of the body is actually extracted. This allows the body a buffer zone for periods of low oxygen delivery, during which the cells must extract more oxygen. Therefore, management of shock is geared toward maintaining oxygen consumption by maintaining adequate oxygen supply, providing hemoglobin through administration of blood products, and optimizing cardiac output. If there is a breakdown in one or more of these components, homeostasis is lost.
- Shock is a progressive, whole-body response to an inadequate supply of oxygen within cells, tissues, and organs, from one or multiple causes. It is commonly classified in four stages, and the mortality rate increases with progression.
  - During initial or early shock, blood flow into the microcirculatory beds decreases and lactic acid levels begin to rise. However, compensatory mechanisms, such as an increase in oxygen consumption, are able to keep vital signs at baseline.
  - During the compensatory stage of shock, neural, hormonal, and chemical mechanisms attempt to compensate for the now severely reduced delivery of oxygen. They, in effect, cover up low circulatory volumes, poor stroke volume, and falling cardiac output, especially in children and healthy young adults. Common signs and symptoms are as subtle as mild tachypnea and tachycardia. The MAP may decrease 10 to 15 mm Hg from baseline. Cardiac output also may drop slightly.
  - During the progressive or decompensating stage of shock, multifaceted systemic responses to cell breakdown occur, affecting nearly every organ of the body. Compensatory mechanisms have begun to fail. Patients have more pronounced signs of shock, including altered mental status, tachycardia, and a drop in MAP of more than 30 mm Hg from baseline. Laboratory analysis shows a progression of acidosis, hyperkalemia, and climbing lactate levels. This is a life-threatening emergency that requires immediate treatment.
  - During the refractory or irreversible stage of shock, compensatory mechanisms have failed. At this stage, the patient is unresponsive to verbal stimuli. Blood pressure will be inadequate and the heart rate will be increased. The respiratory rate is increased and respirations are shallow. Skin will be cold, cyanotic, and/or mottled and peripheral pulses are weak and thready to absent. Urinary output will decrease and bowel sounds will be absent. Anaerobic metabolism progresses to permanent organ dysfunction and treatment no longer can reverse the main effects. Multiple organ failure ensues and the risk of mortality is at its highest.
- MODS is diagnosed when two or more organs stop functioning. The organs affected early in MODS are the brain, kidneys, liver, adrenal glands, and heart. Sepsis is the leading cause of MODS.
- Shock traditionally is classified by cause. More than one type of shock may be present at the same time.
- Cardiogenic shock results when the ventricles are unable to pump blood forward, ultimately decreasing cardiac output. Manifestations vary depending on the underlying cause, but common signs and symptoms are low blood pressure; altered mental status; cool, pale, diaphoretic skin; decreased urine output; weak and thready pulse; distant or abnormal S_1 or S_2 heart sounds; fluid accumulation in the lungs or limbs; and tachypnea. Management focuses on enhancing cardiac output while decreasing left ventricular work load.
- Hypovolemic shock is present when there is too little circulating blood volume within the vascular system, resulting in hypotension. Manifestations include tachycardia; hypotension; signs of poor tissue perfusion; altered mental status; and cold, mottled, and pulseless extremities. Management revolves around treating the underlying condition, administering oxygen, and initiating volume replacement.
- Distributive shock is a term used to describe several types of shock involving loss of vasomotor tone or increased vascular permeability: neurogenic shock, anaphylactic shock, and septic shock.
- Neurogenic shock results from conditions that impede the ability of the sympathetic nervous system to control the constriction and dilation of vessel walls, such as trauma to the brain or spinal cord. The signs and symptoms associated with neurogenic shock can be very different from those

Vital Vocabulary Provide key terms and definitions from the chapter.

- Hemolytic transfusion reactions are caused by ABO or Rh incompatibility, intradonor incompatibility, improper cross-matching, or improper blood storage.
- Immediate hemolytic transfusion reactions may occur during transfusion or within 3 to 7 days following transfusion. Red blood cells are destroyed, and hemoglobin and red blood cell remnants are released into the bloodstream. Symptoms include chest pain, facial flushing, shortness of breath, chills, fever, hypotension, flank pain, hemoglobinuria, oliguria, bloody oozing at the infusion site, burning along the vein receiving the blood, shock, signs of renal failure, and DIC. Treatment of immediate hemolytic transfusion reactions is directed toward prevention and supportive management.
- Delayed hemolytic transfusion reactions do not occur until 3 to 7 days after transfusion. Signs and symptoms are usually mild and include mild fever, chills, and moderate jaundice, with treatment focused on the prevention and the treatment of severe complications should they arise.
- Plasma protein incompatibility is caused by immunoglobulin A incompatibility. Clinical presentations include abdominal pain, diarrhea, shortness of breath, chills, fever, flushing, and hypotension. Management includes oxygen administration, fluids, epinephrine, and corticosteroids as indicated.
- Hypocalcemia may occur when blood products containing citrate are infused too quickly and bind calcium, causing calcium deficiency and leading to arrhythmias, hypotension, muscle cramping, nausea, vomiting, seizure activity, and/or a tingling sensation in the fingers. Slowing or stopping the transfusion may be indicated. Management considerations include the administration of calcium gluconate IV infused slowly.
- High potassium levels in stored plasma may result in potassium intoxication during blood administration. Clinical manifestations include diarrhea, intestinal colic, flaccidity, muscle twitching, oliguria, signs of renal failure, bradycardia, ECG changes with visible tall peaked T waves, and/or cardiac arrest. Management considerations include a diagnostic 12-lead ECG tracing; Kayexalate administration; administration of an albuterol nebulizer; administration of furosemide; and the infusion of 50% glucose, insulin, sodium bicarbonate, or calcium.
- Hypothermia may result from a rapid infusion of large amounts of cold blood products. Hypothermia symptoms include chills, shivering, hypotension, arrhythmias, bradycardia, and/or cardiac arrest. Treatment may include stopping the transfusion, warming the patient, obtaining a diagnostic 12-lead ECG, and warming the blood if the transfusion is restarted.

Vital Vocabulary

ABO-incompatible transfusion reactions A type of transfusion reaction in which the patient possesses antigens to a blood type and receives that blood type.

adaptive immune system The secondary mechanism that protects the host by reacting with and eliminating specific antigens after requiring more time than the innate immune system to mobilize its defense against unknown pathogens.

aerobic metabolism A form of energy production in which mitochondria utilize glucose, amino acids, and fatty acids combined with oxygen and ADP to produce ATP, carbon dioxide, water, and heat.

albumin A blood product containing the specific protein found in the blood, and prepared by the fractionation of pooled plasma; used for volume replacement in certain conditions.

anaerobic metabolism A less efficient form of energy production in which an alternative pathway converts glucose to pyruvic acid with the simultaneous production of ATP and that also results in the production of lactate.

anaphylactic shock A severe hypersensitivity reaction that involves bronchoconstriction and cardiovascular collapse.

anaphylactoid reaction A non-IgE-mediated response that causes the rupture of mast cells and basophils, which then release histamine and other defense mediators.

antigen Any substance that can create an immune response in the body.

arterial oxygen content (Ca_{O_2}) The total amount of oxygen in the arterial blood.

cardiac index A hemodynamic value that adjusts a patient's cardiac output to take into account his or her total body surface area.

cardiac output (CO) The amount of blood pumped by the heart per minute, calculated by multiplying the stroke volume by the heart rate per minute.

cardiogenic shock A condition caused by loss of 40% or more of the functioning myocardium; the heart is no longer able to circulate sufficient blood to maintain adequate oxygen delivery.

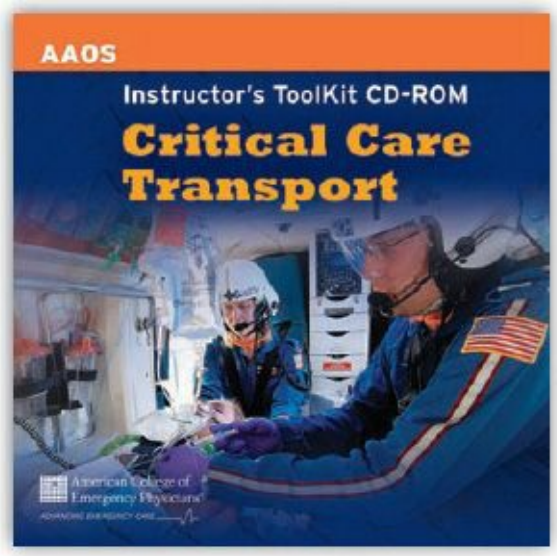
cryoprecipitate A blood product created from plasma and in which clotting factors, especially factor VIII, are concentrated; used to treat patients with coagulation disorders.

cytokines Chemical messengers that enhance cell growth, promote cell secretion, direct cellular traffic, stimulate macrophage function, and destroy antigens; interleukins are a type of cytokine.

delayed hemolytic transfusion reactions A type of transfusion reaction that does not occur until 3 to 7 days after transfusion.

disseminated intravascular coagulation (DIC) A complex condition arising from different causes that activate coagulation mechanisms, resulting in obstructed blood flow as a result

Instructor and Student Resources



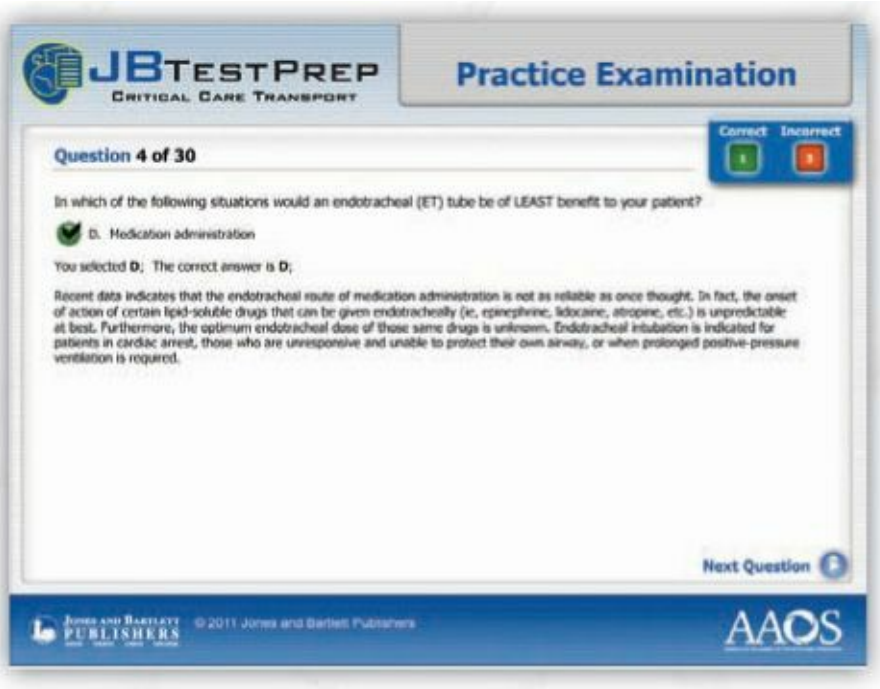
Instructor's ToolKit CD-ROM

ISBN: 978-0-7637-5928-5

This instructor's package contains everything needed to instruct a dynamic critical care transport course. This package includes:

- **PowerPoint® presentations**, providing you with educational and engaging presentations. Following the content of the chapter, the slides also contain images throughout. The presentations can be modified and edited to meet your needs.
- **Lecture Outlines**, providing you with complete, ready-to-use lesson plans that outline all of the topics covered in the chapter. The lesson plans can be modified and edited to fit your course.
- **Image and table bank**, providing you with many of the images and tables found in the text. You can use them to incorporate more images into the PowerPoint® presentations, make handouts, or enlarge a specific image for further discussion.
- **Test bank**, providing you with multiple-choice general knowledge and critical thinking questions. With the test bank, you can originate tailor-made classroom exams and quizzes quickly and easily by selecting, editing, organizing, and printing an exam along with an answer key that includes page references to the text.

The resources found on this CD-ROM have been formatted so that you can seamlessly integrate them into the most popular course administration tools. Please contact Jones and Bartlett Publishers technical support at 1-800-832-0034 at any time with questions.



JBTestPrep: Critical Care Transport

ISBN: 978-0-7637-8565-9

JBTestPrep: Critical Care Transport is a dynamic program designed to prepare students for critical care transport certification exams by including the same type of questions they will likely see on the actual examination.

It provides a series of self-study modules, organized by chapter, offering practice examinations and simulated certification examinations using multiple-choice questions. All questions are page referenced to *Critical Care Transport* for remediation to help students hone their knowledge of the subject matter.

Students can begin the task of studying for critical care transport certification examinations by concentrating on those subject areas where they need the most help. Upon completion, students will feel confident and prepared to complete the final step in the certification process—passing the examination.

Acknowledgments

The AAOS, ACEP, and Jones and Bartlett Publishers wish to thank the many authors, contributors, and reviewers who were involved in the development of this textbook.

Objectives

1. Define the term *critical care* (p 4).
2. Understand the history of critical care transports, both air and ground (p 4).
3. Describe critical care transport team composition (p 8).
4. List the qualifications of members of a critical care transport team (p 8).
5. Identify the modes of transportation used during critical care transports, including mobile (ground) units, rotor-wing aircraft, and fixed-wing aircraft (p 4–7).
6. Discuss the differences between the modes of transportation (p 9, 10).
7. Understand the advantages and disadvantages for each mode of transportation (p 11).
8. Understand the role of dispatch in determining the mode of transportation (p 10).
9. Understand the role of medical control in the critical care transport environment (p 12).
10. Identify stresses specific to the critical care transport professional and their signs (p 13).
11. Discuss state and national standards for critical care transport (p 13).
12. Discuss reimbursement criteria and their relevance to critical care transport (p 13).
13. Understand the importance of interpersonal communications with the patient and family members (p 14).
14. Explain the process of quality assurance and improvement, and understand the importance of maintaining skills and knowledge (p 15).
15. Discuss the role of critical care transport professionals in emergency medical services (p 4).
16. Recognize the impact of specialty/critical care on the health care system (p 4).

Introduction

Critical care transport is at the forefront of the ever-changing world of modern health care. Driven by cost containment, insurers, clinical advancements, new regulations, and a continual shift toward specialty centers, the field of critical care transport will continue to grow exponentially. Transports once managed exclusively by physicians and nurses now include EMTs and paramedics. This expansion of EMS providers into critical care transport brings with it a pressing need for formal education and clinical preparation in the multifaceted and complex area of critical care transport. This education will aid all providers in bridging the gap from their respective educational foundations to the level of **critical care transport professional (CCTP)**.

Critical care is complex, detailed health care that is provided to patients experiencing acute, life-

threatening conditions. CCTPs must have the ability to deal with crucial situations rapidly and with precision using and interpreting data provided by various advanced machines and devices for treating and monitoring patients.

Methods for transporting the **critical care patient** have evolved from horse-drawn carts in the 17th century, to the use of hot-air balloons, to the use of ground, rotor-wing, and fixed-wing vehicles. With more efficient transport methods came rapid provision of medical treatment and increased the survivability of critical injuries and illnesses.

This chapter focuses on the evolution of critical care transports, the members of the health care community involved in patient care, their educational requirements, the various transportation modes used (including their differences, advantages, and disadvantages), the role of air medicine, and the effect of critical care transports on the health care system.

The History of Critical Care Transport

Ground Transport

The area of critical care transport is growing rapidly, and with it comes the challenge of initial and continued training for the staff manning these units. This training involves current and expanded treatment modalities, the use of specialized equipment, and the practice of advanced procedures. During these times of change, CCTPs must maintain the focus of their primary mission—providing care to critically ill and injured patients. Critical care requires the ability to deal with crucial situations rapidly and with precision. Until recently, this type of patient care was limited to intensive or critical care units within a hospital setting. Now, there is an emphasis on critical care treatment in the prehospital setting and during interfacility transports, as well as within the hospital itself.

Over the years, the need for a rapid transport system to move critically injured or ill patients to a definitive care facility has become clear. As will be discussed, early methods of transportation were initially developed out of necessity to reduce the incredibly high rates of **morbidity** and **mortality** among soldiers. Later, these modes of transportation would also be used to move critically ill and injured patients to more definitive care facilities. Because these modes of transportation vary widely, it is advantageous to examine the progression of each separately.

The first record of moving injured patients was in the 11th century during the Crusades by the Knights of St John. The Knights of St John treated and transported injured soldiers after learning about first aid procedures from Arab and Greek physicians. This was the birth of the first emergency medical providers. At the same time, any soldier who carried an injured comrade to receive medical treatment would receive a small monetary reward.

Ground transportation was first used in 1792 to evacuate injured soldiers during the French Revolution. A surgeon in the French army, Dominique Jean Larrey, noticed many of his countrymen lay wounded on the battlefield for as long as 36 hours until they were evacuated by fourgons, or multi-horse wagons **Figure 1-1**. This delay in transport resulted in the death and disability of many soldiers, which Larrey found unacceptable.

Larrey designed and produced several two- and four-wheeled carts called the *ambulance volante* (flying ambulance) **Figure 1-2**, which were fast and maneuverable. These carts were used to transport surgeons and equipment to the battlefield to give first aid and then return the wounded to nearby field hospitals. Larrey's flying ambulance was the first recorded use of an evacuation system to help improve the survival rates of soldiers. He is also credited with creating the first official army medical corps using stretchers, hand carts, and wagons as a means of transporting injured patients.

America's first ambulance service was instituted in 1862 during the Civil War at the Battle of Antietam, by surgeon Jonathan Letterman. Director of the Army of the Potomac, Letterman developed a

plan for an integrated medical treatment and evacuation system with its own vehicles, facilities, and personnel **Figure 1-3**. This system became known as the Ambulance Corps and was the basis of Army medical doctrine. On June 23, 1917, the US Army Ambulance Service was established as a descendent of the initial Ambulance Corps. During this time, the use of train ambulances, steamboat hospitals, and car or trolley ambulances was popular in some cities.

Figure 1-1 The first vehicles used for transport of casualties were horse-drawn.

Figure 1-2 The *ambulance volante* (flying ambulance), shown here, was a two- or four-wheeled cart that transported surgeons and equipment to the battlefield.

In 1869, America's first city ambulance service was established in New York City by Bellevue Hospital **Figure 1-4**. The hospital's Center Street Branch dispatched ambulances via telegraph and was staffed with physicians or surgeons from the hospital. Incredibly, the ambulance responded to more than 1,800 calls throughout the city of New York that first year. As the call volume increased, it became more difficult to staff the ambulances without decreasing the number of physicians in the hospital; in response to this problem, the hospital began placing orderlies or kitchen or janitorial staff on the ambulance. Because these employees had little or no medical training, responded without equipment, and frequently arrived at the scene hours after being dispatched, the mortality rate of seriously ill and injured patients increased dramatically. The continued population growth and the Industrial Revolution fueled the need for better training and easier access to rapid prehospital emergency medical care.

Figure 1-3 The first integrated treatment and evacuation system was established by surgeon Jonathan Letterman in 1862 during the Civil War at the Battle of Antietam.

Figure 1-4 One of New York City's early ambulances.

In 1899, the first motorized ambulance was developed in Chicago, IL, and donated to the Michael Reese Hospital by a group of businessmen. The unit weighed 1,600 pounds and could travel at speeds up to 16 miles per hour.

In the early 1900s, ambulance crews had evolved to include a driver and a person responsible for patient care, but generally the crews only picked up and delivered the patient to a base hospital.

The next milestone for prehospital care came in 1966 in Dublin, Ireland, with the provision of prehospital coronary care by physicians. Research by Francis Pantridge, MD, indicated that most patients experiencing treatable ventricular fibrillation had this fatal arrhythmia outside the hospital. His thought was to have portable, lightweight, battery-driven defibrillators carried as part of the rapid response system he had developed. His foresight was the driving force for the current use of defibrillators by paramedics on mobile coronary care units and automated external defibrillators (also known as AEDs) used by the lay public.

Prehospital defibrillation was not used in the United States until 1969, shortly after the nation's first paramedic program was instituted by the Miami, FL, Fire Department under the direction of Eugene Nagel, MD. Physicians in Los Angeles, CA; Seattle, WA; and Columbus, OH, followed Nagel's lead and began paramedic programs in their states in the hope that prehospital emergency care would reduce preventable deaths. Today, prehospital and interfacility transports are accomplished not only by ground, but also by air.

Air Transport

After witnessing balloon flight demonstrations by the Montgolfier brothers in 1784, physicians began to consider the benefits that flight could bring to their patients. However, it was not until 1870 that the first documented case of air medical transport took place during the Prussian Siege of Paris, when 160 wounded soldiers and civilians were transported from the battlefield by hot-air balloons. At the time, this method was considered a radical means of transport and was met with harsh criticism; however, improvements were made. During the period between 1890 and 1910, M. de Mooy, chief of the Dutch Medical Service, pursued the idea of using litters suspended from balloons to transport patients.

On December 17, 1903, Orville Wright climbed into the plane he and his brother built for the second attempt at flying a motorized plane. The site was Kill Devil Hills, NC, and the plane stayed airborne for 12 seconds and flew for 120′ before landing under the power of its pilot, making history as the first pilot-operated airplane.

In 1909, Captain George Groaman of the US Army Medical Corps built a plane specifically designed to carry patients; unfortunately, it crashed during testing and never received government approval. The first successful use of a motorized aircraft for transporting patients occurred 8 years later when a plane named the French Dorand AR II served as an air ambulance, transporting patients. During the next several decades, the air medical transport industry grew, predominantly as part of the military. In 1914, Igor Sikorsky invented the helicopter, which would later be used by the military to transport wounded soldiers from the battlefield to definitive medical care.

After World War I, the US Army took a new interest in the development and successful use of air ambulances. The chief surgeon of the Army proposed modifications to the de Havilland aircraft, making it capable of transporting a pilot, a medical officer, and two patients. This became the mind-set for the evacuation of injured soldiers during wartime. Further advancements continued to be made, and in the 1930s, air ambulances were specifically designed with multiple engines, heated cabins, and short runway capacity. Within the next decade, the push to create helicopters capable of transporting patients continued **Figure 1-5**.

Figure 1-5 The de Havilland DH89B Dominie loading a mock casualty onto an aircraft in 1945.

On April 23, 1944, several wounded airmen were transported via helicopter in Burma during World War II. This is thought to be the first time wounded soldiers were transported via this means, marking a new era of air medical transport. After the war, the military determined that air evacuation of wounded patients from battlefields would be a major goal. The first official military rescue evacuation was made on August 4, 1950, 1 month after the start of the Korean War. Wounded soldiers were transported to MASH (mobile army surgical hospital) units on cots fitted on the skids of Bell-47 and Sikorksy S-51 helicopters **Figure 1-6**. A drop in the mortality rate was directly attributed to the use of helicopters to rapidly evacuate wounded soldiers from combat and deliver them to surgical care **Table 1-1**.

The Vietnam War brought a significant change in the removal of wounded patients from the front lines. The majority of battlefield rescues, stabilizations, and evacuations were carried out by a much larger helicopter, the Bell UH-1 (Huey), code named *Dnstnff* **Figure 1-7**. This helicopter was capable of carrying more patients and personnel, and patients could be carried inside the aircraft where they could receive medical care en route to the receiving facility. This war saw the transport of more than 800,000 patients to specialty care facilities. The marriage of rapid air transport to specialty care facilities proved successful and kindled interest in the civilian arena.

TABLE 1-1 Mortality Rates in Military Conflicts

Military Conflict	Time From Injury to Surgical Care	Mortality Rate
World War I	12 to 18 hr	8.8%
World War II	6 to 12 hr	5.8%
Korea (with helicopter)	2 to 4 hr	2.4%
Vietnam (with helicopter)	1 to 1.4 hr	1.7%

Adapted from: Holmes E. *Soundings: aeromedical history.* Available at: http://members.cox.net/eholmes333/soun-pg4.html. Accessed January 28, 2008.

Figure 1-6 Soldiers wounded during the Korean War were sometimes evacuated on litters strapped to the skids of aircraft.

Figure 1-7 The Bell UH-1 helicopter, code named *Dustoff*, evacuated patients during the Vietnam War.

In 1958, Bill Mathews, a northern California businessman, was the first to organize a civilian air medical service. He lived in the small town of Etna and was met with skepticism from the town's 700 residents. Fortunately, Granville Ashcroft, MD, the area's only physician, began using the helicopter to transport patients. Soon the town druggist also started using the helicopter to deliver medications during emergencies.

Likewise, during the 1960s, Europeans instituted helicopter programs that were dedicated to patient care and transport. During that same period, the United States saw the emergence of several civilian- and government-funded helicopter projects. These projects were funded to study the feasibility of using helicopters to transport patients in the civilian arena. In 1966, the National Institutes of Health and National Academy of Sciences published "Accidental Death and Disability: The Neglected Disease of Modern Society," paving the way for the initiation and growth of civilian air medical transportation programs and recommending the initiation of a system designed to transport patients via air ambulances based on the successful military model.

In 1969, the state of Maryland received a grant to purchase a Bell JetRanger helicopter and instituted the nation's first public service medevac program **Figure 1-8**. The four helicopters, staffed with paramedics, were part of the Maryland State Police and were strategically stationed throughout the state for quick responses to emergencies. When the helicopters were not being used for medical emergencies, they could be used for law enforcement missions.

Figure 1-8 The Bell JetRanger helicopter was used for the first public service medevac program.

In 1972, the first hospital-based air medical transport program was established at St Anthony's Hospital, Denver, CO. Following continued skepticism about the civilian use of helicopters for medical transports, the National Highway and Transportation Safety Administration (NHTSA) released a study titled "Helicopters in Emergency Medical Systems: Experience to Date." This study stated that the use of helicopters in urban settings was not realistic and had little or no advantage over ground-based EMS systems. In 1981, a second report was released by the NHTSA titled "Air Ambulance Guidelines," in which Willis Winert, MD, indicated that air ambulances were improperly equipped to handle critically ill or injured patients and were nothing more than flying taxis with removable seats. This statement prompted Federal Aviation Association (FAA) regulators to demand better equipment and specially trained crews for air ambulances.

Since the development of air medical programs, the helicopter has been the obvious choice as an air ambulance owing to its ability to land and take off without an airport. Although it was met with much criticism regarding the effectiveness for transporting critically ill and injured patients, the development of

such a system has occurred in great leaps and bounds. With the help of special technologies, providers trained at the intensive care unit level can now deliver care in the transport environment.

Today, there are more than 650 air medical programs in the United States, each with specially trained flight crews. Because of the intensive training they receive and their high level of experience, flight teams are allowed by most medical practices to perform more sophisticated procedures than their prehospital and hospital counterparts.

Figure 1-9 outlines the history of ground and air transport.

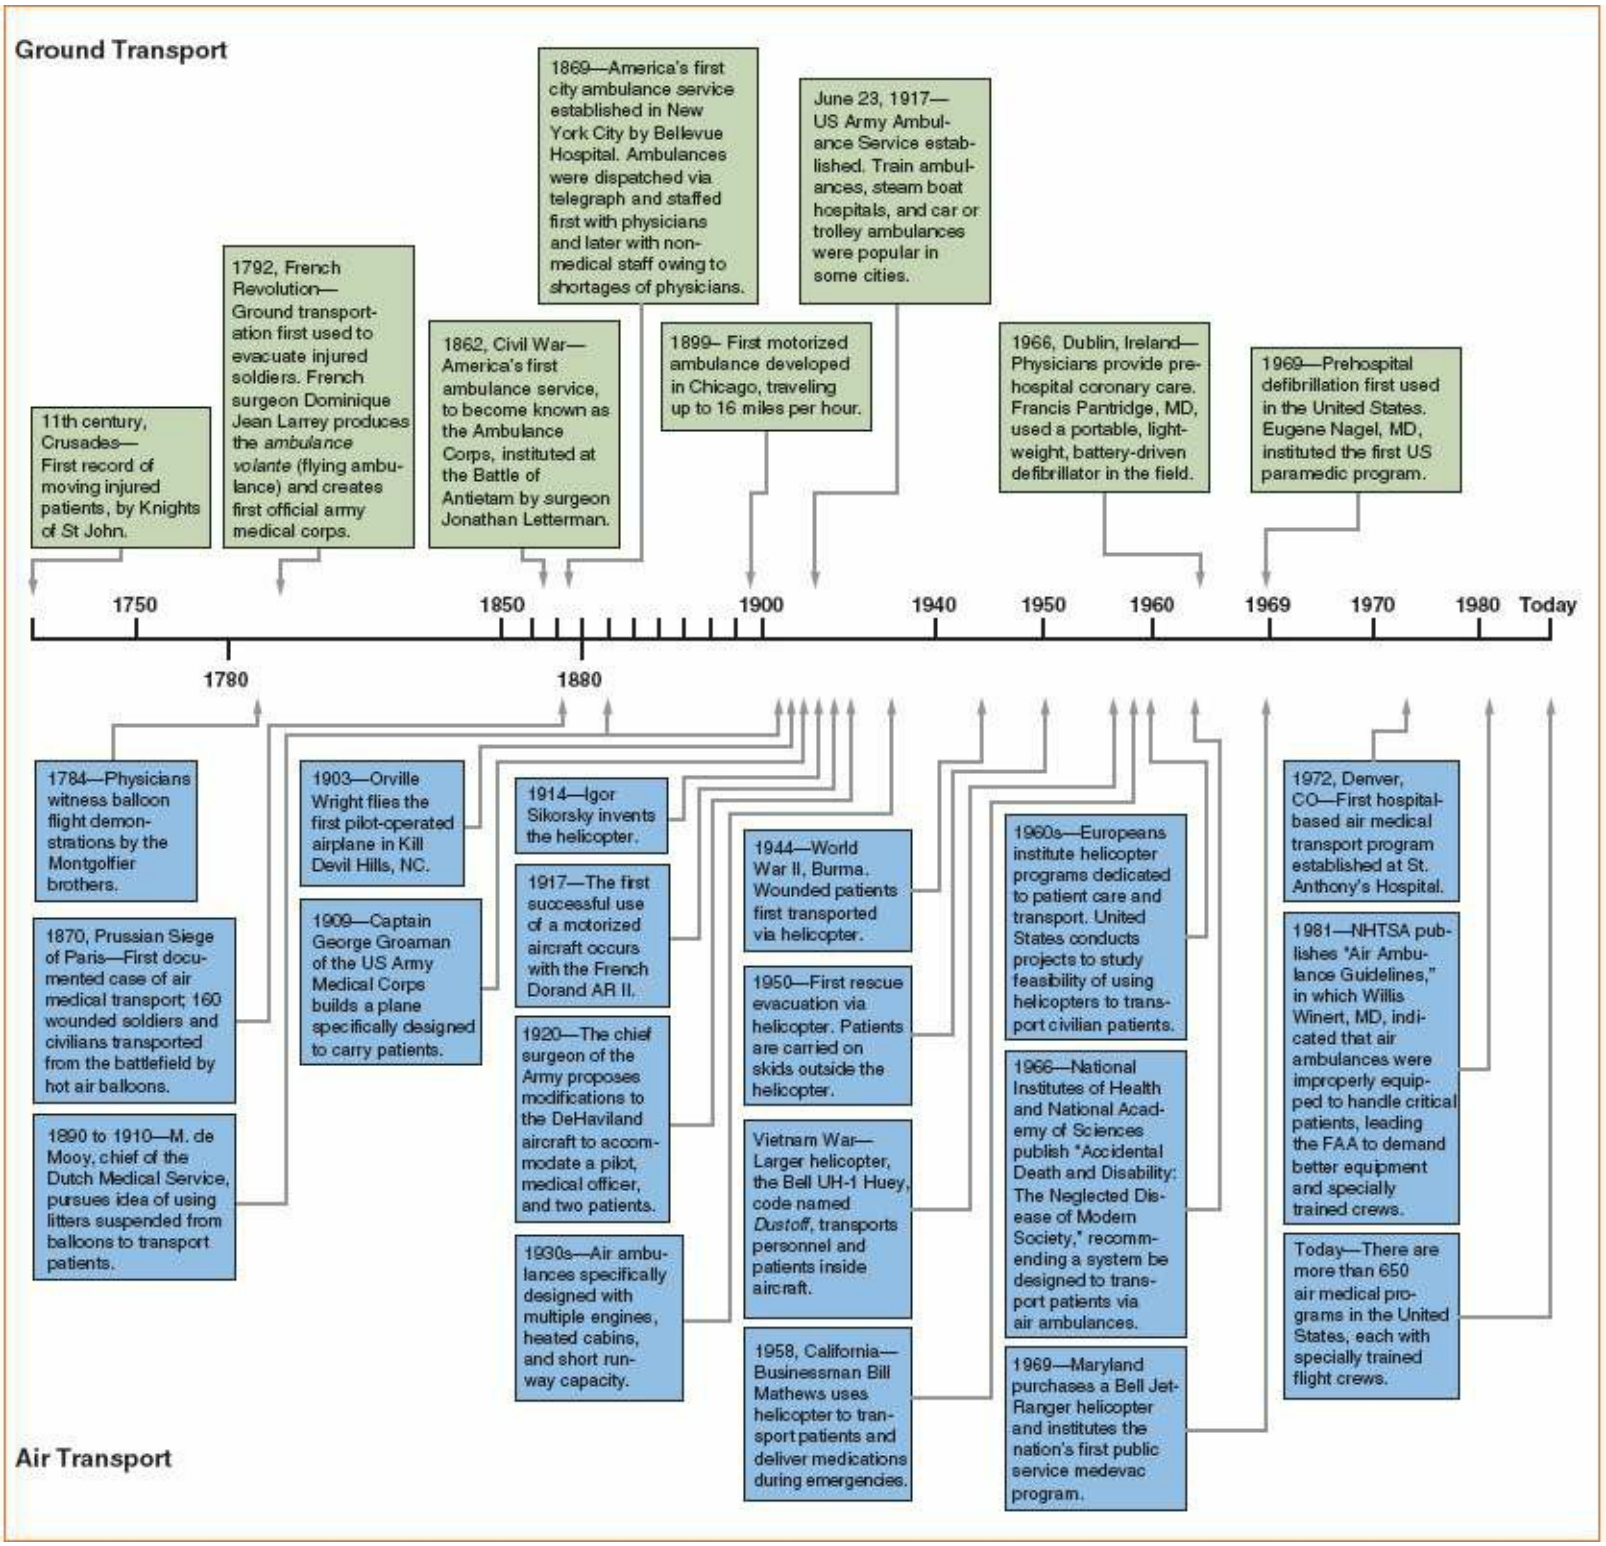

Figure 1-9 Timeline of the history of ground and air transport.

Critical Care Team Composition and Qualifications

The type of crew configurations varies as much as the types of ambulances and helicopters used throughout the United States. Whether in the air or on the ground, the configuration of the critical care transport team depends on the staffing policy of the organization. The combination of physicians, nurses, paramedics, and EMTs on critical care transport teams varies **Figure 1-10**.

The most commonly used combinations of health care professionals are as follows:

- Nurse and paramedic
- Nurse and respiratory therapist
- Nurse and physician

It is important to understand that this is not a comprehensive list, but rather the most commonly seen configurations. Other *less* common configurations include the following:

- Paramedic and physician
- Nurse, respiratory therapist, and physician

Figure 1-10 The critical care team composition varies but often includes a physician, a nurse, and a paramedic.

Additional crew members, including **perfusionists**, neonatalogists, or pediatric intensivists, may be required for certain patients in flight.

The three-team-member configuration is used but is less common because of the increased costs of adding an additional staff member. Most patients requiring transport do not have a condition with the acuteness that would necessitate a third team member.

As much as crew configurations vary, so do the recommended educational qualifications for each of the team members. CCTPs must be able to provide care at the same level and in many cases, at a greater level, than their non–critical care transport counterparts. In addition, CCTPs must be educated and skilled in the use of advanced practice procedures, such as surgical airways, blood product administration, pericardiocentesis, escharotomies, intracranial pressure monitoring, intra-aortic balloon pump therapy, central line and chest tube monitoring, monitoring arterial pressure lines, adult intraosseous infusion, and the use of ventilators and possibly portable ultrasound, which may fall outside of their formal medical education.

Emergency Medical Technicians

An EMT is trained at the basic life support level and frequently fills the role of ambulance driver. This position requires a recommended 150-hour program based on the EMT National EMS Education

Standards. EMTs' employers and the states in which they work may mandate additional requirements. An emergency vehicle operator's course (EVOC) is highly recommended. Finally, an EMT driver is also expected to maintain current certification and proficiency in CPR in order to assist the crew when necessary.

Paramedics

Paramedics must complete a course based on the Paramedic National EMS Education Standards encompassing 1,200 hours of didactic and clinical time, in addition to proving competency in all areas of study. They must also have an average of 5 years' experience in a busy 9-1-1 EMS system. Specialty certifications and verifications must also include courses in basic, advanced, and pediatric life support; basic and prehospital trauma life support; and a sanctioned critical care transport class.

Registered Nurses

Registered nurses must have attended an accredited nursing program, passed a state licensing examination, and have experience in one or a combination of the following areas: critical care, emergency care, and prehospital care. It is also recommended that they have specialty certifications and verifications in numerous areas, including flight medicine; emergency medicine; mobile intensive care; critical care; and advanced, pediatric, and neonatal life support. Finally, it is recommended that they have completed a variety of nationally recognized trauma care courses.

Respiratory Therapists, Perfusionists, and Physicians

Respiratory therapists, perfusionists, and physicians can function as regular members of the critical care transport team or as temporary members as needed. Respiratory therapists and perfusionists must attend and graduate from an accredited program and pass a national accreditation examination before practicing. They may also be subject to the qualifications and certifications required by the state in which they practice. The qualifications and certifications for physicians vary widely and are mandated on a state-by-state basis.

Modes of Transportation and Their Differences

Modes of transportation vary widely from agency to agency and by region of the country. The determination of the optimal transportation mode is dictated by patient acuteness, distance between sending and receiving facilities, weather conditions, and topography of the region. The standard types of **mobile intensive care units** used for critical care transports include mobile or ground units, rotor-wing aircraft, and/or fixed-wing aircraft. Commonalities among these transportation modes include standard equipment **Table 1-2**, the ability to accommodate the need for specialty equipment **Table 1-3**, and advanced medical training among their providers.

Mobile Units

Mobile (ground) units, also known as ambulances, are generally used to transport critically ill or injured patients up to distances of 50 miles from the patient's location to the receiving facility. A mobile unit may also be used when a patient has contraindications for air transport. These vehicles are available in many body types and sizes to suit the needs of the specific provider.

Rotor-Wing Aircraft

Rotor-wing aircraft, also known as helicopters, are used to transport critically ill and injured patients in rural settings and can travel distances of up to 150 miles. A wide variety of helicopters are available for use, including the BK 117, Bell Model 220/230, Sikorsky S-76, AgustaWestland AW109, and the Dauphin **Figure 1-11**. These helicopters can be single or twin engine and have the capability of loading patients from the side or the rear of the aircraft. As with ambulances, the size and type of helicopter varies by program needs and the area serviced.

TABLE 1-2 Standard Onboard Medical Equipment*

Fixed and portable suction units
Invasive monitoring devices
Arterial line kits and pressure monitoring capability
Pulmonary artery catheters
End-tidal carbon dioxide measurement devices
Oxygen
Pulse oximetry
IV infusion pumps
Portable Doppler machines
Electrocardiographic monitor and defibrillator
Transcutaneous pacemaker device
Autosyringe pumps
Central venous line kits
Chest tubes
Needle and surgical cricothyrotomy supplies
Ventilator
Intubation and airway equipment
Fluid warming device
Point of care (POC) testing for blood gases, glucose, hematocrit, and chemistries
Various medications
Indwelling urinary catheter kits
Ostomy management equipment
Peripheral IV supplies

*Varies based on state law and accreditation organizations.

TABLE 1-3 Specialty Equipment
Neonatal isolette
Portable intra-aortic balloon pump
Ventricular assist device
Extracorporeal membrane oxygenation support device

Fixed-Wing Aircraft

Planes or **fixed-wing aircraft** are capable of transporting critically ill or injured patients a distance of 150 miles or more. These aircraft models can range from the Cessna to Learjet and are often used in combination with mobile critical care units, which transport patients to the aircraft site **Figure 1-12**.

Dispatch

Having an organized and competent staff of emergency dispatchers is an integral part of the critical care transport team. Depending on the situation, the dispatch center may be located within a hospital or at a remote, independent site. Regardless of the scenario, the initial triage process starts with the call taker. A standard handwritten form is typically completed by the call taker, as information about the patient and his or her condition is obtained from the referring facility. Examples of pertinent information that should be obtained from the referring facility are as follows:

Figure 1-11 Various types of helicopters include some of those shown. **A.** BK 117. **B.** Bell Model 206. **C.** Sikorsky S-76. **D.** AW109. **E.** Dauphin. Part C: © Sikorsky Aircraft Corporation 2009. All rights reserved. Used with permission of Sikorsky Aircraft Corporation.

Figure 1-12 Fixed-wing aircraft are used for longer transports. **A.** Cessna. **B.** Challenger 604A.

- Patient age
- Patient weight
- Diagnosis
- Number and type of infusions
- Most recent vital signs
- Level of consciousness
- Airway status (patent or intubated)
- Presence of mechanical ventilation
- Presence of cardiac-assist devices

Although this list does not include all information needed about the patient, it does provide dispatch center personnel adequate information for proper decisions. Once this information has been obtained, a clinical supervisor should be involved to decide on the crew configuration and the mode of transportation. In many cases, the attending physician and staff at the referring facility suggest the particular mode of transportation that they believe is necessary. Many critical care transport services honor their request, whereas others make their own determination based on the patient report provided.

Another factor that needs to be considered by dispatch center personnel is the type of call. A critical care transport team should be dispatched and used for patients with any of the following situations:

- Mechanical ventilation
- Vascular access devices
- Vasoactive medications
- Colloid infusions (ie, blood, plasma, or platelets)
- Cardiac-assist devices (ie, intra-aortic balloon pump, extracorporeal membrane oxygenation, or ventricular-assist device)
- Instability requiring frequent interventions such as sedation, paralytics, and/or analgesia

If a situation arises in which a service is asked to transport a patient who requires one of the aforementioned cardiac-assist devices, a certified perfusionist may need to be part of the team to manage and monitor the devices. CCTPs remain responsible for all other aspects of patient care during transport.

Transporting by Ground vs Air

Each mode of transporting critically ill and injured patients has its own set of advantages and disadvantages. **Table 1-4** lists some of the advantages and disadvantages of each mode.

The decision to transport a patient by ground ambulance or helicopter is a decision that must be made as rapidly as possible. In most cases, the patient needs expedient transport to the tertiary care center to receive the care not available in the present location. Helicopters enable more rapid transport than ground vehicles because they can bypass vehicular traffic, intersections, and stop lights, which delay the total transport time. Although a helicopter travels much faster than a ground ambulance, it may not be the most practical solution for transporting a patient to the tertiary care center. Helicopters are usually strategically located throughout a geographic area. Depending on the location of the referring hospital, the helicopter may need lengthy travel time to reach the patient. In a situation like this and if a critical care ground ambulance is significantly closer, the most reasonable solution may be ground transportation.

The acuteness of the patient's condition is one of the major determinants of whether ground or air transportation is needed. The determination is typically made by the referring physician, who is ultimately responsible for patients until they are transported out of the referring facility. Time-sensitive conditions that may require air transport include:

- Acute myocardial infarction
- Acute cerebrovascular accident
- Severe traumatic injury
- Acute intracranial hemorrhage
- The need for emergency surgery (ie, abdominal aneurysm, limb reattachment)

TABLE 1-4 Advantages and Disadvantages of Transportation Modes

Transportation Mode	Advantages	Disadvantages
Mobile (ground) unit	• Large interior • Quieter than aircraft • No special housing needed • Less expensive to operate and maintain • Less specialized training needed to operate vehicle (emergency vehicle operator course) • Multiple provider capabilities • Less weather dependent • Fewer height and weight limitations • Fewer adverse effects on patient and crew	• Usually limited to single-patient transport • Slower than aircraft • Limited travel distance
Rotor wing (helicopter)	• Speed (100–180 mph) • Specialized personnel and technology needed or provided • Few altitude ramifications below 2,000′ • Can serve a larger portion of the community	• Restricted by weather conditions • Interior space limitations • Expensive to operate and maintain • Special landing requirements • Need for FAA communications • Adverse effects on crew

	• Two-patient capabilities	members and patients • Expensive to patient • Requires special housing • Limited space for providers and equipment • Weight limitation
Fixed wing (plane)	• Speed • Multiple patient capabilities • Capable of traveling great distances • Specialized personnel and technology needed or provided • No weight limitation • Instrument-assisted flying	• Adverse altitude considerations • Adverse effects on patient and crew • Need for FAA communications • Expensive to patient • Expensive to operate and maintain • Can only serve a small portion of the community • Requires special housing • Special landing requirements
Abbreviation: FAA, Federal Aviation Administration.		

The list is not all-inclusive, and many other conditions and situations warrant air medical transport. Each case must be individually evaluated, and the determination should be made after all data have been reviewed.

The thought process for determining the mode of transportation is relatively simple; however, certain unpredictable occurrences might preclude use of the first choice. For example, a clinical coordinator could decide to transport a patient by helicopter or fixed-wing service, but weather issues may prohibit the flight. An alternative method must be identified so the patient will arrive at the accepting facility within a reasonable time. Sending a ground unit may be more harmful to the patient due to the extended return time to the accepting facility. In most such cases, the decision is made to wait for the weather to improve and launch the aircraft as soon as is practical. When the distance from the referring facility to the accepting facility is not that great, CCTPs may choose to complete the mission by ground.

Medical Control

There are varying levels of medical control, or medical direction, within any given critical care transport system. The first type is protocols, which allow CCTPs to initiate or maintain certain therapies and treatment without contacting a command physician. The protocols in a critical care transport setting are typically much more aggressive and give CCTPs the opportunity to perform these tasks without contacting online medical control. The second type is online medical control in which CCTPs take part in a real-time interaction with a medical control physician. This task is typically accomplished through telephone or radio communications **Figure 1-13**. The degree of medical guidance provided relies solely on the type of assistance needed. An example in which a CCTP might need to consult with online medical control is

during the transport of a ventilator-dependent patient who experiences hypercarbia. If the local protocol does not allow CCTPs to titrate ventilator settings, online medical control must be contacted immediately to obtain orders for corrective action. This type of guidance must continuously be available to CCTPs, regardless of the given situation.

Figure 1-13 Online medical control involves working directly with a medical control physician via phone or radio.

Interfacility Transport

Part of the responsibility of EMS includes interhospital transfers. The continuum of care during transfer is expected to be maintained at the level at which it originated. **Specialty care transport (SCT)** is the term used by the Centers for Medicare and Medicaid Services (CMS; formerly the Health Care Finance Administration, or HCFA) to define the ground transportation and medically necessary supplies and services for critically ill or injured patients. SCT is a level of interfacility service established to provide these services, which are beyond the scope of practice for providers not trained at the CCTP level. SCT is considered one step above the level of advanced life support transfers because it involves patients in more critical condition, requires the use of specialized equipment, and necessitates additional training or education for registered nurses and paramedics.

Along with using the services of the SCT companies, many facilities are preparing transfer teams to assist in these transports in an effort to provide continuous bed-to-bed care. As the acuteness of the patient's condition increases, the critical care transport team is often supplemented with staff from the sending or receiving facility. This supplemental assistance allows incorporation of health care services with EMS services. The interfacility transport is dependent on collaborative rapport among all team members, in addition to staff and physicians at the referring and receiving facilities.

State and National Standards

Standards vary from state to state; however, most critical care transport programs follow national standards. Some states, such as Maryland, require any air medical service that operates in the state to be certified by the Commission on Accreditation of Medical Transport Services (CAMTS). However, more often than not, a state organization governs the licensure of air medical services and their practitioners. For example, in Pennsylvania, the Department of Health licenses air medical transport services and prehospital care providers. An individual CCTP's scope of practice also varies according to his or her level of certification and the state in which he or she practices. For example, registered nurses may administer any medication ordered by a physician, whereas paramedics may administer only medications

approved and listed on their state's prehospital drug list. The most accurate information on governing organizations and scope of practice is available from the state agency responsible for EMS accreditation and licensure.

Reimbursement Criteria

HCFA was developed in 1977 with the sole purpose of overseeing the Medicare and Medicaid programs. Now, as CMS, it serves 67 billion people and spends more than $230 billion each year on health care services. Its primary responsibility in the critical care transport field is to ensure that patients are taken to the closest appropriate facility. For example, consider a patient who has been diagnosed with an acute myocardial infarction at a local facility without interventional cardiology capabilities. Arrangements are made for transfer of the patient to a hospital with such capabilities, which is 50 miles away. A helicopter is called to transport the patient to this facility for balloon angioplasty; the patient spends 2 days as an inpatient. During billing review by CMS staff, it is determined that the helicopter passed over a hospital 20 miles closer and offered the same cardiac capabilities. This is significant because most air medical transport services charge $50 to $70 per loaded mile. In this situation, Medicare would reimburse for a total of 30 miles instead of 50, which totals $1,000 or more that would not be reimbursed.

Well-Being

The same tenets of well-being in EMS apply to well-being for the CCTP. Proper nutrition, weight control, and a regular exercise program are important.

Shift work can affect a person by disrupting his or her circadian rhythm. These effects and the effects of fatigue are discussed in Chapter 4.

Stress

Working in the fast-paced environment of critical care transport poses unique stressors on the body. *Stress* can be defined as the wear and tear bodies experience during adjustment to the activities of daily life and the environment. Stress is a normal feeling that affects people differently. It is capable of causing positive and negative feelings. Positive stress can heighten awareness of a situation or provide new perspectives, whereas negative stress can cause negative feelings such as depression or anger.

Like other health care providers, CCTPs are susceptible to burnout. Burnout is a consequence of chronic, unrelieved stress. While these stresses may be legitimate, how a person reacts to them can help alleviate the stress. Avoiding perfectionist beliefs can help reduce stress. Symptoms of impending burnout include:

- Chronic fatigue and irritability
- Cynical, negative attitudes
- Lack of desire to report to work
- Emotional instability
- Changes in sleep patterns, or waking without feeling refreshed
- Feelings of being overwhelmed, or being helpless or hopeless
- Loss of interest in hobbies
- Decreased ability to concentrate
- Declining health—frequent colds, stomach upsets, or muscle aches and pains

- Constant muscle tightness
- Overeating, smoking, or abusing drugs or alcohol

Because CCTPs work in proximity to controlled substances, substance abuse can easily become a way of dealing with negative stress when overwhelmed. Be alert to signs of substance abuse among colleagues. Signs and symptoms of substance abuse are wide and varied. Some classic signs include:

- Sudden change in behavior or becoming secretive
- Frequent absences from work or difficulty carrying out usual responsibilities
- Impulsive behaviors and lack of self-control
- Physical symptoms such as dilated or constricted pupils, needle marks, and red eyes

CCTPs must be cautious and not jump to conclusions if colleagues have one or more of the aforementioned signs. CCTPs should report suspected substance abuse to their supervisor, who will follow the program's policies and procedures for managing the situation.

Finally, the CCTP will encounter critical incidents (those that overwhelm the CCTP's ability to cope, either at the scene or later). It is standard practice for EMS systems in the United States and abroad to deploy specially trained teams to conduct critical incident stress debriefings (CISDs) with emergency personnel who have been involved in particularly traumatic calls or other painful incidents. A CISD is usually held within 24 to 72 hours of the incident. The sorts of incidents that are apt to require debriefing include:

- Serious injury or death of a fellow worker in the line of duty
- Suicide of a colleague
- Multiple-casualty incidents
- Serious injury or death of a child
- Intense media attention to an incident

Safety Gear

Appropriate safety gear and clothing are necessities for every member of the critical care transport crew. CCTPs should ensure that the appropriate safety gear (PPE, N95 mask, etc.) and clothing are properly and consistently worn **Figure 1-14**. At a minimum, safety gear should meet the following criteria:

- Clothing should fit properly and be flame retardant. Clothing should include a uniform or flight suit, outerwear such as a coat or vest, and undergarments. Clothing should never be tight or loose fitting.
- Clothing should be layered for proper ventilation and heat regulations. Long-sleeved shirts and pants limit water loss and exposure.
- Head and eye protection should fit snugly and meet or exceed Occupational Safety and Health Administration specifications.
- Leather boots should be worn to protect feet against the elements and fire. Flame-retardant gloves should be worn to protect the hands against the elements and fire.
- Uniforms should have reflective materials or striping to increase nighttime visibility of CCTPs at crash scenes.

Figure 1-14 Proper safety gear and clothing, including snug-fitting head and eye protection, leather boots, and flameretardant gloves. Layers should be worn underneath the uniform and for additional protection. If involved in scene transports, the CCTP uniform should also include reflective material or striping.

Interpersonal Communication

Communicating properly and effectively with patients and families is of utmost importance. Most acute illnesses are not predictable or expected. When they occur, all parties involved experience tremendous fear and anxiety. No matter how acutely ill a patient is, each member of the critical care transport team must make every effort to communicate intentions to the patient and family. Communication starts with an introduction of each team member. These simple introductions help comfort patients and families. When family members desire, they should be in the room when the team assesses the patient.

When preparing to depart with the patient, family members should be given time to speak briefly with the patient, and questions they have should be answered. Requests for a brief prayer by members of the clergy or others should be honored. Although every second counts when transporting critically ill or injured patients, the brief moments for family involvement have effects that words cannot describe.

Death and Dying

Because of the severity of the conditions of the patients with whom CCTPs interact, death and dying are a regular part of the job. Not only will CCTPs interact with seriously ill and injured patients, but they will also interact with the patient's family members who are in various stages of the grieving process. CCTPs should be familiar with Elisabeth Kübler-Ross' five stages of grieving, summarized in **Table 1-5**. CCTPs must realize that these stages will not necessarily occur in the order listed. Also, not all people experience all stages, although they will experience at least two.

TABLE 1-5 Five Stages of Grieving by Kübler-Ross

Stage	Description
Denial	The person cannot believe what is happening.
Anger	The person asks, "Why me?" or thinks, "It's not fair."
Bargaining	The person wishes to live for a certain amount of time, for example to see a child marry.
Depression	The person is sad and feels that nothing matters.
Acceptance	The person comes to peace with the issue and accepts the outcome.

When communicating with critical care patients and their families, CCTPs should follow the same principles as in any other professional health care setting: Listening provides comfort to patients and families, shows empathy, and provides helpful data for effective care. Telling patients and families that the best possible care will be provided offers realistic reassurance and promotes confidence.

Quality Assurance and Improvement

Quality assurance and improvement (QA&I) programs are an essential part of the overall health care system in the United States. The primary function of a QA&I program is to generate data to be used to improve the quality of service provided. A QA&I program is an integral component of a successful critical care transport program. CCTPs are regularly charged with providing advanced care to the "sickest of the sick," often in uncontrolled, unpredictable environments. An effective QA&I program serves as a check and balance system to protect stakeholders.

Once financial and human resources are devoted to a QA&I program, the first step is to define quality. Many critical care transport programs use their mission statement to define what quality means to their stakeholders. Once defined, measurable indicators of quality must be established and baseline data must be obtained.

The second step is to collect and analyze data. Data can be obtained from various sources. Most critical care transport programs obtain data, at a minimum, from patient charts, dispatch records, and customer feedback surveys. Once data are obtained, they must be analyzed for meaning and application to the program's goals, objectives, and indicators of quality.

The third step in the QA&I process is focused on improving quality, which requires analysis of the data and development of an understanding of underlying issues. For example, if an audit of patient charts reveals that several CCTPs are incorrectly documenting the use of transport ventilators, and analysis of the reason for incorrect documentation reveals a lack of knowledge, a continuing professional education course on effective documentation for ventilator-dependent patients can be conducted. The QA&I program should direct the continuing professional education for transport program staff

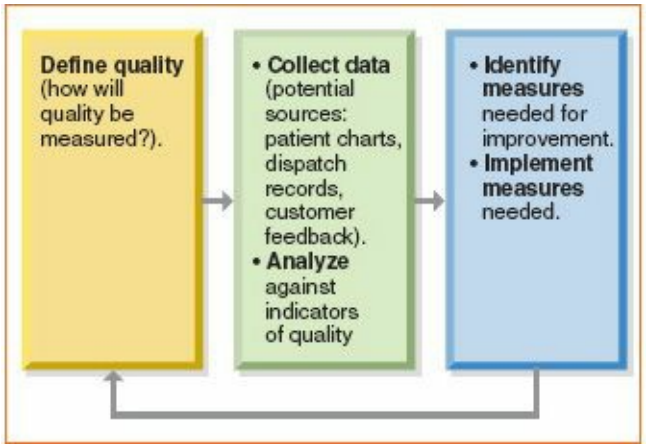

Figure 1-15 The three components of the quality improvement process: defining quality, collecting and analyzing data, and determining and implementing measures to improve quality.

Continuing Education

Critical care medicine is a dynamic, ever-changing science that requires CCTPs to be lifelong learners. Most critical care transport programs require CCTPs to complete frequent continuing professional education classes, which exceed the requirements to maintain the state or national certification and/or licensure necessary for employment. Most critical care transport services hold a variety of mandatory educational and competency training days each year. Topics include review of uncommonly used advanced procedures, skill and competency validation, case studies, and cutting-edge clinical information.

Summary

Much attention has been given to specialty care and critical care transports since the establishment of reimbursement fees by Medicare. As the health care system continues to evolve, so must CCTPs and the agencies providing transports.

Despite the extensive amount of training necessary to become a member of a critical care transport team, clinical care is only one of the many aspects to evaluate when considering how stakeholders perceive quality. Excellence in clinical care is not a "nice to have" but an expectation. CCTPs must remember that a "routine trauma case" to CCTPs is most likely a life-changing event for patients and families. With this in mind, CCTPs must look and act in a professional manner at all times. In addition, CCTPs must use effective communication skills in interactions with patients, families, and other health care providers.

Case Study

AFTER 1 WEEK OF GENERAL PROGRAM ORIENTATION, your first day of duty as a flight paramedic finally arrives. After the morning safety briefing, your preceptor takes you to the helipad to review the aircraft safety and procedures that you learned at the general orientation program. As you make your way back to the base, you hear the klaxon alerting system and the radio say, "Medevac 1 stat page scene run town of Martins Ferry, Belmont County, Ohio." You check with your preceptor and the pilot to see if the flight can be accepted. Once the determination is made to accept the flight, you pack the blood and make your way back to the helipad to complete your preflight checklist.

In flight, your communications center advises that you are responding for a 28-year-old patient who was in an all-terrain vehicle (ATV) crash in a remote area. Ground EMS reports that the patient was an

unhelmeted operator of an ATV that hit a tree head on.

On landing at a remote landing zone, you are transported by a fire department unit to the crash scene. You find your patient lying supine on the ground with obvious head, abdominal, and leg injuries. He responds only minimally to pain and has decorticate posturing. His vital signs are as follows: Glasgow Coma Scale (GCS) score, 7; blood pressure, 190/100 mm Hg; pulse rate, 68 beats/min; and respirations, 8 breaths/min, assisted by ground providers with a bag-mask device. Attempts at oral intubation were reportedly unsuccessful owing to clenched teeth. You and your preceptor quickly determine that the first thing needed is to obtain definitive control of the airway. Your preceptor directs you to establish an intravenous (IV) line of normal saline solution and begin administering drugs according to the rapid-sequence intubation (RSI) protocol. Once the IV line has been established and the drugs prepared, you check your calculations with your preceptor and then administer the appropriate doses of lidocaine, etomidate, and succinylcholine. Your preceptor swiftly places an endotracheal tube and begins manual ventilation while you attach a capnography monitor and confirm tube placement as per protocol. You then administer the appropriate doses of vecuronium and fentanyl. Your preceptor tells you that he will oversee immobilization of the patient and transportation to the aircraft while you contact medical control for ventilator settings for the 25-minute transport to the trauma center. You contact medical control via cellular telephone and are lucky enough to get the program's medical director, command physician 1, and report:

> *"This is Medevac 1. We are currently loading a 28-year-old, 90-kg, male patient, who was the unhelmeted operator of an ATV that hit a tree head on. On arrival, the patient had a GCS score of 7. We used RSI and intubated him orally. Our flight time is 25 minutes, and we need ventilator settings."*

Physician 1 asks several questions about the mechanism of injury and then tells you to set the ventilator at a tidal volume of 900 mL, rate of 14 breaths/min, and a fraction of inspired oxygen (FIO_2) of 100% with +5 of positive end-expiratory pressure (PEEP). You repeat the orders and thank the physician and approach the aircraft, where your preceptor just loaded the patient for transport. The transport ventilator is set up and the patient is "connected" according to the ordered settings.

In flight, you monitor your patient's vital signs, including end-tidal carbon dioxide levels, and administer additional vecuronium and fentanyl as necessary to effectively maintain paralysis and sedation. On arrival at the trauma center, you do a "hot" off-load (unloading the patient without shutting down the aircraft) and transport the patient to the trauma bay, where you give your report to the trauma team. You and your preceptor clean your equipment and get the aircraft back in service. Once you return to base, you complete the patient's medical chart and notify the referring EMS agency. As you and your preceptor are discussing the call and completing your postflight orientation report, the program medical director calls and says he needs to talk about your medical consult report.

1. What are the components of a daily safety briefing?
2. What additional pertinent information should you request from dispatch?
3. What additional information should you have provided to online medical control?

Analysis

The safety briefing should include the daily plan, crew member duties, equipment and aircraft issues, weather expectations, and emergency situations. Safety is an integral part of each shift. Team members must be familiar with the inherent occupational safety risks and procedures in order to protect patients and themselves. Critical care transport teams should hold daily safety briefings at the beginning of each scheduled shift.

Although sometimes information may be limited from crews at a hectic scene, if possible, CCTPs should ascertain the patient's level of consciousness, airway status, and most recent vital signs. Effective interpersonal communication skills are essential to the success of CCTPs. In this case, greater details from the dispatch center would have allowed the CCTPs to be better prepared to provide the appropriate level of care and ensured that all necessary equipment was taken to the crash scene. Specifically, as much information as possible should be obtained from ground crews about the patient's level of consciousness and airway to allow for preparation of RSI equipment and drugs. If the need for RSI and the patient's weight are available en route, drugs can be prepared in the correct doses to allow expeditious airway control on arrival at the scene.

In the field, CCTPs are the physician's eyes and ears and must provide a detailed report. In this case, the medical control physician should have been provided with the mechanism of injury, current vital signs, capnography reading, medications administered, assessment findings, and any other pertinent information about the medical history. Detailed reports to the medical control physician allow for the receiving facility to have necessary equipment and personnel available to care for the patient on arrival.

Prep Kit

Ready for Review

- Critical care transport is the provision of medical care to a critically ill or injured patient during ground or air transport.
- CCTPs include EMTs, paramedics, nurses, physicians, and specialty health care personnel such as respiratory therapists and perfusionists.
- CCTPs must be able to provide care at the same or sometimes greater level than their non–critical care counterparts.
- CCTPs must be educated and skilled in the use of advanced practice procedures that may fall outside of their formal medical education.
- Ground and air transport have evolved along with changes in transportation and technology.
- Crew configurations vary as much as the types of ambulances and helicopters. The configuration depends on the staffing policy of the organization. The most common configurations are nurse and paramedic, nurse and respiratory therapist, and nurse and physician.
- Additional crew members, including perfusionists and neonatal or pediatric intensivists, may be required for certain patients.
- Modes of transportation may vary widely by agency and by region of the country. Possible modes of transport include mobile or ground units, rotor-wing aircraft, and fixed-wing aircraft.
- The mode of transport to be used is dictated by patient acuteness, distance between sending and receiving facilities, weather conditions, and topography of the region.
- Mobile or ground units (ambulances) are generally used to transport critically ill and injured patients up to distances of 50 miles from the patient's location to the receiving facility.
- Rotor-wing aircraft (helicopters) are used to transport critically ill and injured patients in rural settings and can travel distances of up to 150 miles.
- Fixed-wing aircraft (airplanes) are capable of transporting critically ill and injured patients a distance of 150 miles or more.

- Dispatch personnel obtain pertinent information about patients and their condition from the referring facility. A clinical supervisor then helps determine crew configuration and mode of transportation.
- A critical care transport team should be dispatched and used for patients with any of the following: mechanical ventilation, vasoactive medications, colloid infusions, cardiac-assist devices, and unstable conditions requiring frequent interventions such as sedation, paralytics, and/or analgesia.
- Although a helicopter travels much faster than an ambulance, in some cases, a ground ambulance may be located significantly closer to the patient and, therefore, is the preferred mode of transport.
- Patients with the following time-sensitive conditions are typically transported by air: acute myocardial infarction, acute cerebrovascular accident, severe trauma, acute intracranial hemorrhage, and the need for emergency surgery.
- Weather issues may prohibit a flight from taking place. Usually, a decision is made to wait for the weather to improve and launch the aircraft as soon as practical.
- Air transport programs are typically hospital based with many hospitals sharing the responsibility and costs of that service. Air transport programs can also be provided by public service agencies or private services.
- The basic concept of a critical care transport service is to rapidly transport CCTPs to a patient, stabilize the patient's condition, and transport the patient to a tertiary care center as rapidly as possible.
- Patients should be evaluated and assessed for the effects of altitude and other forces that can adversely alter their conditions en route.
- Medical control within critical care transport systems includes protocols and online medical control. Protocols in a critical care transport setting are typically much more aggressive than in other aspects of prehospital care.
- Standards vary from state to state; however, most critical care transport programs follow national standards. Usually a state organization governs the licensure of air medical services and their practitioners.
- An individual CCTP's scope of practice varies according to his or her level of certification and the state in which he or she practices.
- The CMS ensures that patients are taken to the closest appropriate facility. This organization performs billing reviews and determines whether the patient was taken to the closest facility with the necessary capabilities. Medicare and Medicaid make reimbursement decisions based on the CMS assessment.
- Appropriate safety gear and clothing are necessities for every member of the critical care transport crew and include layered clothing with reflective materials and flame resistance, head and eye protection, and leather boots.
- Interpersonal communications are as important in critical care transport as in other health care settings. CCTPs should introduce themselves to patients and family members and maintain professionalism and a caring demeanor.
- Quality assurance/improvement programs are an essential part of the overall health care system. Most critical care transport programs obtain data from patient charts, dispatch records, and process customer feedback surveys.

Vital Vocabulary

critical care Constant, complex, detailed health care as provided in various acute life-threatening conditions; the ability to deal with crucial situations rapidly and with precision using various advanced machines and devices for treating and monitoring the patient's condition.

critical care patient Any patient who experiences an actual or potential life-threatening illness or injury that requires continual monitoring and care by a specially trained physician, registered nurse, or paramedic.

critical care transport The transport of a patient from an emergency department, critical care unit, or incident scene during which the patient receives the same level of care as was provided in the hospital or originating facility.

critical care transport professional (CCTP) A health care professional who has successfully completed a recognized critical care program and meets the minimum qualifications set forth by the employing transport program.

fixed-wing aircraft Airplanes; these are capable of transporting critically ill and injured patients a distance of 150 miles or greater.

mobile intensive care units Ambulances or helicopters that are used only for maintaining specialized or intensive care treatment; used primarily for interfacility transports.

morbidity An illness or an abnormal condition or quality; the rate at which an illness occurs in a particular area or population.

mortality The condition of being subject to death; the number of deaths per unit of population in any specific region, age group, disease, or other classification.

perfusionists Highly trained technicians who are intimately familiar with the operation of intra-aortic balloon pumps and adult and pediatric extracorporeal membrane oxygenation machines and who may assist during any medical situation, including critical care transports, in which it is necessary to support or temporarily replace a patient's circulatory or respiratory function.

rotor-wing aircraft Helicopters; these are used to transport critically ill and injured patients in rural settings and can travel distances of up to 150 miles.

specialty care transport (SCT) The term used by the Centers for Medicare and Medicaid Services to define ground transportation and medically necessary supplies and services for critically ill and injured patients.

Medical-Legal Issues

Authors

Leah J. Heimbach, JD, RN, EMT-P

Alan J. Azzara, Esq, EMT-P

Objectives

1. Discuss the Emergency Medical Treatment and Active Labor Act (EMTALA), its implications for critical care transport, and the potential consequences of violating the law (p 22).
2. Describe how the transport provider's certification level and scope of practice affect the steps of planning and executing a critical care transport (p 25).
3. Recognize and discuss patient rights and the legal risks and liabilities they pose in critical care transport (p 26).
4. Describe the legal principles of consent, negligence, and abandonment (p 26–28).
5. Discuss the major steps and pertinent issues in accepting a patient transfer (p 30).
6. Discuss the major steps and pertinent issues in assessing and preparing for transfer of a patient (p 30).
7. State the responsibilities of CCTPs during transport (p 31).
8. State the role of other health care providers who accompany the patient during transport (p 32).
9. Discuss the ways in which communications capabilities and agreements about medical direction affect medical decision making in the transport environment (p 30).
10. Discuss the major steps and pertinent issues in transferring care to the receiving facility (p 33).
11. Identify areas of potential liability for CCTPs and the transport agency (p 26).
12. State how risks can be minimized in the critical care transport environment (p 32).
13. Discuss the general concepts established by current EMTALA case law (p 22).

Introduction

Legal considerations are a constant presence in health care. One way for caregivers to reduce their level of concern about legal action is to give diligent attention to the various elements contributing to the quality of care they provide: skills maintenance, continuing education, protocol familiarity and compliance, and interpersonal communications, among others.

In addition, care providers have to devote a certain amount of attention to remaining familiar and complying with the laws and regulations that govern their practice. These include federal laws that apply across all American jurisdictions and state and local requirements that differ considerably from one area to another.

This chapter reviews general legal principles and specific laws that affect CCTPs. It concludes with discussions of specific cases that have helped clarify federal law on the subject.

The Emergency Medical Treatment and Active Labor Act

Interfacility transport is the main responsibility of a critical care transport service, whereas scene

transports are less common. The number of interfacility transports has risen dramatically, as demonstrated by the increase in the number of critical care transport services established throughout the United States and the increased interest in critical care transport training courses. It has become a crucial and specialized component of EMS. Interfacility transport comprises an ever-increasing portion of the calls for many EMS agencies and results in a great deal of income. With the evolution of specialized interfacility transport come additional areas of legal liability, most of which relate to negligence (discussed later in this chapter).

Many interfacility transport agencies have evolved as services provided by hospitals, although a substantial and ever-increasing number of such transports are handled by non–hospital-based services. Transporting critically ill or injured patients is a complex process and requires the cooperation of all entities involved. Hospitals that participate in Medicare reimbursement programs are subject to the **Emergency Medical Treatment and Active Labor Act (EMTALA)**, so personnel who perform interfacility transports need to be familiar with EMTALA and how it applies to them. The addition of EMTALA, enacted as part of the Consolidated Omnibus Budget Reconciliation Act (COBRA) in 1986, was initially designed to prevent financially motivated transfers of patients in unstable condition. EMTALA is also known as the "antidumping act" because its primary focus is to add safeguards to prevent facilities from selecting the most favorable patients (capable of paying for their services) and transferring patients who are unable to pay. Although EMTALA is intended to regulate hospitals and the manner in which they conduct transfers, EMS providers involved in these transfers must be familiar with the law.

EMTALA requires all medical facilities that receive Medicare funding to choose "qualified personnel and transportation equipment" for each patient transferred in unstable condition. But because COBRA neither defines qualified personnel nor transportation equipment, it was left up to others to do so in an effort to determine guidelines for such transfers.

To comply with EMTALA, a hospital has certain obligations to the patient that must be met. These include the following:

- Provide an appropriate medical screening examination within the capabilities of the hospital to any individual who presents to the hospital, using all available resources to determine whether an emergency condition exists. It is important to understand that a screening examination is different from triage and must involve several basic elements that include a triage record; initial vital signs; oral history; physical examination; use of appropriate diagnostic resources to determine if an emergency condition exists; use of on-call physicians, if necessary; and discharge vital signs. All of the foregoing must be documented. The screening examination should be conducted by a physician or, if properly designated by the hospital, a mid-level provider such as a physician's assistant or nurse practitioner.
- Provide such treatment as may be required to stabilize the condition if an emergency condition is found or transfer the patient to another medical facility with specialized capabilities not available at the first hospital in accordance with other sections of the law. For purposes of EMTALA, an emergency condition is deemed to exist if the following exists:
  - The patient has acute symptoms that could reasonably be expected to result in serious impairment or serious dysfunction of any organ or part, or
  - In the case of a pregnant woman having contractions, there is inadequate time to safely transfer the patient to another hospital.

  It is important to note that an interfacility transfer requires the consent of the patient or a legal representative. In some cases, when the patient is incapable of providing consent and no legal representative is available, a transfer may occur without consent. (A more detailed discussion of

the transfer requirements is given later in this chapter.)

A hospital is subject to EMTALA when the patient comes onto hospital property. The scope and further refinement of EMTALA are ongoing as cases are tried in courts all over the United States; for example, one case's judgment indicated that EMTALA is not triggered until the patient presents to the hospital's emergency department. This legal evolution has had substantial impact on EMS agencies that provide interfacility transport. For example, there are specific portions of EMTALA that require "qualified personnel" and "appropriate equipment" for each transport. More recent findings indicate that hospital property includes ambulances owned by the hospital, even if the ambulance is not on hospital grounds.

The use of helicopters and the implications of EMTALA have been the subject of much interest in recent years. The *State Operations Manual*, published by the US government's Centers for Medicaid and Medicare Services, describes the circumstances under which helicopter use will and will not trigger the provisions of EMTALA:

- If a hospital-owned helipad is used by a local EMS as a pickup point for the transport of a patient to another hospital, the provisions of EMTALA will not apply.
- If the flight or EMS crew requests the intervention (examination or treatment) of the hospital's physician, the provisions of EMTALA will most likely apply.

Consequences of Violating EMTALA

First, it is necessary to understand that EMTALA is clearly intended to regulate and apply to hospital and physician conduct and was never intended to apply to the EMS community. The exception to this rule is when an ambulance or helicopter is owned by a hospital. For purposes of EMTALA, a patient is considered to have "come to a hospital" if the ambulance is owned by the hospital and the patient is in the ambulance for purposes of examination and treatment.

If a hospital or physician is found to have violated the provisions of EMTALA, several possible penalties may be imposed. These include the following:

- A hospital may be fined between $25,000 and $50,000 per violation.
- A physician may be fined up to $50,000.
- A hospital or physician may be terminated from the Medicare and Medicaid programs.
- A patient may commence civil litigation against a hospital or physician for injuries arising out of an EMTALA violation.

The fact that a non–hospital-based ambulance service may not be subject to the provisions does not mean that it cannot be held accountable for injuries arising out of an EMTALA transfer. The patient may file a claim for negligence, as described more fully later in this chapter.

EMTALA Case Law

This summary of current EMTALA case law includes implications for interfacility transport. Because more and more cases are being decided, interfacility implications may become more far-reaching. As mentioned, the intention and purpose of EMTALA were to prevent hospitals from "dumping" patients for inability to pay. Because EMTALA is a federal statute, cases are most appropriately filed in federal court, which differs from a medical malpractice action, a form of negligence filed in state court.

There are many EMTALA cases that have bearing on critical care transport. Specific judgments made in particular EMTALA cases include the following:

- EMTALA is not a substitute for malpractice action.
- Emergency stabilization is not long-term.
- The plaintiff has the burden of proof.
- A patient can be transferred, even if in unstable condition, if the benefits of transfer outweigh the risks.
- Stabilization relates to available capabilities.
- The patient must present to the emergency department (ED) to trigger EMTALA.
- The patient must have an emergency condition.
- Transfer by ambulance is not required.
- Radio medical control does not invoke EMTALA.
- The physician has an obligation to "certify" transfer.
- Active labor requires treatment.

These examples of lessons learned from EMTALA cases can give CCTPs an idea of the implications of EMTALA and how this law can play out in the critical care transport setting. The following are examples of the specific judgments in the preceding list.

Transfer Benefits vs Risks

Barris v. County of Los Angeles, 70 Cal. Rptr. 2d 281 (1997). (Note: This case also limits the damages that a plaintiff can collect for personal injury to that available under state law.)

On May 6, 1993, an 18-month-old girl was taken by ambulance to the ED of King/Drew Medical Center. The patient was a member of the Kaiser Foundation Health Plan but was not taken to a Kaiser participating hospital. Instead, she was taken to King/Drew, the nearest emergency medical facility. She was lethargic and had vomiting, diarrhea, difficulty breathing, and a temperature of 106.6°F. The physician in the pediatric ED of King/Drew noted signs and symptoms of sepsis. He contacted a Kaiser physician, who told the King/Drew physician that Kaiser would treat the patient.

Kaiser has a program called Emergency Prospective Review Program that facilitates patient transfer when a member is brought to a non-Kaiser facility for emergency care. At 7:00 PM, Dr Dang, the King/Drew physician, spoke with Dr Thompson, the Kaiser physician, to arrange transfer. Dang expressed concern that certain blood tests should be performed at King/Drew to rule out sepsis but was instructed by Thompson not to do the tests. At 8:00 PM, the patient had a seizure and became lethargic and nonresponsive. At 9:00 PM, she was transferred to Kaiser. Within 15 minutes, she arrested and died.

The plaintiff (the patient's mother) sued Dang and Thompson, the county, and Kaiser for professional negligence and EMTALA violations. Her EMTALA claim was failure to provide appropriate screening and stabilization of patient condition before transfer. The jury returned a verdict for the plaintiff of $1.35 million. The superior court ruled to cap the EMTALA portion of the claim and the professional negligence action. It reduced the award to $250,000, the maximum allowed under state law. The plaintiff appealed, but the court of appeals and the state supreme court affirmed the decision. However, it should be noted that hospitals and physicians could receive a separate penalty under EMTALA of up to $50,000 for each violation.

This case demonstrates that it is not necessarily inappropriate to transfer a patient whose condition has not been stabilized. EMTALA states that a patient can be transferred, even if in unstable condition, if the benefits of transfer outweigh the risks.

"Stabilization" Relates to Available Capabilities

Cherukuri v. Shalala (DHHS), 175 F.3d 466 (6th Cir. 1999).

On September 15, 1991, five patients were brought by ambulance to the ED at Appalachian Regional Hospital (ARH), South Williamson, KY. Two had serious internal injuries and head injuries. The hospital had no trauma center or equipment for monitoring anesthesia during brain surgery and had a long-standing policy of not performing neurosurgery on brain injuries. ARH had always transferred patients with these types of injuries to larger hospitals with the expertise to deal with them.

Dr Cherukuri, a general surgeon, was on call. He arrived and treated the five patients for several hours. On stabilizing their blood pressure and other vital signs, he transferred the two seriously injured victims to a hospital in Huntington, WV. One patient died during the transfer, and the other survived.

The Department of Health and Human Services (DHHS) fined Cherukuri $50,000 for each of the two transfers. This is the largest penalty imposed against a physician in the history of EMTALA. They claimed Cherukuri could have performed surgery and "stabilized" the conditions of the patients because an anesthesiologist was willing to "put the patients to sleep." Cherukuri appealed the decision; DHHS denied the review. He then appealed it to the Sixth Circuit Court of Appeals.

The circuit court dismissed the fine and all EMTALA charges against Cherukuri. In doing so, the court of appeals looked to the Act, which states that a patient whose condition has not been stabilized may be transferred (1) only on "a certification that based upon the information available at the time of transfer, the medical benefits reasonably expected from the provision of appropriate medical treatment at another medical facility outweigh the increased risk to the individual … from effecting the transfer" and (2) only if "the receiving facility… has agreed to accept the transfer of the individual and to provide appropriate medical treatment."

The court found that Cherukuri did not violate the stabilization provision of EMTALA. Stabilization requires an objective standard of reasonableness based on the situation at hand and "requires merely that a hospital stabilize patients within the staff and facilities at the hospital." The patient must be evaluated and, at a minimum, provided with whatever medical support services and/or transfer arrangements that are consistent with the capability of the institution and the well-being of the patient.

Radio Medical Control Does Not Invoke EMTALA

Johnson v. University of Chicago Hospitals, 982 F.2d 230 (5th Cir. 1994).

During February 1990, the defendant hospital (UCH) served as the resource facility for the South Chicago Mobile Intensive Care System. UCH's responsibilities included providing telemetry communications to ambulance paramedics and this, in turn, required UCH to direct paramedics transporting emergency patients to the appropriate hospital in the system. On February 2, the plaintiff, a 1-month-old girl, stopped breathing. Her mother called 9-1-1. Chicago Fire Department paramedics arrived and began treating the infant. Because she remained in cardiac arrest, the paramedics contacted UCH. Although they informed UCH that they were only 5 blocks from UCH, they were instructed to go to a second hospital because UCH was on "partial bypass." She was treated at the second hospital but was subsequently transferred to a third hospital with a pediatric intensive care unit. She died sometime after her transfer to the third hospital.

The mother filed suit against UCH alleging four counts, including violation of EMTALA. The lower court dismissed this count because the plaintiff failed to allege that the infant actually *came to* the emergency department at UCH. The plaintiff appealed, and this court also found that the plaintiff never came to UCH or its emergency department. Nothing in the language of EMTALA—or in the legislative history that has been cited—suggests that an extension of EMTALA would create a duty in a telemetry operator that would be actionable under the present facts. Accordingly, EMTALA liability is not invoked.

Physician Obligation to "Certify" Transfer

Burditt v. U.S. Department of Health and Human Services, 934 F.2d 1362 (5th Cir. 1991).

A mother who was near term with her sixth child arrived in the emergency department of DeTar Hospital at 4:00 PM. She was experiencing 1-minute, moderate contractions every 3 minutes, and her membranes had ruptured. Two nurses examined her and found a dangerously high blood pressure. The mother had received no prenatal care and had no means of payment. One nurse notified Dr Burditt, who was next on the rotating call list. Burditt stated that he "didn't want to take care of this lady" and asked the nurse to prepare the mother for transfer to another hospital, 170 miles away. The two examining nurses notified the nursing supervisor and the hospital administrator of their belief that it was not safe to transport the mother. Burditt called back and was told by an examining nurse that he was legally required to examine her and personally arrange for transfer.

This same nurse asked for an order to administer magnesium sulfate ($MgSO_4$) to prevent seizures. He told her that she could, only if the mother could be transported by ambulance afterward. At 4:50 PM, Burditt arrived and confirmed her blood pressure to be 210/130 mm Hg. He knew there was a strong possibility that the mother's blood pressure would precipitate complications that might kill the mother and the baby and that infants of hypertensive mothers are at higher-than-normal risk of intrauterine growth retardation. He estimated the baby to weigh less than 6 lb—less than normal weight. Still, he obtained acceptance at the second hospital, started $MgSO_4$ treatment, and instructed an examining nurse to arrange the transfer. She attempted to show him the EMTALA regulations, but he refused to read them. The nurse insisted that he sign a Physician Certificate Authorizing Transfer, which he did. He stated that "until DeTar Hospital pays my malpractice insurance, I will pick and choose those patients that I want to treat."

Burditt did not reexamine the mother, although he was there to witness her being wheeled to the ambulance. The mother delivered a healthy baby in the ambulance approximately 40 miles into the 170-mile trip and was taken to a nearby hospital for oxytocin administration to reduce bleeding. While there, the transport nurse telephoned Burditt to inform him of the birth. He instructed her to continue transport. Despite the physician's orders, the accompanying nurse returned to DeTar Hospital, where Burditt refused to see the mother. He directed that the mother be discharged if she was in stable condition and not bleeding excessively. A DeTar official pressed Burditt to allow another doctor to examine the mother. The mother stayed at DeTar for 3 days and left in good health.

DeTar Hospital had executed a Medicare provider agreement and, so, was obligated to treat the mother in accordance with EMTALA. In mid-1988, the Inspector General of the US DHHS demanded a $25,000 civil penalty from Burditt for violations of EMTALA. On appeal, an administrative law judge reduced the fine to $20,000. The Department of Appeals Board upheld the fine. Burditt appealed this decision. Burditt contended that he stabilized the mother's emergency medical condition by administering $MgSO_4$.

The court held that he could not have stabilized the mother's condition unless he provided treatment that medical experts agree would prevent the threatening and severe consequences of the mother's hypertension during transit. Burditt also contended that there was adequate time to safely transfer the mother to the second hospital before she delivered—that she was not in active labor. The court held, based on expert testimony, that this was not so.

Burditt testified that he was completely ignorant of the EMTALA requirement for the Physician Certificate Authorizing Transfer certifying that the benefits outweigh the risks of transfer. He said he signed the certificate just so he could transfer her. The court upheld the board's decision that the certification was so unacceptable that it is unlikely that Burditt actually made the required certification. Finally, Burditt contended that he sent the mother with the appropriate equipment and qualified personnel. The court said that the obstetric nurse and two EMTs were qualified to deliver the baby in the absence of complications. But it is undisputed that they were unqualified to perform a cesarean section or treat the other complications that could have developed as a result of the hypertension.

Responsibilities of CCTPs

The refinement of EMTALA has far-reaching implications that make CCTPs responsible to minimize risks associated with interfacility transport. This chapter examines the role of CCTPs in that setting, the performance of appropriate transfers, and ways to minimize legal risks.

Legal Practice Constraints for CCTPs

Specializing in interfacility transport can be challenging and rewarding. It can be challenging because you most often transport critically ill and injured patients and rewarding because of the satisfaction gained by ensuring that the patient receives excellent care. The downside of any profession, especially professions related to health care, is that the potential for litigation looms over each decision. The provision of emergency care, no matter what the setting, is governed by civil law—as opposed to criminal law **Table 2-1**—and consists of laws (statutes) and regulations originating from a number of legal sources **Table 2-2**.

TABLE 2-1 Law Types

Type	Basis
Civil	The law of civil or private rights as opposed to criminal law; two major areas—torts (civil wrongs) and contract law
Criminal	The body of law that defines offenses against society at large

Laws are usually general and include things such as the **scope of practice** and definitions of EMS provider "classes." Regulations, which are more specific, govern the types of procedures that can be performed in certain circumstances, the training required for initial licensure or certification, and the requirements for relicensure or recertification.

CCTPs can be sued by anyone, even if they perform appropriately. However, the burden of proof is on the person bringing the lawsuit (the plaintiff). Defending yourself in litigation can be expensive. Therefore, be certain to review your employer's malpractice insurance policy to ensure that the coverage extends to interfacility transports. Most states require employers to provide certain minimum amounts of malpractice insurance coverage for employees and volunteers of the organization. Most likely, your employer will provide malpractice insurance to cover CCTP actions *within the scope of employment;* these policies will not cover emergencies that you respond to on your own time. However, these policies usually are written to protect the interests of the employer (because they pay the insurance premiums). In all probability, this employer-provided insurance is more than sufficient to cover your actions within your work.

On the other hand, if you have your own insurance, it will frequently provide an attorney to represent you and your interests. A problem may arise if your insurance company and your employer's insurance company both provide attorneys and the two disagree about how to defend the case. This could create a situation in which you and your employer try to put the focus of liability on each other.

Whatever the decision, to obtain your own insurance or rely on the employer's, educate yourself on your state's requirements for malpractice insurance, your employer's policies about malpractice, and your risks.

Functioning as a CCTP requires special skills and knowledge. CCTPs also have significant legal responsibility to patients, the medical director, and the public. The scope of practice for CCTPs is limited

to skills taught in the program that resulted in advanced-level licensure or certification and any additional skills defined by state law or regulation. Additional skills may be incorporated into the scope of practice through protocols and standing orders. Exceeding the scope of practice (performing skills that you may know how to do but are not permitted by law or regulation), even if it would help the patient, could result in litigation and loss of licensure or certification.

TABLE 2-2 Law Sources

Source	Description
Constitutional	Governmental (federal or state) law based on the constitution
Statutes	Codifications established by government (Congress and the state legislatures)
Regulations	Rules or orders having the force of law issued by an executive authority of government; agencies created by state government often empowered to enact regulations (such as state EMS offices)
Common law	Law derived from judicial decisions rather than from statutes or the constitution

Figure 2-1 Transport practice takes place under the supervision of a medical director.

CCTPs need **medical direction** to practice. Medical direction occurs two different ways. **Online medical control** occurs by telephone or radio, and **off-line medical control** is in the form of approved standing orders or protocols. The ultimate responsibility for the action or inaction of a CCTP rests with the medical director **Figure 2-1**.

Finally, CCTPs have significant legal and ethical responsibility to the public to function competently. Regular skill performance, ranging from maintenance following the initial licensure or certification period to expert mastery of the skill, helps meet this responsibility. Attending continuing education and refresher programs helps ensure maintenance of adequate skill levels. Participation in case review sessions, to identify methods of improving patient assessment, treatment, and team communications, is another important component of practice.

The Patient's Rights

Several general areas of liability can arise in the provision of transport, most of which stem from violation of the patient's basic rights. These violations include assault, battery, false imprisonment, and

negligence.

The Right to Establish Advance Directives or Do Not Resuscitate Orders

To withhold resuscitative efforts, you must have a written order from a physician. If there is a question about the status of a **do not resuscitate (DNR) order**, always err on the side of providing resuscitation rather than withholding it. State laws regarding DNR orders vary substantially. Be familiar with the laws in your state.

The Right to Self-Determination

The right to refuse treatment, a basic right of all patients, is based on a fundamental concept: every person of adult age and sound mind has a right to determine what is done or not done to his or her body. Providing care without this **consent** puts CCTPs at risk of liability for **assault** or **battery**, even if the care is necessary to save the patient's life.

Figure 2-2 Explaining the need for treatment and the risks of refusal may persuade the patient to consent.

If the patient refuses care, you must explain the possible consequences. Patients who refuse treatment may be afraid or in emotional distress. Attempting to calm them with rational explanations and reassurance may lead to consent. If the patient persists in refusing treatment, follow local protocol, which will include thorough documentation and, possibly, contacting **medical control**.

To minimize legal risk, explain to the patient what may be wrong, the treatment that is indicated and why, and the consequences that may result without the treatment. Urge the patient to obtain medical care with a personal physician. When possible, encourage a family member to stay with the patient until the patient agrees to seek care or the condition resolves **Figure 2-2**. Attempt to obtain signatures on the EMS record from the patient and witnesses verifying that the patient is refusing care or transport. Thorough documentation should include the patient's history, your physical findings (including indications of the patient's mental **competence**), the stated reasons for refusing treatment, and any explanations or advice you have given to the patient or family members.

The patient also has the right to terminate treatment at any time—before or after transport is initiated. To refuse treatment, the patient must be mentally competent and of legal age. Refusal can be expressed verbally or nonverbally. Examples of nonverbal refusal are pulling away, making gestures, and using the hands to bar your access to equipment or the patient's body. However, you should still ask if the patient is actually refusing care.

Transporting a patient against his or her will can lead to **tort** actions for **false imprisonment**, assault, and/or battery. In some circumstances, criminal charges could result, although this situation is

rare. Give special consideration to patients who may be impaired by the influence of alcohol or drugs, may exhibit suicidal tendencies, may have signs of a head injury, or are not behaving normally according to family members because they may not be able (competent) to make rational decisions. In these situations, seek assistance from hospital personnel and online medical direction. In general, restraint and transport against a patient's will constitute a rare circumstance that could occur after a patient had been determined not competent to make health care decisions. If usual resources cannot or will not assist, carefully consider the potential liability for false imprisonment, balanced against the medical necessity of treatment and the risk that the patient may harm himself or others.

Authority to consent for or refuse treatment for a minor (even against the minor's wishes) rests with the custodial parent or legal guardian. If the parent or legal guardian refuses care, then proceed as you would with an adult patient who refuses care. Several states have enacted laws that mandate reporting any case in which a parent or legal guardian refuses emergency care for a minor. In that case, a court may order care to be provided, require verification that it has been given, or order an investigation to determine whether a child is still in need of treatment.

The Right to Consent

Consent must be obtained before proceeding with treatment or transport. Consent can be express or implied, and the rules for minors vary in cases of emancipation.

Informed (Express) Consent

To consent to treatment, the patient must be of legal age and sound mind. In some states, consent is not informed unless the patient is given the following information: (1) the procedure to be performed, (2) risks of the procedure, (3) any alternatives to the procedure, (4) risks of the alternatives, and (5) likely outcomes or risks if the procedure is not performed.

In general, consent must be obtained for any medical treatment, including transport. For consent to be effective, it must be informed. However, in some situations, a CCTP may provide treatment and transport under the doctrine of implied consent (discussed next). The legal responsibility for obtaining **informed (express) consent** most often rests with the physician. Most procedures associated with transport do not require an informed consent discussion with the physician, but the consent must be obtained, or health care personnel providing treatment are at risk of civil and/or criminal actions. The act of transferring a patient in unstable condition to a specialty center may require (by EMTALA) a discussion between the physician and the patient and written documentation of the risk–benefit analysis of the transfer or the patient's request for transfer.

Implied Consent

Implied consent is an exception to the rule of informed consent. Implied consent is the assumption by law that a patient who is unconscious or for some reason unable to express consent would want to receive lifesaving treatment **Figure 2-3**. Implied consent has been extended to include children who have a life-threatening condition, when the parent or legal guardian is not available. Some states also consider implied consent to apply to situations in which the patient is mentally ill, emotionally disturbed, or developmentally disabled. To implement the doctrine of implied consent, the patient must have a true emergency condition—a significant risk of death or the possibility of serious injury or illness.

Figure 2-3 The unconscious patient is considered to give implied consent to treatment and transport.

Special Populations

Although legislation varies in different areas, in most states, a pregnant teenager is "emancipated" during her pregnancy and can make all legal and medical decisions for herself and her unborn baby. However, the minute she delivers the baby, she once again assumes "minor" status, and her parents or legal guardians make all of her medical and legal decisions. She does, however, remain the legal guardian for her baby and can make all medical and legal decisions for her child (even though she cannot make them for herself).

Emancipation

One additional consideration must be given to a nuance in some states' laws—obtaining consent for treatment from emancipated minors. A minor child is emancipated by decree in a court of law. **Emancipation** can be sought by the child or the parent. The child gives up the right to maintenance and support from the parent, and the parent (or guardian) relinquishes the right to control the child. Minors are often emancipated because they get married. The same may hold true for a minor child who becomes pregnant, although pregnancy in and of itself does not constitute emancipation. State law may allow an emancipated minor to give consent for treatment or to refuse it. Emancipation may also occur "by operation of law." This means that certain events or actions can automatically result in emancipation without petitioning the court. For example, in some states, the marriage of minors automatically emancipates them. Furthermore, in some states, service in the armed forces also automatically emancipates minors.

The Right to Receive Care Without Interruption

The patient has the right to receive uninterrupted care. A CCTP could be held liable for **abandonment** if care is interrupted. Some examples of abandonment include the following:

- Initiating care and then leaving the patient or turning the patient over to someone who does not have sufficient training to provide care in the current situation.
- Leaving the patient unattended for a brief period, if the condition worsens or the patient sustains additional injury.
- Failing to transfer information to the receiving facility regarding the patient's history, treatment, or current condition, if the failure results in further injury or harm.

- Failing to respond to or complete an ambulance call.
- Failing to immediately report one's inability to complete an emergency response because of equipment failure or one's own health status.

The Right to Appropriate Care

The patient has a right to appropriate care. "Appropriate" means that you are expected to have the same training, skills, and ability as other CCTPs and are expected to exercise reasonable care and diligence in applying the skills and knowledge in caring for patients. **Negligence** results when a CCTP fails to meet this standard of care. To prove negligence, the plaintiff must prove all four elements of the claim:

1. CCTPs have a **duty to act** when they or their employer have incurred a legal obligation to provide patient care. This duty can be established formally, when the transport service has contracted to provide emergency care to the citizens of a given geographic region. It can also be established when a CCTP initiates treatment and when the sending facility calls for a transport vehicle and the dispatch center confirms that it will be sent. States have different rules about other actions or situations that establish duty. One example is whether an off-duty CCTP (or other health care professional) has an obligation to treat someone. The majority rule is that an off-duty CCTP has no duty to stop and treat someone in need; however, a CCTP who begins to provide aid is obligated to ensure appropriate care without interruption.
2. A **breach of duty to act** can be proven by offering evidence that a CCTP did not conform to the standard of care by providing inappropriate care, failing to act, or acting beyond the scope of practice. A CCTP must act as a reasonable, prudent CCTP would in the same or similar circumstances.
3. **Damage** must result from the breach of duty. All states recognize physical injury resulting from a breach of duty as damage. However, there are differences in the way states treat psychological injuries. Many states do not recognize psychological injuries or recognize them only in limited circumstances.
4. The **proximate (direct) cause** of the injury must have resulted from a CCTP's actions or failure to act. For example, imagine that a cardiac patient who is being transported sustains injuries in an ambulance crash. If the driver of the ambulance is found to be at fault, the plaintiff will most likely be able to prove that the crash was the proximate cause of the injuries.

Some situations may exist in which there is no legal duty to act but in which an ethical duty is imposed. In some states, EMS personnel are not obligated to stop and provide assistance at the scene of a motor vehicle crash. However, there is a more compelling argument about the ethical duty to do so if the EMS personnel are in an ambulance and observe a crash.

The Right to Confidentiality and the HIPAA Privacy Rule

The patient has a right to expect that any information obtained in preparation for, during, or after transport will be kept confidential. Legal protection for this expectation was given with the implementation of the **Health Insurance Portability and Accountability Act (HIPAA)** of 1996. CCTPs must be especially familiar with the Privacy Rule portion. The HIPAA Privacy Rule obligates health care personnel to ensure that confidentiality of patient information is maintained. HIPAA is a federal law that was implemented by Congress and stemmed from concerns about the following:

- Electronic transmission of information
- Information crossing state lines with different laws

- Reports of violations of privacy in certain industries
- The volume of information available

The primary goals of HIPAA are to create consistent standards for protection of patient privacy and to increase patient rights and inform them of their rights while allowing state laws to be more protective. As a general rule, HIPAA applies to "covered entities," which include health care providers who transmit information electronically, health plans, and health care clearinghouses. It requires enhanced security and privacy protection for **protected health information (PHI)**, establishment of patient rights and use of a privacy notice, implementation of policies and procedures, discipline for breaches and violations, and training for all personnel of the covered entity.

For EMS providers, the most important aspects of HIPAA are related to disclosures of PHI. In most states, the state law is more stringent than federal law. Federal law allows state law to control when the requirements are the same or more stringent. Therefore, most cases that would violate HIPAA are brought under state law. In many cases, state civil and criminal sanctions are more severe than those under federal law.

There are potential legal consequences for violating HIPAA, including civil penalties (fines) of up to $250,000, criminal penalties, and personal liability. A covered entity is responsible for its own personnel. When its employees or agents violate HIPAA, the covered entity must take appropriate disciplinary action such as providing additional training, formal warning, suspension, or even termination. In addition, violation can result in the patient filing a complaint to the Office of Civil Rights and subsequent investigation.

The Privacy Rule protects the confidentiality of PHI. PHI includes individually identifiable information (such as name, social security number, and date of birth), health information (such as laboratory results and medical history), and demographic information (such as address and telephone number). It is important to note that HIPAA protects PHI in *any* form whether it is written, verbal, or electronic. A criminal violation occurs when a provider knowingly discloses PHI for a purpose not permitted under HIPAA and with the intent to use the PHI for personal gain. Note the "knowingly" standard for criminal prosecutions. This means that inadvertent disclosure will not bring criminal sanctions; however, civil sanctions may still result.

There are situations when it is permissible to disclose PHI. Disclosure can be made without written authorization of the patient or legal representative for purposes of treatment, payment, and other health care operations. Disclosure for treatment purposes includes situations in which PHI is shared in the process of providing health care, coordinating health care among providers, referring a patient from one provider to another, and coordinating a patient's care or other services with third parties. Disclosure of PHI is also permitted (without specific written authorization) when dealing with payment issues, including determining coverage of health benefit claims, billing, claims processing, reviewing health care services (such as medical necessity, coverage, and appropriateness), and when a covered entity is undertaking utilization review activities. Finally, a covered entity may disclose PHI in the course of performing other health care operations, such as quality assessment and improvement, evaluating performance of its health care providers, and performing general administrative functions such as conducting audits.

Other than for treatment, payment, and other health care operations, a covered entity may disclose PHI when the patient or the patient's legal representative provides authorization, in response to an *appropriately executed* court document compelling release of the PHI (such as a court order) or when required by law (such as to report child abuse). Depending on state law, a patient's legal representative may include a custodial parent of a child, a family member or next of kin, a legal guardian, or a person with medical power of attorney. There are other situations in which PHI may be disclosed but may be

impacted by variances in state law, such as when it is required by state law (eg, elder abuse or a wound resulting from violence), is pursuant to a state health oversight function, involves activities related to organ donation, and is for the purpose of averting threats to public health or safety.

HIPAA Case Law

The following is an example of a civil case related to EMS that violated HIPAA and that was brought under state law.

Pachowitz v. LeDoux, 2003 WL 21221823 (Wis. App., May 28, 2003) decided under Wis. Stat. § 895.50.

On April 21, 2000, four EMS personnel, including volunteer EMT Katherina LeDoux, responded to a 9-1-1 call at the Pachowitz residence for a possible overdose. The patient, Julie Pachowitz, was transported to Waukesha Memorial Hospital at her husband's request. LeDoux had not met Pachowitz before.

Approximately 2 weeks earlier, LeDoux had learned from her friend, Sally Slocomb, that Pachowitz, a work colleague, had a medical condition. After the emergency call, LeDoux, believing that Slocomb and Pachowitz were close friends, spoke to Slocomb about having transported Pachowitz. LeDoux testified that she called Slocomb because she was concerned about Pachowitz and thought Slocomb could help Pachowitz. Slocomb then drove to West Allis Memorial Hospital where she and Pachowitz worked. There, she discussed Pachowitz's emergency call with staff.

Pachowitz later filed suit against LeDoux and was awarded $3,000 in compensatory damages and $30,460 in attorney fees.

The Patient's Fundamental Rights

Under the HIPAA Privacy Rule, patients have five fundamental rights that are briefly but separately addressed:

1. Patients have the right to inspect and copy their medical records. Patients have the right to inspect their medical records, although the covered entity can require sufficient notice to make it available and, in many situations that vary with state law, charge patients for copies of their record.
2. Patients have a right to request restrictions to what is disclosed when the covered entity releases PHI. There are situations in which the covered entity does not necessarily need to honor this request but should consider doing so. If the covered entity grants this request, there are other requirements for compliance with the HIPAA Privacy Rule.
3. Patients have a right to request that amendments be made to their medical records; however, there are specific requirements for this process and rules that apply when the request is granted.
4. Patients have a right to request confidential communications. Patients can, for example, request that information regarding their care be sent to an alternative location other than their home address.
5. Patients have a right to request an accounting of disclosures. This request requires the covered entity to track disclosures of PHI that are made and unrelated to treatment, payment, or other health care operations.

A covered entity has specific responsibilities to comply with the HIPAA Privacy Rule. These include the following:

- Ensuring that the patient or legal representative is offered a copy of the organization's Notice of Privacy Practices at the first patient encounter. The notice must be offered once. Some EMS agencies have adopted a practice of simply mailing a copy of the notice to patients following transport if they are unable to indicate their desire to receive the notice owing to illness or injury.

- Training staff (and students affiliated with the organization) in the Privacy Rule.
- Developing and implementing policies and procedures to ensure compliance.
- Monitoring compliance of its employees and agents.
- Responding to concerns or complaints.
- Providing appropriate discipline for violations.
- Retaining HIPAA-related records for at least 6 years.

There are several practical aspects for ensuring compliance with the HIPAA Privacy Rule. For example, CCTPs should ensure that telephone communications are not overheard, especially when discussing PHI. With fax communications, CCTPs should confirm the appropriate fax number before sending a document, include a fax cover sheet that clearly states the name of the intended recipient, and confirm that the fax is received by the appropriate person.

In honoring a patient's right to confidentiality, CCTPs should ensure that the patient or a legal representative signs a written authorization before any information can be released. If confidential information is released without authorization, the CCTP could be sued if the release results in injury to the patient's character, name, or reputation by false or malicious writings (libel) or by spoken words (slander), although laws regarding possible legal actions for breach of confidentiality vary from state to state. To minimize the risk of breaching confidentiality, CCTPs should relay communications about a patient's condition only to appropriate personnel and not release patient-identifying information over the radio.

Transport Preparation

Care History and Pretransport Condition

To prepare for transport, find out the nature of the transport (the patient's diagnosis and condition). Some agencies have established protocols that address the types of situations in which patients can be transported and the level of care provider needed in each situation. Once a patient has been accepted for transport, work efficiently to minimize the time spent and procedures performed at the sending facility. Before initiating transport, ensure the following:

1. The patient has a patent and secured airway.
2. The patient has patent and secured IV access, when indicated.
3. Appropriate measures are instituted to treat hemodynamic instability.
4. Chemical or physical restraint is used for confused or agitated patients who pose a threat to themselves or transfer personnel.
5. Appropriate monitoring is used as indicated, including cardiac rhythm, blood pressure, pulse oximetry, and end-tidal carbon dioxide.

Trauma patients should have appropriate spinal immobilization as indicated, including a long backboard, a cervical collar, and a cervical spine immobilization device.

Communication With the Health Care Team

When preparing for a transport, you should make every effort to communicate effectively, professionally, and succinctly with other members of the health care team. In some rare cases, conflict may arise between a CCTP and the sending physician regarding the interventions needed before transport. If this happens, state your concerns clearly and professionally. If there is still disagreement, contact the receiving

facility's physician to attempt a cooperative resolution. If the situation cannot be resolved, contact the critical care transport agency's medical director for assistance. The ultimate step may be to refuse to transport, but this step should be carefully considered. Although it may involve substantial additional legal risk, one other alternative is to begin transport and then consult with online medical direction about the most appropriate interventions.

Some requests for transport originate in a physician's office or clinic. The physician in this setting may not be familiar with local protocols. In this situation, thoroughly communicate capabilities and limitations to the sending physician. A plan of care must be developed that is within your scope of practice. If the physician is unwilling to do this, politely insist that the sending physician accompany the patient to the receiving facility. If this is not acceptable to the sending physician, proceed as outlined in the preceding paragraph or contact medical control for assistance in resolving the conflict. Consider having the sending physician speak directly with medical control to develop a plan of care for transport.

A patient's ability or inability to pay for the transport can also present a difficult situation for the transport agency. If the agency insists on payment without regard to clinical condition, awkward situations can arise but can be mitigated if the agency policy to refuse transport for people unable to pay is *clearly communicated in advance* to the sending facility. If a CCTP learns of an inability to pay only after arriving at the sending facility, refusing the transport can substantially increase the transport agency's liability risk, especially if adverse outcomes result from the delay in securing an alternative means of transport. Also, the agency may experience problems with its reputation in the community. Communicating clearly and concisely before agreeing to transport can help avoid this situation.

Transfer Preparation

In preparation for transport, obtain the pertinent patient information, including the following:

- The reason for transfer
- The name of the receiving hospital and/or physician
- Whether a BLS or an ALS provider must accompany the patient, in addition to the CCTP, and whether the sending facility plans to provide an escort
- Treatment provided at the sending facility
- Medical treatment and drug orders for the duration of the transfer
- Complications to anticipate

In addition, obtaining the name of the receiving physician before transport will serve to avoid unnecessary delay, embarrassment, and potential conflict at the receiving facility. There must be physician-to-physician contact before the transport is initiated.

Review the transport orders for treatment *before* leaving the sending facility. Ensure that the orders do not exceed your scope of practice. If they do, talk with the sending physician to modify the plan of care. If the plan cannot be modified, the sending facility must provide additional personnel to accompany you and facilitate the provision of needed care.

Patient Information

EMTALA requires that certain patient information be obtained from the sending facility and provided to the receiving facility. Although you can take reports from ancillary personnel (such as the nurse assigned to arrange transfer), you should also speak with the sending physician about the information needed.

Under EMTALA, the sending physician must send copies of medical records with the patient to the receiving facility. Failure to do so constitutes an EMTALA violation and can result in fines that include the cost of performing the tests required to obtain the information that was not provided. The sending

physician must provide the following documentation:

1. Pertinent records of the patient's emergency condition
2. The patient's signs or symptoms
3. A current diagnosis and any treatment provided
4. The results of any tests that were conducted (including laboratory tests and radiographs)
5. Written consent of the patient or a person with legal authority agreeing to the transfer
6. Verification from the sending physician that the benefits of transferring the patient outweigh the risks associated with the transfer

In addition, the sending physician must provide samples of pertinent laboratory specimens (such as peritoneal lavage fluid, blood cultures, or cerebrospinal fluid). Patient report at the time of transfer should address the current condition: subjective symptoms, especially the chief complaint; objective signs such as lung sounds and vital signs; an assessment of the patient's physical status, including a preliminary diagnosis; treatment provided at the sending facility; and a plan of care to be provided during transport. Finally, necessary demographic information includes name, age, sex, race, address, billing information, next of kin, and telephone number.

A special case occurs when transferring a patient in unstable condition. Federal law does not regulate the transfer of patients once their condition has been stabilized. Conversely, EMTALA allows transfer of patients in unstable condition only when certain conditions are met. The transfer of a patient in unstable condition for medical reasons (specialty services available at the receiving hospital but not at the sending hospital) requires the patient's written request for transfer following informed consent *or* certification by the physician, based on the information available at the time of transfer, that the medical benefits of transfer to the receiving facility outweigh the risks of transport. Obtaining the patient's written request for transfer may significantly protect CCTPs and the agency against liability. The previously listed requirements for the receiving facility and documentation also apply. Another important specific case involves the transfer of a pregnant woman with contractions. EMTALA specifies that stabilization is defined as delivery of the baby. Thus, any pregnant woman with contractions is considered in unstable condition for transfer purposes, and the aforementioned documentation requirements apply.

Patient Assessment

Before initiating transport, you should perform a rapid baseline physical examination to determine any changes in the patient's condition and whether the transfer warrants additional personnel or resources **Figure 2-4**. This assessment consists of a brief review of the ABCs and the cardiovascular, neurologic, gastrointestinal, and genitourinary systems. (Chapter 5 discusses patient assessment in more detail.) For example, ensure that lung sounds are present equally bilaterally in an intubated patient before and during transport. If the physical examination reveals a problem, seek a solution as outlined in the *Communication With the Health Care Team* section presented earlier in this chapter.

Figure 2-4 A brief physical examination before transport may reveal changes in the patient's condition or the need for further personnel.

Transport Responsibilities

Medical Direction

During transport, CCTPs usually operate with off-line medical direction using established written protocols. If treatment beyond protocol is indicated or consultation is needed, establish contact with medical control and proceed under online medical direction. Ensure the availability of online medical direction before transport. Also confirm that the sending and receiving physicians understand who will provide medical direction and that this may necessitate alteration in the established plan of care. Distance ranges of communications equipment may require shared responsibility between the sending and receiving physicians or even with the transport agency's medical director.

In determining who is most appropriate to provide medical direction, a primary criterion is communication capabilities. If only one physician can maintain direct communication with the vehicle during the transport, that physician should perform medical direction. If more than one physician has communication capabilities, it is appropriate to use one agreed on by the sending *and* receiving physicians. Protocols should include appropriate actions for cases in which communication with the established medical director is not possible. When continuous communications are not available, transport orders should enable you to respond appropriately to medical crises and changing patient status. Standing orders or protocols may be developed to meet these needs.

CCTPs may need to remind the sending physician that prehospital protocols for EMS systems do not apply automatically in the interfacility transport environment. Prehospital protocols may be limited to use in specified environments by personnel who are described under state rules for the EMS system; hospital personnel who accompany the patient usually do not fall under these protocols and often are not familiar with them. When sending physicians write transport orders, they should designate the protocols by name in the transport orders, write pertinent sections into the orders, or attach a printed copy.

Personnel Qualifications

EMTALA requires that the sending physician designate the qualifications of personnel accompanying the patient during transport. EMTALA does not specify what constitutes "qualified personnel," and government regulations have not been developed to define "qualified." The Centers for Medicare and Medicaid Services is responsible for enforcing EMTALA sanctions that involve suspension or termination of Medicare participation. The Office of the Inspector General of the DHHS is responsible for assessing civil monetary penalties for EMTALA violations. These agencies have enforced EMTALA

in a way that affects transport personnel. Personnel who accompany the patient must be medically trained and certified, as required by law, at a level that will allow performance of whatever procedure *might* be necessary to support the patient during transfer, including medical procedures required not only for the patient's current condition, but also for any *reasonably foreseeable* complications.

To determine the level of personnel necessary to care for the patient and manage specialized equipment during transport, the physician should consider that personnel aboard local transport vehicles (ground and air) may be trained in a variety of skill levels, ranging from EMT to paramedic. Some systems also staff transport vehicles with nurses and physicians. For these ambulance personnel, state statute or regulation clearly and narrowly defines the scope of practice. In addition, the personnel will be functioning under medical direction that provides protocols, including standing orders, for prehospital providers within their system. As part of the advance preparation and policy development process, physicians should learn the certification levels of EMS personnel used to staff public and private transport vehicles in the community. It is also important that all necessary and appropriate equipment, medications, and supplies that are within the scope of practice of the personnel onboard and that may be required by the patient be available in sufficient quantities. This is the responsibility of the CCTP.

If the patient's current condition and all reasonably foreseeable complications can be managed within the licensure, training, and capability of the crew on the transfer vehicle, the patient may be transferred without the provision of ancillary personnel. When faced with the need to provide care beyond your scope of practice, request additional personnel.

Ancillary personnel may provide specialized skills (such as a balloon pump technician or a credentialed registered nurse) or may assume overall responsibility for care (such as a neonatologist for a neonatal intensive care patient). Be aware that when ancillary personnel assume ultimate responsibility for the care of the patient, you should provide support to them as needed. You have less liability when care is assumed by another provider with more advanced training and relatively more risk when the ancillary crew is technicians, but in both situations, the risk of liability will undoubtedly be shared because a plaintiff tends to name as many defendants in a lawsuit as possible (to maximize collection efforts). Although CCTPs can be held liable, the primary responsibility for patient appropriateness and stability for transfer rests with the sending physician and facility.

If the sending facility provides ancillary personnel and special equipment, it is that facility's responsibility to maintain the special equipment and provide for its return.

Actions During Transport

To minimize risk of liability during a transport, CCTPs must assess the patient, discuss potential complications with the sending physician, and ensure that the sending physician understands the capabilities and limitations of the transport team. During transport, CCTPs provide appropriate care within the scope of practice and inform medical control or the receiving facility of changes in the patient's condition or any extenuating circumstances **Figure 2-5**. During transport, CCTPs do the following, as indicated:

1. Provide continued support of respiratory and circulatory systems
2. Provide continued fluid volume replacement (and blood, if trained in transfusions)
3. Use appropriate medications as ordered by the medical physician or authorized by written protocol; any medications not normally carried must be obtained before the transfer, and their use specified in transfer orders, including whether they should be administered by a registered nurse or paramedic, if they are not included in protocols.
4. Monitor vital signs

5. Maintain communications
6. Maintain accurate records of the transport

Transport Completion

On arrival at the receiving facility, ensure continuity of care by giving a report to the designated receiving care provider. The report should include the following: (1) the patient's name, age, and sex; (2) the names of sending physician and facility; (3) the reason for transfer; (4) a brief review of systems; (5) the patient's history; (6) medications administered; (7) fluid intake; and (8) a summary of the patient's condition during and tolerance of the transport in a clear, concise, and logical format. Transfer specimens, records, and laboratory and radiography results to the receiving provider, and make yourself available to answer questions after the transfer of care.

Figure 2-5 During transport, monitor the patient's condition, give care as needed, and maintain thorough documentation.

Documentation

All health care personnel are taught the importance of documentation. Nowhere is accurate and complete documentation more important than when dealing with a patient who is seriously ill or in critical condition. When a patient's status changes rapidly and without warning, numerous interventions are carried out and transfer orders may have to be modified during transport. It is often a challenge to keep up with documentation during a transfer that requires your constant attention to the patient.

Each service uses its own forms and reports to document patient care, but regardless of the forms used, it is essential that a completed run report paint an accurate and detailed picture of everything that occurred during the trip. Providers should keep in mind that they may be asked to defend the run report in a court of law.

In the critical care transport setting in which transfer often involves a team effort, it is important for team members to understand who has the responsibility for each aspect of documentation. When dealing with an acutely ill patient, it is easy to assume that the other team member may have documented an intervention or a set of vital signs only to later learn that the documentation was not included in either report. Team members should work together at the conclusion of a run to ensure that documentation is accurate and complete.

It is particularly important to record certain essential elements of every transfer. These include the

following:

- The times of each set of vital signs and each assessment finding
- The details and times of each intervention (such as drug doses and routes of administration)
- Patient responses to all interventions
- Untoward or adverse reactions
- Communications with medical control
- Deviation from transfer orders or standing orders
- Diversion to another hospital
- Refusal of treatment by the patient

If it is necessary to amend a run report following its submission to the receiving facility, make sure that the amendment is done in accordance with local protocol.

Summary

The first line of protection against legal problems lies in maintaining a professional and compassionate demeanor. Treat patients, family members, and personnel at the sending and receiving facilities with respect, and cooperate fully with other agencies to ensure continuity of care. Make it clear that you care about the patient's well-being and are doing everything possible to serve it.

The second is the discipline that produces medical excellence. Important factors include preparing thoroughly for transports, ensuring the presence of adequate and functional equipment, maintaining skills and certifications, knowing and complying with protocols, staying within the standard of care for your level of training, and documenting the transport thoroughly.

Knowing and complying with laws and regulations regarding critical care transport constitute the final step. Local laws vary, but general legal principles such as consent and negligence apply in all jurisdictions. Likewise, all transport providers are subject to, and should clearly understand, EMTALA.

Case Study

YOU AND YOUR CRITICAL CARE TRANSPORT TEAM have been requested to provide an interfacility transport from a rural hospital. The patient is a 28-year-old woman who is 29 weeks' pregnant. She presented to the local emergency department around 10:30 PM complaining of labor-type pain every 10 minutes. Emergency department staff placed the patient on a fetal monitor and confirmed their suspicions of preterm labor. The fetal monitor showed normal variability with no decelerations. The patient received a 0.25-mg subcutaneous injection of terbutaline.

When you and your critical care transport team arrive, you find the patient in the emergency department. She has responded to the terbutaline and her uterine contractions have slowed to 15 minutes apart and are less intense. The physician reports to you and your team that the fetal monitor has shown normal variability with no decelerations. You assess the patient and prepare her for transport, when you realize that the transport fetal monitor was accidentally left in the ambulance. Since the transport time was only 20 minutes, you decide not to go to the ambulance to retrieve the fetal monitor and plan to place the patient on the fetal monitor once you reach the ambulance.

During the short transfer time to the ambulance, the patient begins experiencing an increase in the contraction frequency. You load the patient into the ambulance and begin your transport. The patient's contractions have increased to every 5 minutes. Your critical care protocols state to administer magnesium sulfate, with the initial loading dose of 4 to 6 g IV over 20 minutes, followed by a

maintenance drip of 1 to 4 g/h. While you are mixing the loading dose, the patient is screaming and crying hysterically in pain. Your partner is attempting to calm her while you prepare the drip.

You place the magnesium sulfate on the transport drip. The transport pump beeps, indicating that there is air in the line. You disconnect the drip, flush the line, and reattach it to the pump. The pump beeps again, indicating air in the line. You again disconnect the line in attempts to flush it. The patient continues to scream in pain and her contractions continue to increase in frequency. You once again flush and reattach the line; the pump gives the green light indicating that it is functioning. Your ETA to the hospital is 5 minutes. You and your team reassess the patient and determine that the contractions are slowing in frequency. As you and your team arrive at the receiving hospital, you realize that you had forgotten to attach the fetal monitor during the commotion. You quickly attach the fetal monitor without reviewing the strip. You unload the patient from the ambulance and transfer her to the obstetrics (OB) unit. You report to the staff that the patient was administered magnesium sulfate because of an increase in her contractions.

You and your team disconnect the patient from your equipment and transfer the patient to the hospital bed. The OB nurse attaches the patient to the hospital fetal monitor and becomes concerned with the fetal monitoring strip. She immediately calls for a physician. The fetal strip was showing late deceleration. The nurse and physician asked to see the previous strip during the transport. You report that you had forgotten to place the patient on the monitor.

The patient is rushed to the operating room for immediate surgery. The infant was delivered with an Apgar score of 0, and required full resuscitation efforts. The infant did not survive the intense resuscitation efforts.

1. Was the critical care transport team responsible for the infant's outcome?
2. Is this a case of negligence?
3. What has to be proven for a negligence lawsuit?
4. What should have been done to prevent this outcome?

Analysis

The symptoms of preterm labor include a contraction every 10 minutes or more, frequent pelvic pressure, lower back pain, and abdominal cramping. This patient was indeed in preterm labor.

Terbutaline is used to relax the smooth muscles of the uterus. Terbutaline is not approved by the Food and Drug Administration (FDA) for use in preterm labor; however, it is widely used. Terbutaline is only approved by the FDA for the treatment of asthma and breathing problems.

In this case, the critical care transport team was responsible for the infant's death. The transport team's failure to monitor the fetus proved negligence on their part. In order for negligence to be proven, the plaintiff is required to prove the following: The critical care transport team had a duty to act, the team violated this duty to act, and the violation of conduct caused the injury or death of the infant.

The critical care transport team should have returned to the emergency department to stabilize, reassess, and ensure that all appropriate monitors were in place. By performing these simple steps, the situation would likely have resulted in a positive outcome.

Prep Kit

Ready for Review

- CCTPs should understand and comply with the legal principles and specific laws and regulations that govern their practice, and they should give attention to the various elements that contribute to the

quality of care they provide, namely, skills maintenance, continuing education, protocol familiarity and compliance, and interpersonal communications.

- The transport of critically ill or injured patients is a complex process requiring cooperation from everyone involved. Hospitals that participate in Medicare reimbursement programs are subject to EMTALA, which is intended to regulate hospitals and the manner in which they conduct transfers. Personnel who perform interfacility transports need to be familiar with EMTALA and how it applies to them.
- Hospitals or physicians found in violation of the EMTALA provisions face several possible penalties, including fines, termination from Medicare and Medicaid programs, and civil litigation against the hospital and/or physician for injuries arising from an EMTALA violation.
- Current EMTALA case law includes implications for interfacility transport, with the intention and purpose of preventing hospitals from "dumping" patients because of inability to pay. There are many EMTALA cases that have bearing on critical care transport, and as more cases are decided, interfacility implications may become more far-reaching.
- EMTALA has far-reaching implications that make CCTPs responsible to minimize the risks associated with interfacility transport.
- The provision of emergency care, regardless of the setting, is governed by civil law, as opposed to criminal law, and consists of statutes and regulations originating from a number of legal sources. CCTPs are required to have medical direction to practice, in the form of online medical control occurring by telephone or radio or off-line medical control in the form of approved standing orders or protocols.
- Areas of liability can arise in the provision of transport, most of which come from a violation of the patient's basic rights; violations include assault, battery, false imprisonment, and negligence.
- To withhold resuscitative efforts, there must be a written order from a physician. If there is a question as to the status of a DNR order, err on the side of providing resuscitation rather than withholding it.
- The right to refuse treatment is a basic right of all patients and is based on the belief that every person of adult age and sound mind has a right to determine what is or is not done to his or her body. Providing care without allowing this consent puts CCTPs at risk of liability for assault or battery, even if the care is necessary to save the patient's life. If a patient refuses care, the CCTP must explain to the patient the possible consequences that may result without treatment.
- Consent, which can be informed (express) or implied, must be obtained before proceeding with treatment or transport, and the rules for minors vary in cases of emancipation.
- The patient has the right to receive uninterrupted care, and CCTPs could be held liable for abandonment if care is interrupted.
- The patient has a right to "appropriate" care, which means that a CCTP is expected to have the same training, skills, and abilities as other CCTPs and is expected to exercise reasonable care and diligence when using the skills and knowledge in the care of a patient. Failure to meet this standard of care results in negligence on the part of the CCTP.
- The patient has a right to expect that information obtained before, during, or after transport will be kept confidential, and to reduce the risk of breaching confidentiality, CCTPs should relay communications about the patient's condition only to the appropriate personnel and not release patient identifying information over the radio.
- In preparation for transport, CCTPs should find out the patient's diagnosis and condition and should

ensure that the patient has a patent and secured airway; patent and secured IV access if necessary; appropriate monitoring as needed for cardiac rhythm, blood pressure, pulse oximetry, and end-tidal carbon dioxide; appropriate measures to treat hemodynamic instability; appropriate chemical or physical restraints if needed for confused or agitated patients; and appropriate spinal immobilization or pneumatic antishock garments for trauma patients as needed.

- In preparing for transport, CCTPs should communicate fully with the other members of the health care team at the sending and the receiving facilities, and a plan of care should be developed that is within the CCTP scope of practice.
- In preparation for transport, CCTPs need to obtain the reason for transfer and the name of the receiving hospital and/or physician; they need to determine whether a BLS or an ALS provider must accompany the patient in addition to the CCTP and whether the sending facility plans to provide an escort; and they need to obtain the treatments provided at the sending facility, the treatments and drug orders for the duration of the transfer, and any potential complications that may arise during transport.
- The sending physician must send copies of medical records with the patient to the receiving facility that document the patient's current diagnosis and condition, symptoms the patient is experiencing, treatments given, results of tests conducted, written consent of the patient or a person with legal authority agreeing to the transfer, and the physician's verification that the benefits of transferring the patient outweigh the risks. The sending physician must also send samples of pertinent laboratory specimens.
- Before transport, CCTPs should perform a brief physical examination to determine if there are changes in the patient's condition that would require additional personnel or resources during the transfer.
- CCTPs operate with off-line medical direction using established written protocols, and if treatment beyond protocol is indicated or consultation is needed, CCTPs should establish contact with medical control and proceed under online medical direction.
- EMTALA requires that the sending physician designate the qualifications of personnel accompanying the patient during transport and that all necessary and appropriate equipment, medications, and supplies that may be required by the patient are available in sufficient quantities and are within the scope of practice of the personnel accompanying the patient during transport.
- CCTPs must assess the patient, discuss potential complications with the sending physician, and ensure that the sending physician understands the capabilities and limitations of the transport team. During transport, CCTPs must monitor the patient's condition, provide the appropriate care within the scope of practice, inform medical control or the receiving facility of any changes in the patient's condition or of any extenuating circumstances, and maintain thorough documentation.
- On arrival at the receiving facility, CCTPs ensure the continuity of care by giving a detailed report to the designated receiving care provider that includes all patient information, the names of the sending physician and facility, the reason for transfer, all documentation and records (including the patient's history, medications, fluid intake, condition during transport, and tolerance of transport), any transfer specimens from the sending facility, and any laboratory and/or radiography results from the sending facility. CCTPs should be available to answer questions from the receiving care provider after the transfer of care is complete.
- Documentation to record certain essential elements of every transfer is important and should include the times of each set of vital signs and each assessment finding, the details and times of each intervention (such as drug doses and routes of administration), the patient's responses to all interventions and any adverse reactions, all communications with medical control, any deviations from

the transfer or standing orders, any diversions to another hospital or facility, and any refusals of treatment by the patient.

Vital Vocabulary

abandonment The termination of an established patient-care provider relationship by the care provider without simultaneous transfer of health care responsibility to another care provider of equal or greater competence.

assault The act of putting someone in reasonable apprehension of imminent harmful or offensive contact.

battery Harmful or offensive touching of another without consent.

breach of duty to act A case in which a health care provider does not conform to the standard of care by providing inappropriate care, failing to act, or acting beyond the scope of practice.

competence Capacity or ability to understand the nature and effects of one's decisions or actions.

consent Voluntary agreement by a patient with sufficient mental capacity to capably choose assessment, treatment, or transport offered by the care provider; a patient not accepting care demonstrates the right to refuse.

damage In a legal context, damage must result from a breach of duty for a health care provider to be found negligent. Usually, the injury is physical.

do not resuscitate (DNR) order A type of advance directive that describes which life-sustaining procedures should be performed in case of a sudden deterioration in a patient's medical condition.

duty to act A legal obligation of public and certain other ambulance services to respond to a call for help in their jurisdiction. When the duty to act applies varies from state to state; it can be when a CCTP initiates treatment or when the dispatch center confirms that a transport vehicle is being sent.

emancipation A legal status in which a person who is younger than the legal age in a given state is legally considered an adult; he or she gives up the right to maintenance and support from a parent, and the parent relinquishes the right to control the child.

Emergency Medical Treatment and Active Labor Act (EMTALA) A federal law passed by Congress in 1986, with a primary focus of preventing hospitals from transferring patients to other facilities because they are unable to pay for services. Initially, EMTALA was a portion of the Consolidated Budget Reconciliation Act of 1985 (COBRA).

false imprisonment Intentional and unjustifiable detention of a patient.

Health Insurance Portability and Accountability Act (HIPAA) A law enacted in 1996, providing for criminal sanctions and civil penalties for releasing a patient's protected health information (PHI) in a way not authorized by the patient.

implied consent Assumption on behalf of a person unable to give consent that he or she would have consented.

informed (express) consent A patient's voluntary agreement to be treated after being told about the nature of the disease, the risks and benefits of the proposed treatment, alternative treatments, and the choice of no treatment at all.

medical control The oversight designed to ensure that actions taken by providers on behalf of patients are appropriate; divided into direct medical control, available in real time via radio, and indirect medical control such as standing orders and protocols.

medical direction Supervision of medical care, provided online (telephone or radio) or off-line (protocols, standing orders, education, and quality improvement).

negligence Failure to provide the quality of care (as defined by applicable standards) usually expected with conditions requiring that care; negligence is established when the plaintiff proves four elements: duty to act, breach of the duty, injury to the patient, and the breach was the direct cause of the injury.

off-line medical control Medical direction given through a set of protocols, policies, and/or standards.

online medical control A type of medical direction in which the care provider is in direct contact with a physician, usually via two-way radio or telephone.

protected health information (PHI) Individually identifiable information (such as name, social security number, and date of birth), health information (such as laboratory results and medical history), and demographic information (such as address and telephone number) that is protected by HIPAA.

proximate (direct) cause The reason an injury occurred; the final element that must be proven for a health care provider to be found negligent.

scope of practice The body of knowledge, skills, and therapies that health care providers can legally apply in patient care, based on training, certification, medical direction, and applicable law.

tort A wrongful act that gives rise to a civil suit.

Objectives

1. Explain the role of the Commission on Accreditation of Medical Transport Services (CAMTS) and the concepts of visual flight rules, instrument flight rules, and a sterile cockpit (p 40).
2. Discuss the concept of flight following (p 41).
3. Describe the various types of air medical helicopters that have been used and that are currently in use (p 43).
4. Describe the advantages and disadvantages of the use of rotor-wing aircraft (p 42).
5. Describe the advantages and disadvantages of the use of fixed-wing aircraft (p 43).
6. Briefly discuss the emphasis of the air medical role to facilitate critical care transports (p 40).
7. Summarize Federal Aviation Administration guidelines that are pertinent to air medical transport (p 52).
8. List standards created to enforce safety (p 49).
9. Summarize crew resource management (p 50).
10. Understand the importance of taking safety precautions, including an understanding of crash and survival skills (p 51).
11. List techniques for safety and survival in the aircraft environment (p 56).
12. Discuss common employment criteria for medical flight team members (pp 53, 54).
13. Discuss the critical care provider certifications that are prevalent and required flight crew training (p 54).
14. Describe the various crew configurations used by air medical programs (p 53).
15. Describe accreditation of the air medical program (p 54).

Introduction

The CCTP may work in the aircraft environment as a part of the course of his or her duties. Some CCTPs may be permanently assigned to an aircraft, whereas others may rotate on to aircraft as part of their staffing assignments. The CCTP needs to be familiar with both rotor-wing (helicopter) and fixed-wing (airplane) operations. The aircraft environment is unique in that patient care is not the primary concern—that is, aircraft safety and aircraft operations will always come before patient care in this setting. This concept is difficult for some providers to understand, but is essential to the successful completion of the mission.

The Air Medical Role

Many organizational models for air transport programs are possible, although three dominate current practice. One is a hospital-based air program, with many hospitals sharing the responsibility and costs of the service. A second model is the public service agency—a structure that allows government agencies to

use the air transport program outside the medical setting while also serving the needs of critically injured and ill patients. The third model is the private service, which has recently gained attention and is growing because of its ability to meet the needs of health care systems. This model primarily offers interfacility transfers but in some systems also offers emergency scene responses.

The basic concepts of an air medical service are to rapidly transport CCTPs to a patient, stabilize the patient's condition, and transport that patient to a tertiary care center as rapidly as possible. The patients who benefit most from air medical transport are those who are critically ill or injured and who would have a negative outcome with a prolonged transport.

Although air transport offers many benefits, CCTPs must weigh the benefit to the patient vs the risk of the specific mode of transport. Before going this route, patients being transported should be evaluated and assessed for the effects of altitude and other forces that can adversely alter their conditions en route. For example, cardiac patients with activity-sensing pacemakers may encounter a severe complication if the pacemaker malfunctions because of flight vibrations. It is also necessary for air medical programs to consider the adverse effects of air transport on their employees. They, too, may have adverse reactions to aircraft humidity, noise, and vibrations, resulting in possible dehydration, hearing loss, and fatigue, respectively. Effects of altitude are discussed in Chapter 4.

Air medical transports are shown to decrease mortality rates and are indicated for all critically injured or critically ill patients. Nevertheless, they are often contraindicated in the following circumstances:

- Severe anemia
- Hemoglobinopathy
- Myocardial infarction (MI) within 10 days or complications in the 5 days before the flight (with the exception of a patient with an acute MI being flown to the catheterization lab, which is done routinely)
- Uncontrolled arrhythmia
- Pregnancies past 24 weeks' gestation
- Recent eye surgery affecting the globe
- Nonacute hypovolemia

If air medical transport is undertaken in such cases, special considerations—such as flying at a lower altitude than usual—may need to be taken to optimize patient outcome. Although patient conditions and possible complications must always be considered, terrain, weather, and geographic location of the closest facility must also be factored into whether air medical transport is the best option. In addition, it is important to recognize transport crew capabilities and to ensure their safety.

There are drawbacks associated with air medical transport, but history has shown that air medical transports decrease mortality rates and allow access to more specialized tertiary care facilities. Air medical transports allow rapid access into the health care system, especially for patients who may live in otherwise inaccessible areas. Such programs have proven that they are capable of providing a major source of support to community hospitals and rural areas confronted with critically ill or injured patients.

Communications

The **Commission on Accreditation of Medical Transport Services (CAMTS)** is a program dedicated to ensuring high-quality patient care and safety within ground, rotor-wing, and fixed-wing services. CAMTS has set many communication standards to help improve the overall safety of most critical care transport systems. Much of its effort has focused on rotor-wing and fixed-wing divisions because proper

communication procedures within the cockpit are important for ensuring the safety of both patients and crew.

Sterile cockpit is a term used by the pilot in command to describe the atmosphere during takeoffs, landings, and any other critical phase of flight. During this time, no communication is allowed that could distract the pilot in command unless it is related to the safety of the flight **Figure 3-1**. Air carrier standards state that a sterile cockpit should be enforced at all altitudes less than 10,000′; however, most helicopters fly only between 2,000′ and 5,000′. In such situations, the sterile cockpit times are determined by the pilot in command, but will always include takeoff, approach, and landing. Once the rotor-wing aircraft has reached its cruising altitude and speed, the pilot in command will permit crew members to take part in casual conversation.

Communications with operation centers and dispatchers should also be observed during this phase of the flight process. The rule of thumb should be that communications to operation centers, such as those that give lift-off times, ETAs, fuel, and number of crew members, should be relayed prior to lift-off, after the aircraft reaches its cruising altitude, or until the pilot declares a nonsterile cockpit. A sterile cockpit should also be observed while communicating with patients during flight. Most pilots have the option of "isolating" crews (by flipping a switch in the cockpit, the pilot can take the crew out of the communication loop with air traffic control [ATC] and ground units).

Figure 3-1 A sterile cockpit (no unnecessary communication) must occur during critical phases of flight to prevent potential distractions to the pilot.

If, during flight, the pilot in command experiences a mechanical issue or there is a dramatic change in the patient's condition, it may be necessary to land short of the original destination. In most cases, when mechanical issues arise, the pilot in command seeks out the closest airport as a landing site. If the patient's condition deteriorates to the point that immediate medical attention is needed, the pilot in command will land at the closest appropriate medical facility, where the patient will be taken inside for advanced medical care that is unavailable in the aircraft. The crew should also be alert at all times for potential mechanical malfunctions such as smoke in the patient care area, smell of abnormal odors, unusual vibrations not reported by the pilot, abnormal sounds, or fluids leaking into the patient bulkhead. Pilots may also choose to declare an "emergency" to ATC. This should immediately result in a sterile cockpit.

Instrument Flight Rules vs Visual Flight Rules

In the aviation industry, all parties must be familiar with the two possible modes of flight.

Visual flight rules (VFR) describe a mode of flight used when weather conditions are good,

meaning there is generally good visibility and minimal cloud cover. A pilot can fly VFR in many areas without being in contact with ATC and is responsible for keeping the aircraft clear of clouds; however, in populated areas such as large cities, the pilot must be in contact with ATC even when flying VFR.

Instrument flight rules (IFR) describe flight rules that apply when minimum cloud clearance and visibility requirements cannot be met. During these conditions, the pilot may not be able to see outside the aircraft (ie, owing to clouds or fog) and must rely on the instruments inside the cockpit to maintain control and navigation of the aircraft **Figure 3-2**. A pilot flying IFR must receive an ATC clearance prior to takeoff and maintain contact with ATC during the flight, which will ensure proper distance from other air traffic is maintained.

Very few rotor-wing programs conduct IFR operations because pilots who perform certified-instrument approaches need to be able to land safely and legally during IFR weather, and rotor-wing air medical aircraft often land at hospitals and unimproved landing zones. The few programs that conduct rotor-wing IFR usually require two pilots for these operations. Fixed-wing aircraft routinely operate IFR as they use **Federal Aviation Administration (FAA)**-certified approaches at airports for takeoff and landing and usually require two pilots for IFR operations as well.

Figure 3-2 A pilot depends on the instrument panel when flying under instrument flight rules.

Flight Following

A critical care transport is initiated when the communication center receives a request for service from an authorized agency such as local police, fire, EMS, or a referring hospital and then passes that request on to the flight team. The flight team then either accepts or declines the mission after taking the relevant factors, such as weather, terrain, and nature of injury or illness, into account. Some programs require that the pilot make the decision without any knowledge of the patient. This prevents pilots from being influenced and taking on extra risk, for example deciding to transport a pediatric patient when it is actually not safe. Once the aircraft launches, the communication center and/or ATC remains in contact with the aircraft throughout the flight.

When a pilot is flying IFR, the ATC is legally mandated to be in contact with the aircraft to ensure it maintains a safe distance (ie, separation) from other IFR aircraft. When a pilot is flying VFR, a type of monitoring called **flight following**, or radar advisory service, may be provided by an authorized ATC facility. The service consists of a controller notifying the aircraft about traffic in the area when the controller is available to do so **Figure 3-3**. The flight following provided by ATC is advisory only and provided by the controller when the workload allows. While most controllers try to accommodate requests for flight following, at times of peak workload, services may not be available.

When a pilot is flying VFR, it is good practice to maintain constant contact with other local traffic

and ATC facilities in proximity of the aircraft.

Figure 3-3 Flight following occurs when an air traffic control center stays in contact with a pilot.

When a pilot is flying VFR, flight following is not mandatory but is highly recommended because it can assist the pilot in avoiding a collision with terrain or other aircraft. When a pilot is flying IFR, a filed flight plan, flight clearance, and ATC contact are mandatory.

When a pilot is flying VFR in a helicopter, contact is usually maintained with one of two entities: ATC or an EMS communications center. If the pilot in command decides not to flight follow with ATC, real-time radio contact with a communications center must occur every 15 minutes.

During fixed-wing operations, when a flight plan has not been filed, the pilot in command must make contact with ATC or a communications center every 30 minutes. It is industry standard practice, however, to operate fixed-wing aircraft on an FAA flight plan, and most air transport agencies enforce either filing a flight plan or regular contact with their own communications center when in flight.

During patient transport in a ground unit, any lapse in communication must not exceed 45 minutes. During check-in times, CCTPs should provide updates of both the patient's condition and the geographic location. Regardless of who is tracking the various ambulances, airplanes, or helicopters, a complete record of these communications should be kept for 30 days.

The communications center should be secured at all times, with only authorized personnel allowed access to this facility. Personnel should be familiar with flight operations and specially trained in the procedure of flight-following aircraft.

Identifying Flight and Scene Locations

It is critical that the flight-following center utilize global positioning system (GPS) technology to be able to constantly track the aircraft's movement even when not in radio contact with the center. Several commercial flight-tracking programs are available that use a GPS signal that is sent from the aircraft and received by the center. In the event of an in-flight emergency requiring an emergency landing, the center can use this signal to immediately determine the aircraft's last known position.

The flight-following center also needs to have computer software available that can allow for a physical address to be input and converted to GPS coordinates. In the rotor-wing environment, responders to the scene frequently use a handheld GPS device to obtain coordinates for the geographic location. These devices are extremely accurate and if the coordinates are properly read and relayed, they will lead the aircraft to within a few hundred yards of the scene. To prevent inaccuracies in the relayed coordinates, at least two sets of coordinates should be obtained for all scene flights.

Rotor-Wing Transport vs Fixed-Wing Transport

As mentioned earlier, the CCTP needs to be familiar with both rotor-wing (helicopter) and fixed-wing (airplane) operations. Both types of transport have advantages and disadvantages.

Rotor-Wing Transport

Rotor-wing transport has the distinct advantage of vertical takeoff and landing, allowing the helicopter access to areas that are inaccessible by ground vehicles and/or fixed-wing aircraft **Figure 3-4**. Rotor-wing aircraft generally have sustained speeds in excess of 150 mph, can operate at altitudes less than 2,000′, and can move from point to point. (Depending on local terrain, the altitude at which an aircraft will be able to fly may vary and is always at the discretion of the pilot in command.) Air medical providers that use such aircraft serve all types of population bases, from dense urban to extremely rural. A relatively small number of helicopters can serve a large population because of the quick turnaround time for most flights.

Rotor-wing transport has some disadvantages. Helicopters are more restricted than fixed-wing aircraft regarding weather limitations, as they generally cannot fly IFR. They also have more interior space limitations, oftentimes making it difficult to perform complex procedures while the CCTP is in the aircraft. For example, because of space constraints, when being transported in a helicopter, a patient may be inaccessible from the waist down, or there may not be enough space behind the patient's head to allow intubation. These situations can have major management ramifications.

Figure 3-4 Helicopters can access locations that ground vehicles and fixed-wing aircraft cannot, making them ideal for certain situations.

Helicopters are also expensive, averaging between $2 and $5 million for a new aircraft. For this reason, there must be justification for the necessity of the helicopter to offset operating costs. Specifically, helicopter transport is more expensive when compared with ground transport, averaging almost four times the cost of an ambulance.

Helicopter transport is also subject to weight limitations. This concern becomes more problematic in the summer when the air is less dense, decreasing the amount of lift that the blades can achieve (ie, lift capacity).

Fixed-Wing Transport

As a general rule, transport by fixed wing is safer than transport by rotor wing. Fixed-wing aircraft use established landing areas (airports) and fly at designated cruising altitudes that minimize the risk of colliding with human-made objects. Most fixed-wing air medical aircraft are IFR certified and fly with a

two-pilot crew, further increasing safety.

Fixed-wing aircraft offer several advantages for medical transport. Two of their greatest advantages are their high speeds—ranging from 250 to 600 mph—and their ability to travel greater distances. Fixed-wing aircraft generally have the ability to carry multiple patients, ranging from two on smaller aircraft to hundreds on large military air medical aircraft **Figure 3-5**. There are usually no weight limitations regarding patient size, and the aircraft can carry multiple medical crew members and a variety of equipment.

There are some distinct disadvantages to fixed-wing aircraft, including the high cost of obtaining an aircraft for air medical purposes. Many air medical providers do not purchase or lease their own aircraft, but instead contract with various executive aircraft services to provide aircraft as needed. The cost of patient transport by fixed-wing aircraft can exceed $10,000 or more for short-distance flights and can exceed $100,000 for international flights. Most fixed-wing services secure reimbursement from patients or insurance companies prior to initiating flight because of the high costs involved.

Fixed-wing aircraft must use maintained landing fields, and restrictions on runway length may apply depending on the size of the aircraft. Last, fixed-wing aircraft require hangers, which increases the overall operating costs.

Figure 3-5 C-130 Medevac of Hurricane Katrina patients.

Rotor-Wing Aircraft

Mission Profiles for Air Medical Helicopters

On average in the air medical industry, 54% of flights will be for interfacility transports (hospital to hospital), 33% for scene responses, and 13% for other types of events (eg, organ procurement and search-and-rescue operations). Some air medical helicopters are also used to transport surgical staff to emergency scenes to provide patient care, such as field amputations.

Air medical helicopters may perform a wide variety of missions. The majority of air medical programs limit their capabilities to the transport of the sick and injured, however, and do not incorporate other services into their mission profile. A limited number of air medical programs also support search-and-rescue and law enforcement operations.

Types of Air Medical Helicopters

No standard makes or models of helicopters exist for medical transport **Table 3-1**. Instead, the type of helicopter used depends on several factors, including patient load capacity, over-water operations, requirements for VFR or IFR flight, altitude of operations, economy or budget of the program, and

(geographic) range of flights. The program type also varies based on community need. For example, some programs are hospital based, others are community based, and still others are operated by a local government program (ie, law enforcement, fire, or a county EMS program) or state government program (ie, state police). Likewise, some programs are nonprofit operations, whereas others are for-profit businesses. There is no single ideal program, as the best option for one community may not be suitable for another.

Most air medical programs use an aircraft vendor, which provides the aircraft and pilots and all of the required aircraft maintenance. With such an arrangement, it is the responsibility of the air medical program to provide the medical crew and medical equipment. This option may deliver significant savings when a program is initially started up, as a hospital or EMS agency may not have to make a large capital outlay for the purchase of an aircraft. A vendor usually operates several bases, which allows for sharing of maintenance personnel, maintenance facilities, check pilots, and spare aircraft. The vendor and the air medical program usually participate jointly in billing and share a predetermined percentage of the reimbursements.

Single-Engine vs Twin-Engine Air Medical Helicopters

Air medical helicopters are divided into two categories: single-engine and twin-engine models **Figures 3-6 and 3-7**. Both types of aircraft have distinct advantages and disadvantages, so each program must determine which type of aircraft best fits its overall mission profile.

A longstanding debate in the history of helicopter aviation is whether a twin-engine aircraft truly is better than a single-engine aircraft. Intuitively, it makes sense to have two engines instead of one. It is

more reassuring to have two engines for long flights over water or inhospitable terrain. However, the turbine engines used today have become increasingly reliable and have few failures. Thus, a single-engine aircraft is more economical. Many communities that would not otherwise be able to afford aircraft coverage are currently served by a single-engine aircraft.

Several factors need to be taken into account when deciding between twin-engine and single-engine aircraft, including the types of missions flown, the space available to land the aircraft, the required payload, and the available money to operate the program. Programs that mainly perform interfacility transports tend to require larger aircraft to handle items such as neonatal isolettes for neonates in critical condition **Figure 3-8**, balloon pump consoles for patients with heart failure **Figure 3-9**, and other large and bulky equipment.

Figure 3-6 Single-engine helicopter (Bell 407).

Figure 3-7 Twin-engine helicopter (BK117 C1).

Figure 3-8 Flight team loading a neonatal isolette.

Figure 3-9 A console for an intra-aortic balloon pump, secured for transport. Note that this piece of equipment takes up a substantial amount of room and may limit the number of other items you transport in the crew cabin.

The advantages of a single-engine aircraft compared with a twin-engine aircraft are as follows:

- Aircraft start-up times of 3 to 5 minutes for a single-engine aircraft compared with 8 to 10 minutes for a twin-engine aircraft
- Less downtime for maintenance
- Lower maintenance costs
- Lower operating costs
- Lower fuel requirements
- Smaller landing zones needed

The advantages of a twin-engine aircraft compared with a single-engine aircraft are as follows:

- Two-patient capacity vs one-patient capacity in the single-engine aircraft
- Larger openings for patient loading and unloading
- Larger patient care area
- Dual engines in case one fails (especially useful for transport over water)
- Greater lift capacity

Fixed-Wing Aircraft

Mission Profiles for Air Medical Fixed-Wing Aircraft

Fixed-wing aircraft are typically used for flights of 200 nautical miles (300 miles) or greater, although they may sometimes be used for shorter distances. For example, in some rural, mountainous states in the United States, fixed-wing transport is used for flights as short as 60 nautical miles (90 miles) because of severe weather that prohibits helicopters from flying. Fixed-wing air medical transport would also be more commonly used for international transports, for example in the military.

Types of Air Medical Fixed-Wing Aircraft

The two main types of fixed-wing aircraft are propeller driven (turbo prop) and jet aircraft. A turbo prop aircraft has a jet engine and propellers.

Fixed-wing aircraft can be single engine or multi-engine. As with helicopters, the type of aircraft utilized once again depends on the transport needs. For example, some fixed-wing models are more spacious than others **Figures 3-10 and 3-11. Table 3-2** lists commonly used fixed-wing air medical aircraft.

Air Medical Efficacy

One of the most heated debates in emergency medicine today is the efficacy of air medical transport. Since the inception of air medical transport, critics have questioned whether air transport offers measurable (ie, quantifiable) benefits. Advocates on both sides of the debate provide compelling evidence to support their theories.

Benefits of Air Medical Transport

Emergency departments in community hospitals have declined from just over 5,000 in 1992 to approximately 4,600 in 2002, a trend that is expected to continue. The number of Level I trauma centers has also declined slightly. The remaining Level I trauma centers in the United States maintain 95% bed capacity, resulting in frequent diversions of patients to other comparable facilities. With the use of air medical transport, 65% of the US population has access to a Level I trauma center within 60 minutes, and half the US population has access to 10 Level I or II trauma centers within 60 minutes.

In some regions, air transfer could mean the difference between life and death. For a patient with a myocardial infarction in a typical suburban area, the difference between ground and air transfer may be only minutes; however, in some areas of Alaska, Canada, Central and South America, Africa, Asia, or Australia, conventional ground transfer could take hours to reach definitive care. An aircraft may only take one fourth of that time.

Air transfer is also about specialty. Most patients who require critical care transport are not considered a routine transfer. These patients usually receive multiple drips such as nitroglycerin, dopamine, amiodarone, and heparin. In addition, the same patient may need continuous sedation and neuromuscular blockade, necessitating patient transfer to a ventilator by the flight crew. A flight crew member must be skilled in many areas to make this transfer quickly and without delay.

In addition, specialty care is increasingly being housed in urban specialty centers and is less available in nonurban settings, meaning that patients in nonurban settings who require specialty care may need transport over longer distances than in the past. Air medical transport has been found to significantly reduce treatment times in the following situations, all of which involve specialty care:

- Incident-to-catheterization lab time for patients with acute MI

- Incident-to-operation room time for surgical patients
- Incident-to-thrombolytic time for patients with acute MI and stroke

The greatest reduction in time to reach treatment is seen with patients who bypass the emergency department and are directly admitted at the receiving facility. Many flight teams have preestablished protocols for direct admission of certain types of patients, which allows them to receive specialized care immediately upon arrival. A flight crew's protocols may allow a higher level of care than a critical care transport ground crew's protocols.

Specialty resource centers, such as cardiac, stroke, pediatric, and burn centers also have critical care ground transfer units available that can be used by the flight team if weather prevents the aircraft from flying. In some regions, referring hospitals are required to have a registered nurse accompany critical patients (depending on state laws or regulations). In some cases, this causes difficulty because the ambulance is leaving its first-due coverage district (ie, the area where the ambulance is the primary medical transport provider and is expected to be first on the scene, rather than serving as a backup) and the hospital is short one registered nurse. Therefore, the benefit of air transfer allows the flight team to retrieve a patient, receive transfer of care, and transfer following local protocols.

The benefit of air medical transport in mass-casualty situations has been definitively proven. Postdisaster analysis indicates between 60% and 80% of patients transport themselves to the nearest facility during a mass-casualty incident, quickly overwhelming the capabilities of the nearby hospitals. In such cases, it is prudent to begin transport of patients by air to outlying hospitals because the majority of ambulatory patients flock to the closest hospitals.

Hazards of Air Medical Transport

Air medical transport should be used only after conducting a risk–benefit analysis. Incorporating a helicopter into a chaotic rescue scene increases the risk to responders and patients, even when established safety measures are followed. Even the most skilled helicopter pilots cannot control the amount of debris that is blown about, nor can they totally eliminate the hazards associated with the main rotors and tail rotors (with the exception of fully enclosed tail rotors).

Only patients who are critically injured or seriously ill should be considered as candidates for air medical transport. The decision to transport a patient by air should be made after carefully considering all of the transport options. Some patients will clearly benefit from the speed and advanced skill of air medical transport teams, whereas other patients could be transported by ground more quickly and with less potential danger.

Controversies

Your service may or may not transport prisoners. Some services have opted not to provide these transports for the safety of the patient and crew. Instead, a service staffed by law enforcement personnel performs this service.

Financial Implications of Air Medical Transport

The cost of air medical transport varies greatly depending on the region, distance flown, care provided, and other factors. According to the 2000 Annual Transport Statistics and Fees Survey, the average cost ranges from $2,600 to $6,200 per flight. In 2002, Medicare reported that the average cost of air medical transport via helicopter was between $5,000 and $10,000, requiring Medicare to increase its

reimbursement rates for this type of transport. The number of helicopter transports has skyrocketed in recent years. Medicare reported that it had a 58% increase in number of flights reimbursed in 2004 relative to the number reimbursed in 2001. These data confirm that helicopters are expensive to fly and maintain, with operational costs per helicopter averaging $1 million per year.

Not surprisingly, to obtain reimbursement from insurance companies, helicopter use for medical transport must be justified. Many insurance companies balk at paying $10,000 for transport and will aggressively review whether such helicopter usage was appropriate. In response to aggressive billing reviews, Medicare—whose standards often filter down to other payers—established a list of criteria that justify the use of air medical transport. To satisfy the Medicare criteria, many flight programs routinely list all applicable justifications for air transport within the medical report to facilitate insurance reimbursement.

Helicopter transport is 400% more expensive than fixed-wing transport for flights of more than 101 nautical miles (1 nautical mile = 1.5 miles). For this reason, many services choose to send patients by fixed-wing aircraft, if available, for flights exceeding 100 nautical miles. Some air medical helicopter programs do not charge for their services and are instead funded by taxes or donations. Other air medical services offer a membership program that allows people to pay an annual subscriber fee for their household; this fee covers the cost of any air medical transport during that period.

Special Populations

Any high-risk complication of pregnancy, childbirth, or miscarriage qualifies as criteria for air medical transport.

Determining Air Medical Transport Suitability

When you are considering whether to use air medical transport, the requesting EMS provider or physician must avoid three critical errors:

- Requesting air medical transport for a patient when a more suitable means of transport is clearly indicated
- Requesting air medical transport when the patient could arrive at the receiving facility more quickly by ground transport
- Requesting air medical transport for a patient when cardiac arrest is ongoing or imminent

In most situations, air medical transport compares unfavorably to ground transport on the basis of safety, cost, and availability. On average, air medical transport costs at least four to five times more than ground transport over the same distance. In terms of availability, one air medical aircraft may serve a population of 500,000, whereas 20 or more ambulances may be available to serve the same population. Given this disparity, providers who are requesting air medical transport need to determine whether they will be needlessly tying up resources that could be better utilized elsewhere.

One other consideration to take into account when determining ground vs air transportation is the level of care that can be given. In some states, the highest level of ground provider is a paramedic. When considering flight programs, registered nurses are usually the highest level of provider, thus allowing the higher level of care such as balloon pumps, certain critical medications, and IV infusions of nonparamedic approved medications.

Thirty nautical miles (34.5 miles) or 30-minute transport is considered to be the minimum for which air medical transport is quicker than ground transport. (The industry-wide average for miles transported per flight is 61 miles.) However, factors such as traffic, construction, and weather have to be considered

when making this determination. Some patients who require extended extrication time or have limited accessibility may benefit from air medical transport. Other patients may benefit from the advanced caregiving skills of the flight team, including their ability to perform rapid-sequence intubation, place chest tubes, or administer blood.

Other Justifications for Air Transport

A helicopter may sometimes be requested because the ground EMS unit is overwhelmed by the severity of the patient's injuries and needs the expertise of the flight crew. Air medical programs are frequently called to scenes where the ground EMS units have waited on the helicopter to perform advanced procedures such as rapid-sequence intubation. This situation is not strictly limited to ground EMS units, but is frequently observed in smaller hospitals as well. The medical flight team from the helicopter is often well respected in the medical community and is viewed as a "safety net" that can be relied upon when the provider on the ground requests assistance. As a member of the flight crew, you should be fast, proficient, and skilled in your area or expertise. By being proficient and skilled, you can ensure that your team is maintaining a limited on-scene time, which helps reduce the overall flight time to higher levels of care.

Transport of Patients in Cardiac Arrest

It seems counterintuitive to not utilize air medical transport for a patient who is in cardiac arrest or on the precipice of arrest. Cardiac arrest represents one of the most serious medical situations and would, in theory, stand to benefit the most by air medical transport. Nevertheless, most air medical providers do not routinely transport patients in active cardiac arrest for the following reasons.

First, it is against federal air regulations for passengers or crew onboard an aircraft to not be restrained in seatbelts during takeoffs and landings or as requested by the pilot. Providing effective CPR in the aircraft often requires the medical crew to be unbuckled.

Second, CPR is often futile, with fewer than 5% to 8% of all patients who receive CPR being resuscitated. Use of air medical transport for a patient in cardiac arrest is, therefore, generally viewed as a poor use of resources.

Last, to provide effective resuscitation, CPR generally requires a minimum of three providers: one provider performing chest compressions, one managing the airway, and one providing pharmacologic therapy. Rotor-wing aircraft typically carry only two medical providers, thus limiting the effectiveness of resuscitation. Although a patient in cardiac arrest should not be placed in the aircraft and flown, the CCTP must realize that occasionally a patient may arrest in flight and should be prepared to deal with this situation.

Triage of Air Medical Transport Patients

Intuitively, the use of air medical transport makes sense: It expedites transport of critical patients to appropriate facilities. However, numerous studies have concluded that air medical transport tends to be overused. This section discusses considerations when triaging critical care patients.

Overtriage in the Field

A retrospective review of pediatric trauma patients transported by helicopter reveals a trend toward **overtriage**, in which a patient is considered to be in more serious condition than he or she actually is. For example, a study in central Ohio found that nearly 70% of pediatric trauma patients transported by air were discharged from the emergency department. Similarly, a study at Children's National Medical Center in Washington, DC, found that 85% of pediatric trauma patients sent to the hospital by air were

actually overtriaged and did not require air medical transport. A study that reviewed pediatric trauma patients flown to hospitals in Los Angeles, CA, found that 33% were overtriaged and were discharged home from the emergency department. However, many of these cases involved appropriate use of air transport: 37% of these patients had multiple injuries, 14% were intubated in the emergency department, 18% were admitted to the intensive care unit, and 4% were taken directly to the operating room. To curtail the trend toward overtriage, some are advocating for better triage training for prehospital personnel.

An estimated 10% or fewer of all patients (pediatric and adult) sent to hospitals require multiple interventions. By contrast, more than 90% of the patients transported by rotor-wing or fixed-wing aircraft require multiple interventions. The patient acuteness (ie, the seriousness of the patient's condition) is much higher in the air medical industry because of the triage by experienced providers prior to the initiation of air medical transport.

Undertriage in the Field

Although many believe air medical transport is overused, there is some benefit to overtriage. **Undertriage** in the field, in which a patient is considered to be in less serious condition than he or she actually is, is a problem as well.

Some trauma physicians state that an overtriage rate of 25% is acceptable to ensure that those patients who most desperately need care are not overlooked. A recent literature review, however, indicates that this number can be as low as 10% and still encompass most outliers. Most trauma surgeons agree that a discharge rate from the emergency department of less than 10% is an indication of undertriage and suggests that patients who would most benefit from quick transport and trauma team activation are not being appropriately triaged.

Air Medical Use Criteria

Table 3-3 lists guidelines for determining whether use of air medical transport from one facility to another is appropriate. When you are making this determination, it is important to identify those patients who will *not* benefit from air medical transport. **Table 3-4** identifies some of the absolute and relative contraindications to air medical transport.

Current **helicopter emergency medical service (HEMS)** criteria use both mechanism of injury and physiologic parameters to determine which patients might benefit most from transport in helicopters. Strictly basing the need for air medical transport on the mechanism of injury is no longer a clinically accepted practice because it has resulted in needless trauma team activations and emergent transports of stable patients. In contrast, new models that use both mechanism of injury and physiologic parameters to triage patients have been found to be effective at including appropriate patients and excluding patients who do not require trauma activation.

HEMS providers should have frequent discussions with the local trauma team about which criteria are used to triage patients. In addition, a formal system to track the "time to discharge" on all patients flown should be implemented. Air medical services whose overtriage rates exceed accepted limits should create opportunities to educate local providers about triage criteria.

Controversies

Controversy exists concerning specialty referral centers refusing transfers from outlying emergency departments unless their particular air medical service is used—even when ground transport would be

perfectly acceptable. This practice needs to be addressed in the industry.

TABLE 3-3 Patient Characteristics That Warrant Air Medical Transport

Burns ≥ 18% total body surface area (second degree or greater)
Burns resulting from an explosion with severe respiratory distress *or* altered level of consciousness (patient not alert)
Burns with sustained unconsciousness
CO inhalation or HazMat exposures with sustained unconsciousness
Postresuscitation from near drowning Diving accident with suspected neck injury SCUBA accidents
Electrocution or lightning strike with sustained unconsciousness
Long fall (from heights exceeding 6′) with sustained unconsciousness
Stab, gunshot wound, or other penetrating trauma to the torso or head with sustained unconsciousness
Childbirth or miscarriage with high-risk obstetric complication: • Viable premature infant (≥ 20 weeks' gestation) • Viable multiple births (≥ 20 weeks' gestation) • Maternal bleeding disorder • Maternal use of blood thinners
Traffic or transportation crashes with patient pinned *and* sustained unconsciousness
Traffic or transportation crashes with sustained unconsciousness *and* high mechanism: • All-terrain vehicles • Automobile vs bicycle or motorcycle • Ejection • Personal watercraft • Rollover crash • Vehicle off bridge/height
Need for advanced life support or specialized care not available by ground services
Time-critical illness or injury: • Stroke or acute coronary syndrome with potential for interventional care • Amputated limb with potential for reattachment

Controversies

Organ donation is a major concern in a critical care unit, but should not be relevant to critical care transport. CCTPs care for critically ill patients as though they are expected to survive. The patient's status as an organ donor should have no impact on care.

TABLE 3-4 Patients Who Will Not Benefit From Air Transport
Contraindications
Patients with terminal illnesses
Patients with do not resuscitate orders
Patients in arrest without return of spontaneous circulation
Patients whose conditions will overwhelm the capabilities of the
crew
Relative Contraindications
Severe anemia
Hemoglobinopathy
Myocardial infarction within 10 days or complications in the
5 days before the flight
Uncontrolled arrhythmia
Pregnancy > 24 weeks' gestation
Recent eye surgery affecting the globe
Nonacute hypovolemia

Air Medical Crashes

Currently, 770 helicopters in the United States are dedicated to air medical service. Patient transports are increasing at a rate of 5% per year as the industry continues to grow. As the number of air medical providers has increased over the years, so has the number of air medical crashes.

To some extent, the trend toward more air medical crashes is simply linked to the concurrent rise in the number of aircraft in the fleet and the number of missions flown. In the United States between 1998 and 1999, flight hours increased by 12%. This trend is expected to continue.

Helicopter EMS is one of the most dangerous forms of aviation, with a high accident rate compared with other sectors of aviation.

Causes of Air Medical Crashes

The **National Transportation Safety Board (NTSB)** has found that aircraft crashes are never caused by one single event. Instead, they are caused by a series of factors that ultimately contribute to the final event. The FAA Advisory Circular Number 60-22 states, "One bad decision often leads to another. As the string of bad decisions grows, it reduces the number of subsequent alternatives for continued safe flight."

When crash statistics are examined, they reveal that 55% of crashes occur during scene flights; however, scene flights account for only 35% of HEMS missions. Forty percent of flights occur at night; however, they account for more than 60% of the crashes. The NTSB has identified four major factors contributing to HEMS crashes:

1. Human error (68% of crashes)
2. Weather (30% of crashes)

3. Mechanical failure (25% of crashes)
4. Controlled flight into terrain (20% of crashes)

The NTSB has concluded that weather poses the single greatest hazard to HEMS operations (human error is the number 1 cause of accidents, whereas weather is the main contributing factor). Although weather is a contributing factor, in only two crashes was adverse weather the primary cause of the crash. Notably, the cause of weather-related crashes is not the pilot's disregard for weather at takeoff, but rather encounters with unpredicted **instrument meteorological conditions (IMC)** (cloudiness or low visibility) during flight.

As helicopters become more reliable, the chance of mechanical failure has dropped. In the last 15 years, the number of crashes due to mechanical failures has decreased by almost 10%.

Of the HEMS accidents in the past 10 years, only 30% occurred on patient-related missions; the remaining 70% of crashes occurred during maintenance flights, check flights, relocation, and public relations flights. The average crash rate for HEMS has increased. HEMS is one of the most dangerous forms of helicopter aviation and carries some of the highest line-of-duty death rates for EMS providers, second to motor vehicle collisions.

Making the Industry Safer

Within the industry, several solutions have been proposed to reduce the number of air medical crashes. Crew resource management training for all flight team members is now the industry standard. All new flight team members are required to attend initial training, and most programs offer annual refresher training.

Another important safety measure is information sharing between competing agencies. In the air medical industry, the term **helicopter shopping** describes the practice of making sequential calls to numerous air medical providers in an attempt to find a service that will accept a mission request that has been declined by other services based on safety factors such as poor weather, limited landing zone availability, exceptional distances, or other factors. To prevent helicopter shopping, air medical providers should share their decisions to decline certain missions based on safety issues with surrounding air medical services, even if they are in direct competition with the other services.

Air medical programs also need full support from their business's administration and the aircraft vendor when they choose to decline a mission. Some believe that stiff competition in the air medical industry prompts some services to take missions even when safety is in question. Although this may have been a factor in the past, currently no data support this claim. With intense scrutiny on the air medical industry from the federal government, other oversight agencies, and the community, air medical services have implemented numerous guidelines to prevent flight crews from being pressured into taking questionable flights.

To facilitate cooperation among the various parties involved in the transport decision, joint agency training is encouraged between air medical providers and different agencies. Air medical providers should routinely train with other area HEMS programs, EMS agencies, fire departments, and hospital providers. This training should include aircraft familiarization, landing zone requirements, flight activation criteria, and flight request training.

Advanced technology is now available that can increase the safety of flight operations. Many HEMS programs are now implementing night vision goggles **Figure 3-12** on the aircraft. Unfortunately, the implementation throughout the industry is slow because of the cost of the equipment, required modifications to the aircraft cabin, and extensive flight crew training.

Figure 3-12 Night vision goggles.

As mentioned earlier in this chapter, flight-tracking software is now used throughout the industry to assist with realtime tracking of the aircraft at all times. The practice of flight following helps locate an aircraft that crashes or loses radio contact. Some air medical programs have also begun implementing ground-proximity warning systems and obstacle detection and alerting systems on the aircraft.

Most rotor-wing aircraft do not have real-time weather data available in the aircraft. Instead, the pilot must rely on weather data obtained before launch as well as weather information given by the flight-following center. To provide for better in-progress forecasts, some aircraft now have weather display and alerting systems installed that can give pilots realtime weather data and warnings.

Cockpit voice recording and flight data recorders have been used for years in fixed-wing aircraft. Flight safety advocates are now asking for rotor-wing aircraft to have the same technology so that investigators can better analyze the factors that lead to a crash or near-crash situation.

Crew Resource Management

With the implementation of cockpit voice recorders and flight recorders in the 1960s and 1970s, investigators found that many crashes were not the result of mechanical or technical malfunctions of the aircraft or its systems, nor were they caused by poor piloting skills or lack of knowledge or experience from the crew. Instead, more than 80% of crashes involved human error—primarily related to the inability of the crew to respond appropriately to situations in which they found themselves.

Crew resource management evolved as a result of that statistic and the KLM/Pan Am crash on Tenerife, Canary Islands, in 1977, in which two 747s collided on the runway. This was the deadliest crash in aviation history, and was primarily due to unclear communication between the KLM pilot and the control tower regarding takeoff. The pilot understood that they were cleared for takeoff, but the control tower was only confirming position for takeoff, not actually clearing the flight for takeoff. The control tower made a clarifying statement, but KLM could not hear it because of interference. The Pan Am aircraft was taxiing on the main runway when the KLM aircraft started to take off. The KLM flight engineer heard a transmission from the Pan Am crew and asked the pilots if Pan Am was clear of the runway; the KLM pilot assumed Pan Am was clear and continued with takeoff. All KLM passengers and crew members died (248 total people), and most (335) of the 396 people on the Pan Am flight died.

In response to this crash and alarming statistics, the National Aeronautical and Space Administration (NASA) held a workshop in 1979 focusing on ways to improve air safety. Before this workshop, the captain or pilot in command of the aircraft was considered to be the only person who was able to make decisions regarding the operations of the aircraft. The other crew members, including the first officer, had

minimal input into the final decision that was made. The new procedure advocated as a means to overcome this reliance on only one person's judgment was called **crew resource management**, defined as "using all available resources—information, equipment, and people—to achieve safe and efficient flight operations."

Crew resource management challenged the assumption that the pilot should make decisions alone. Flight crews were encouraged to speak up when they did not agree with the pilot; pilots were encouraged to listen and take into account flight crew input. In short, the aviation industry learned to accept that human-to-human interactions are an integral part of any team performance.

Today, the **International Civil Aviation Organization (ICAO)** requires crew resource management for airlines in 185 countries. A study by the University of Texas Human Factors Research Project found that commercial airline flights experience an average of four threats per flight. Most of these threats or errors are caught through crew resource management and have no detrimental consequences.

Crew resource management is not concerned with the technical aspects of flying an aircraft. Instead, it focuses on the cognitive and interpersonal skills needed to successfully complete the flight:

- Cognitive skills take into account the mental processes needed to maintain situational awareness, make decisions, and solve problems.
- Interpersonal skills focus on individual and group behavior, communication, and teamwork.

Crew resource management allows for subordinate crew members to participate in the decision-making process, but it does not imply that all decisions are made by committee without considering rank. That is, the amount of participation by subordinate crew members depends on the situation. For the most part, the medical crew member's role in crew resource management focuses on passive monitoring. Such crew members typically do not provide flight instructions to the pilot, nor will they be involved in technical decisions made in regard to operation of the aircraft. Instead, the obligation of the medical crew member is to intervene if the level of skill being displayed by the pilot falls below a safe standard (eg, if the medical crew member notices that the aircraft is on an imminent collision course with a radio tower, or to advise the pilot of nearby air traffic).

One area of crew resource management in which all members of the crew should hold equal empowerment is the decision of whether to accept a mission. In the past, it was often solely the pilot's decision to accept or decline a mission. More recently, this practice has been changed by the majority of air medical providers and replaced by the "three to go, one to say no" rule (also called the 51% rule, which means it takes all members of the crew to agree to take the mission, but if one member says no, the mission is declined). Under this rule, every member of the crew—regardless of time or grade—has the power to decline a flight. Although the pilot does have the ultimate authority over all operations of the aircraft, if any crew member does not feel comfortable with a mission, the mission should be aborted.

Medical crew members must never wonder what is going on in regard to operation of the aircraft. If this occurs, either the pilot has not announced his or her actions or is not aware of the situation. Consider the following scenario: The pilot says he or she is going to hold in a hover. The aircraft begins to hover, but then slowly drifts backward. The crew needs to communicate to the pilot that they are drifting backward or they may miss an opportunity to correct an error.

Types of Human Errors

According to the NTSB, "Accidents are never caused by one single event. Instead, they are caused by a series of factors that contribute to the final event." Human factors contributing to error can be classified into three types—those that involve skill deficiency, perception errors, and decision-making errors.

Pilots and other members of the flight crew are expected to have the basic skills to fly an aircraft

safely. When there are deficiencies in these basic skills, a number of hazards can occur. Examples of the types of errors that can occur include losing control of the aircraft on the runway, flying at an improper speed, and not following standard operating procedures in the event of an emergency.

Errors in perception involve **spatial disorientation** (covered in Chapter 4), a **somatogravic illusion**, or a mistake in judgment regarding distance, altitude, or airspeed. Spacial disorientation may occur during a flight that becomes out of control in midair. Errors in perception also occur during nighttime landings and landings that involve reduced visibility.

Errors in decision making also may lead to an undesirable outcome. Decision-making errors include failing to choose the appropriate emergency procedure and failing to take corrective action when the aircraft is flying below minimum altitude.

Air Medical Safety

Air medical transport has inherent hazards but is rich with rewards. Air medical providers encounter a complex myriad of hazards. They are expected to rapidly launch after a request has been made (most rotor-wing programs require launch within 5 minutes of the request), placing stress on the flight crew to become airborne. Air medical aircraft often land at chaotic scenes where a hasty landing zone has been established **Figure 3-13** and where a variety of emergency personnel are operating in close proximity to the landing zone. Air medical providers are called to situations where patients are facing catastrophic injury or illness, requiring the flight crew to give maximum attention and decision-making abilities to the treatment of the patient. Frequently the aircraft is called because the patient's condition is so serious that it has exceeded the capabilities of the medical personnel on the ground, putting additional stress on the air crew. Finally, the aircraft environment is physically demanding and can induce heat illness, dehydration, motion sickness, and physical and mental exhaustion in air medical personnel after extended operations.

Figure 3-13 Chaos of a scene flight.

Risk Factors

Retrospective studies regarding air medical crashes conducted by the NTSB, the FAA, and the **Air Medical Physician Association (AMPA)** have found several areas within HEMS operations that need improvement as follows:

- Weather forecasting
- Flight operations during instrument meteorological conditions
- Personnel training

- Design standards
- Crashworthiness
- Operations management

Other areas of HEMS operations identified as risk factors for air medical personnel include the following:

- Unprepared landing sites
- Complacency
- Additional stress of responding and caring for critical patients

Safety reports also indicate that communication problems with air traffic control and collision with ground objects are problems that warrant improvement.

Adding to the risk is the time-critical nature of the job. As mentioned, rotor-wing providers are generally expected to launch within 5 minutes of receiving a request for services. Because of the rapid preparation involved, crews do not have the luxury of conducting a leisurely preflight inspection of the aircraft, nor do they have plenty of time to check and recheck weather. Instead, crews must move quickly to provide timely, life-saving care. Use of crew resource management has improved the decision-making process after receipt of a request. Most program policies have all flight crew members perform a quick walk-around the aircraft prior to initial start up. The rule of thumb is that three sets of eyes are better than one. Usually all crew members report to the front of the aircraft after performing the walk-around and report any abnormal findings before the pilot enters the cockpit.

As mentioned earlier, a disproportionate percentage of crashes occur at night. A study by the AMPA in November 2002 concluded that the time of day when the flight takes place has a significant impact on safety. The study found that more crashes occurred when crews were en route to pick up a patient than at any other time during flight.

The FAA has taken steps to increase the safety of HEMS operations. In 2004, the Helicopter Air Ambulance Task Force was created to make recommendations to reduce the crash rate. Some of the recommended safety measures include the following:

- Stricter weather guidelines
- Night vision goggles
- Instrument-rated pilots and aircraft
- Dual pilots
- Enhanced pilot minimum qualifications
- Better usage criteria

As yet, these are FAA recommendations and not regulations.

Federal Aviation Administration Guidelines

All aircraft fall under one or both of the following guidelines set forth by the FAA:

- **Title 14 Code of Federal Regulations (CFR) Part 91** governs the operation of all aircraft within the United States, including the waters within three nautical miles of the US coast. All aircraft must abide by this guideline. General aviation (private) aircraft operate under these less restrictive rules.
- **Title 14 Code of Federal Regulations (CFR) Part 135** governs the operations of all commuter or on-demand commercial operations. The guidelines for 14 CFR Part 135 operations are much stricter than those for 14 CFR Part 91 aircraft and apply to almost all air medical operators.

One of the significant differences between 14 CFR Part 91 and 14 CFR Part 135 is the minimum weather conditions in which the aircraft is allowed to operate. Section 91.155 in 14 CFR Part 91, titled "Basic VFR Weather Minimums," states that helicopters must remain clear of clouds when operating less than 1,200′ above the ground. By contrast, the stricter 14 CFR Part 135 guidelines specify that HEMS aircraft must have a weather minimum of at least 1,000′ ceilings and 3 miles of visibility. A pilot could potentially accept a mission under 14 CFR Part 91 weather requirements, fly to the scene, and then be under 14 CFR Part 135 weather requirements for the transport to the hospital. This discrepancy poses a major safety hazard in that the aircraft would be allowed to launch under weather standards that are not conducive for patient transport with the hopes that the weather will improve by the time the patient is loaded on the aircraft.

If a flight is unable to be flown under 14 CFR Part 135 weather minimums for the complete flight, the flight should not be attempted. A retrospective review of 55 HEMS accidents that occurred from January 2002 to January 2005 found that 10 of the flights crashed while operating under 14 CFR Part 91 weather minimums; they would not have been able to take the mission if they were operating under 14 CFR Part 135 for the complete mission. For the purposes of the CCTP, only Part 135 is relevant as all commercial operators must abide by Part 135 regulations. Only a few government operators (such as law enforcement) can operate solely under Part 91.

The FAA, in addition to providing the requirements of 14 CFR Part 91 and 14 CFR Part 135, requires that air medical transport programs designate someone as **operational control**. This term is usually given to the chief pilot or operational manager for an air medical program and denotes the person who has the ultimate authority to initiate, conduct, and terminate the EMS mission. Although the pilot and the medical crew members have the right to accept or refuse a mission, the person in operational control has ultimate authority over all of the flight operations for the program.

Weather-Related Issues

Weather has an obvious impact on the ability to accept and complete missions. Some mission requests result in a **weather decline**—that is, an air medical provider is requested, but the pilot and the flight team determine that the weather does not meet established company or FAA guidelines for flight operations. The FAA states the following weather requirements in FAR Part 135, Section 135.201:

> *Except when necessary for takeoff and landing, no person may operate under VFR*
>
> *(a) An airplane*
>
> *(1) During the day, below 500 feet above the surface or less than 500 feet horizontally from any obstacle; or*
>
> *(2) At night, at an altitude less than 1,000 feet above the highest obstacle within a horizontal distance of 5 miles from the course intended to be flown or, in designated mountainous terrain, less than 2,000 feet above the highest obstacle within a horizontal distance of 5 miles from the course intended to be flown; or*
>
> *(3) A helicopter over a congested area at an altitude less than 300 feet above the surface*

CAMTS has established weather guidelines that take into account several variables, including local area response, crosscountry response, nonmountainous and mountainous areas, day light, night with high light, and night with low light. These standards exceed the requirements established by the FAA and have been accepted by many air medical providers. All air medical providers, regardless of whether they are CAMTS certified, are encouraged to follow the CAMTS-recommended weather standards for operations.

Crew Safety Precautions

CAMTS strongly emphasizes the need for adequate crew rest and ongoing safety precautions, both of which affect CCTPs and patients. The following are standards that CAMTS suggests for all CCTPs:

- Shifts longer than 24 hours are discouraged.
- Personnel should have at least 8 hours of rest before any shift longer than 12 hours.
- Personnel should not be on duty more than 16 hours within any 24-hour span.
- Crew members who must work longer than 16 hours must have the right to take an unscheduled break.

Other requirements have been adopted by CAMTS for pilots. Some CAMTS standards indicate that pilots must have the following:

- A minimum of 2,000 total flight time hours, with 1,500 of the hours in a helicopter
- 1,000 hours qualified as pilot-in-command time
- 200 hours of night flying
- A minimum of 500 hours of turbine time, with 1,000 hours encouraged
- 5 hours of geographic orientation with another pilot before accepting a mission alone

The Air Medical Crew

Being part of the air medical crew is competitive. Air medical personnel must have flight experience, but the only way to obtain experience is to be part of the crew. Most air medical services routinely have between 10 and 50 qualified applicants for a single flight position. Within the medical industry, a flight position is one of the most difficult to obtain. Working as a flight paramedic, a flight nurse, a flight respiratory therapist, or a flight surgeon is often viewed as the apex of the profession. That being said, an interested applicant should not be discouraged. Often you have to have considerable ground experience at both scene response and interfacility transports before being considered for a flight position. If your dream is to be a flight crew member, get the required experience, and apply broadly.

Because of the severity of the patients seen on the aircraft, flight team members must be clinically competent and prepared to deal with a myriad of medical and traumatic emergencies. Medical flight team members are sometimes only called to provide rapid transport to an appropriate facility, and other times are called to a scene or a hospital because the severity of the patient's condition requires their expertise. Flight team members must be willing to obtain numerous advanced certifications so that they will be prepared to care for the most critical patients.

Air Medical Crew Configuration

Several different medical crew configurations are used throughout the industry. Studies have not shown a definitive increase in survivability with any particular crew combination. Ultimately, the best crew configuration is one that is able to offer the most optimal care to the patient.

Air medical transport improves mortality rates when the HEMS crew capabilities exceed that of noncritical care ground personnel. In particular, air medical programs that operate under physician-level standing protocols experience lower mortality rates. Those programs that operate under aggressive protocols with an advanced scope of practice have the best opportunity to improve patient outcome. Protocols alone, however, do not make the CCTP more expert than ground personnel. Continued practice, experience, and education combine with aggressive medical protocols to lead to better patient outcomes.

In the air medical environment, the most common configuration is flight nurse/flight paramedic, a synergistic combination that provides a great amount of experience and diversified training in the medical

crew. The flight nurse is well experienced in the critical care environment, whereas the flight paramedic is well adapted to airway management and emergency scene management. Both providers are proficient in dealing with the comorbid or multitrauma patient.

The nurse/respiratory therapist configuration offers advantages in that the most important aspect of treatment is airway management. Some air medical transport agencies fly a nurse/nurse combination, although this configuration is controversial as nurses may not have the necessary prehospital experience and airway management experience. Similar to the nurse/nurse combination is the paramedic/paramedic combination, whose configuration does not provide the advanced scope of practice that would be seen with the addition of a flight nurse.

Air medical services that transport patients on balloon pumps may utilize perfusionists on the flight team. These highly trained technicians are experts in the operation of intra-aortic balloon pumps and adult and pediatric extracorporeal membrane oxygenation machines.

A few air medical transport teams include physicians; however, given the increased scope of practice of flight team personnel, most air medical services have found that having a physician onboard does not significantly increase patient survival.

Air Medical Crew Employment

Working on a rotor-wing or fixed-wing aircraft is demanding and requires personnel to be highly proficient in a myriad of prehospital and critical care skills. Paramedics and nurses may treat a critical trauma or medical patient in fewer than 10% of their cases; by contrast, flight crew personnel encounter critical patients on almost every mission. **Table 3-5** lists industry minimums and recommendations for training flight nurses, flight paramedics, and flight respiratory therapists. Individual states may require additional training prior to employment as a flight crew member.

TABLE 3-5 Industry Minimums and Recommendations for Air Medical Personnel

Position	Required Minimums	Recommended
Flight nurse	Five years of experience as a nurse with critical care and emergency department experience Current certifications in: • Advanced Cardiac Life Support (ACLS) • Pediatric Advanced Life Support (PALS) • Neonatal Advanced Life Support (NALS) or Neonatal Resuscitation Provider (NRP) • International Trauma Life Support (ITLS) or PreHospital Trauma Life Support (PHTLS) • Cardiopulmonary Resuscitation Provider (CPR)	Bachelor's/Master's degree Advanced Trauma Life Support (ATLS) audit Certified Emergency Nurse (CEN) Certified Transport Registered Nurse (CTRN) Certified Flight Registered Nurse (CFRN) Critical Care Registered Nurse (CCRN) Emergency Medical Technician certification Paramedic certification TNATC, TNCC, ATCN Instructor credentials in ACLS, PALS, NALS, ITLS, PHTLS, and CPR
	Five years of experience as a	

Flight paramedic	paramedic in a busy 911-response EMS system National Registry Paramedic (NREMT-P) • Advanced Cardiac Life Support (ACLS) • Pediatric Advanced Life Support (PALS) • Neonatal Advanced Life Support (NALS) or Neonatal Resuscitation Provider (NRP) • International Trauma Life Support (ITLS) or PreHospital Trauma Life Support (PHTLS) • Cardiopulmonary Resuscitation Provider (CPR)	Bachelor's degree Critical Care Paramedic (CCEMT-P, or CCP) Certified Flight Paramedic (FP-C) Paramedic instructor Instructor credentials in ACLS, PALS, NALS, ITLS, PHTLS, and CPR
Flight respiratory therapist	Bachelor's degree in respiratory therapy Registered Respiratory Therapist (RRT) Three years of critical care experience (including adults, pediatrics, and neonates) EMT certified Current certifications in: • Advanced Cardiac Life Support (ACLS) • Pediatric Advanced Life Support (PALS) • Neonatal Advanced Life Support (NALS) or Neonatal Resuscitation Provider (NRP) • International Trauma Life Support (ITLS) or PreHospital Trauma Life Support (PHTLS) • Cardiopulmonary Resuscitation Provider (CPR)	Paramedic certification Instructor credentials in ACLS, PALS, NALS, ITLS, PHTLS, and CPR Member of the American Association of Respiratory Care (AARC) and member of the Surface and Air Transport specialty section

Rotor-Wing Operations

Rotor-wing aircraft are generally operating at maximum capacity when they complete 1,000 flights or

more per year. When a service completes 1,000 flights, it can be safely assumed that there were at least 1,500 requests for services.

One of these requests for service comes in the form of a **standby**. A standby generally occurs when an HEMS provider is notified of a potentially life-threatening emergency call. As the paramedics on the ambulance are responding, they may put the local rotor-wing provider on standby, notifying it of a potential request for a response. When placed on standby, members of the air medical crew will check weather suitability (and may decline the mission if the weather does not meet FAA minimums both for launch and for the duration of the flight), gather necessary equipment (ie, blood, warmed fluids), and conduct a preflight inspection on the aircraft **Figure 3-14**. They will also obtain landing coordinates and appropriate radio frequencies. The flight crew will then wait at the aircraft until they are launched or cancelled.

Figure 3-14 The air medical crew conducts a preflight inspection.

Some programs have an **auto launch** protocol. Under this system, when the aircraft is placed on standby, the aircraft launches en route to the scene instead of waiting for the formal launch request. This measure is frequently taken for responses that involve distances of greater than 30 nautical miles. This procedure is often not practical given the considerable cost and inherent hazards in launching the aircraft.

Some emergency medical services make an HEMS standby request automatically as part of their dispatch protocol, depending on the severity of the call. In such a case, the EMS places the aircraft on standby based on the 9-1-1 caller's information instead of waiting for the first emergency responder to arrive. When the location of the scene is greater than 30 miles, the aircraft will usually go ahead and launch to be closer to the scene if it is actually needed. There are clear advantages to early notification of HEMS in more expeditious response, reducing both underuse and overuse, and employment of the myriad of first-hand and crash reporting data often received in the 9-1-1 center.

Establishing a Helicopter Landing Zone

One of the most dangerous aspects of rotor-wing air medical operations is landing the aircraft at scenes where a landing zone has been hastily established. Ideally, the aircraft should be landing at predesignated landing zones that have already been carefully assessed for hazards. Many fire departments and EMS agencies have established numerous landing zones throughout their response area. The coordinates for these landing zones are recorded and given to their dispatch center to pass along to the HEMS program upon launch activation.

When a landing zone needs to be established, several factors must be considered. Ideally, the landing zone will be at least 100′ × 100′ **Figure 3-15**. Some programs require 60′ × 60′ during the day and 100′ ×

100′ during the night. The actual landing surface does not have to be this wide; rather, the site needs to be clear of any obstacles for at least 100′ × 100′. In particular, the landing zone should be free of the following obstacles:

- Wire (no high-tension power lines within half a mile)
- Towers (no television, radio, or cellular towers within half a mile)
- Trees
- Signs and poles
- Low-height ground obstacles such as stumps, small trees, fence posts, mailboxes, and rocks
- Buildings
- Vehicles
- People
- Animals
- Loose debris (traffic barrels or trash)

The landing zone should be a hard surface, rather than a field or other undeveloped or uncleared surface. A hard landing surface facilitates moving the stretcher to and from the aircraft, and fewer personnel are required to load the patient. Unimproved surfaces also have the potential for more dust, dirt, and debris to be blown about by the rotor wash from the aircraft. The landing zone also needs to have less than a 5° slope to avoid the danger of the blades coming in contact with an object or a person on a slope. Most rotor blades droop significantly when they are idling on the ground.

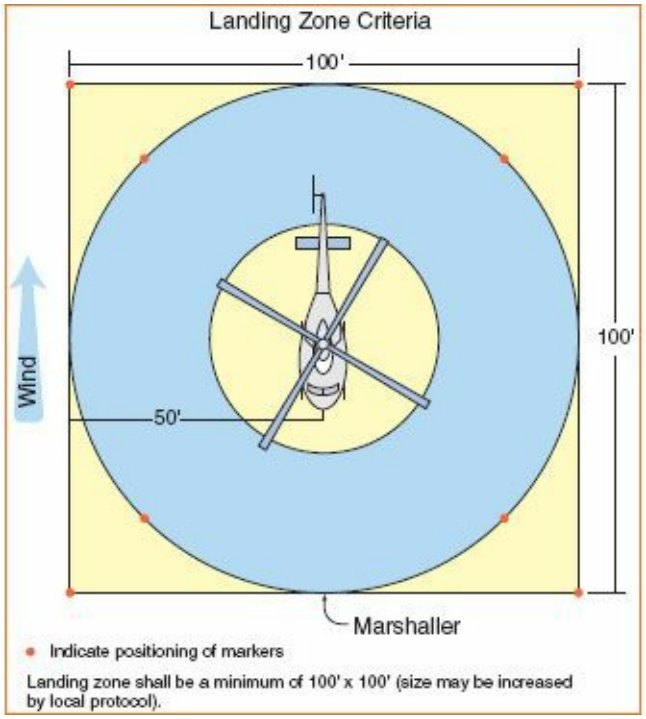

Figure 3-15 Establishing a landing zone.

In ideal circumstances, the landing zone will be outlined by four markers, one on each corner of the landing zone **Figure 3-16**. The markers could be cones for daytime operations and lighted markers for nighttime operations. In the absence of markers, vehicles can be used to establish the landing zone by blocking off access to the area. Emergency vehicles can also be placed so that their headlights cross to mark the landing zone **Figure 3-17**. When emergency vehicles are used to establish the landing zone, it is recommended that they have all of their emergency lights on to enable the aircraft to quickly identify the

landing zone. On clear nights, the aircraft can see the lights from emergency vehicles from several miles away, making it easy to identify the landing zone.

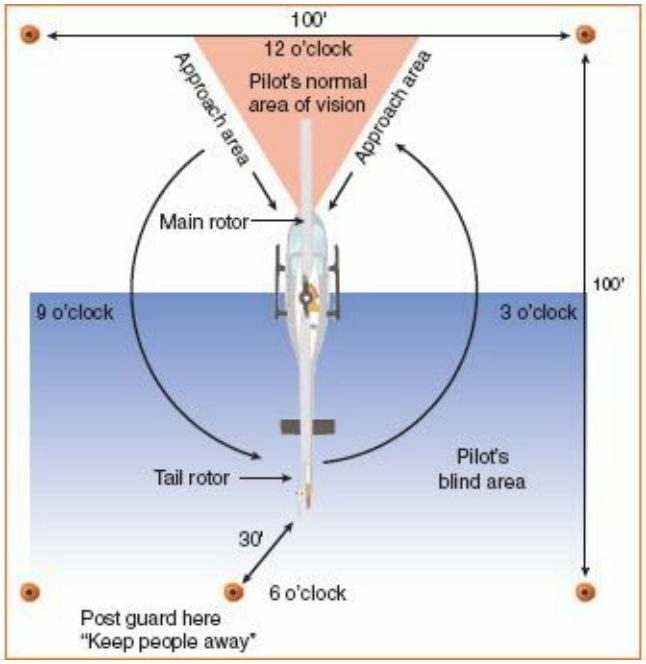

Figure 3-16 Landing zone with cones/warning devices in place.

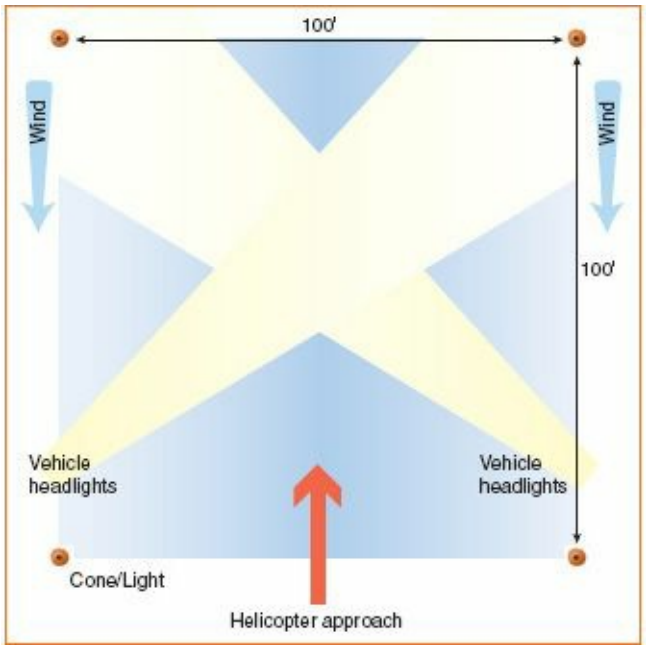

Figure 3-17 Use of headlights to mark a landing zone.

The use of strobe lights is discouraged at the landing zone because of their propensity to cause temporary blindness or disorientation of the flight crew. The use of any flammable type of lights such as flares is not allowed at the landing zone.

Landing zone personnel should be taught proper hand signals to assist the helicopter with landing **Figure 3-18**. Although basic helicopter hand signals are universal, it is recommended that the pilot coordinate the training of hand signal use, as he or she may prefer particular signals.

Precautions After Landing the Helicopter

All landing zone personnel should wear eye and ear protection at all times to protect themselves from

flying debris and the noise of the aircraft. All loose items should be secure, including helmets, equipment, and sheets from the patient stretcher.

No personnel should ever operate near the tail rotor. The tail rotor spins so fast that it is nearly invisible. At night, it is almost impossible to see the tail rotor. This is the area of greatest hazard on the aircraft and all precautions should be taken to ensure that no one comes near the tail of the aircraft. When patients are being loaded into the aircraft by personnel such as fire fighters, paramedics, or nurses, one member of the flight team (usually the pilot) should stand between the auxiliary personnel and the tail rotor to ensure that no one operates in that area. No personnel other than the flight crew should be aft of the loading door of the aircraft.

At no point should anyone approach the aircraft unless directed by the flight crew, and then only from the front right side of the aircraft in full view of the pilot. With some aircraft, the lowest point of blade dip is at the front of the aircraft. Most aircraft are designed to be approached from a 90° angle to the doors. Every aircraft is different, and personnel must abide by manufacturer recommendations and pilot instructions. The key point is never approach unless the pilot indicates it is safe to do so and then only following the pilot's directions.

Hot Loading

Hot loading refers to loading a patient into a helicopter while the helicopter is running. Whether or not a service performs a hot load depends on many factors, including the type of landing zone, type of helicopter, and scene time. For example, a hot load may be necessary when there is no time to power-down and power-up the helicopter, or if there is any question about being able to start up the helicopter in the location where it landed.

When you are loading and unloading a rotor-wing aircraft, certain precautionary measures must be observed. Failure to observe proper safety procedures could result in severe injury or death. Each service must follow a specific, consistent hot load procedure. This procedure needs to consider the helicopter's design; for example, some helicopters load from the side while others load from the rear. The type of load performed should be discussed before landing at the scene. As always, crew must wear proper personal protective equipment.

Although the specific procedure varies, it is critical to have safeguards in place to ensure that no one approaches the tail rotor. One method to address this is to assign a crew member as a tail rotor guard. The tail rotor guard and pilot must be in direct communication with each other or must be able to see each other. The tail rotor guard must remain in position until all assisting personnel have safely moved away from the helicopter.

Before a hot load is done, the crew needs to determine that it is safe before starting. When the hot load is being performed, the pilot and at least one other person remain in the helicopter. The helicopter must not be approached until a crew member signals to do so. The air medical crew and assisting personnel approach the helicopter only once they have been given the go-ahead. The aircraft should be approached in a crouched position. If the helicopter is on a slope and conditions permit, loading personnel should approach the aircraft from the downhill side. Once the patient is loaded, any assisting ground personnel exit the aircraft.

Aircraft Safety and Survival

Numerous books have been written about safety and survival. This section briefly addresses some of the key points in aircraft safety and survival of a hard landing or crash. Medical flight team members must have thorough knowledge of aircraft safety and survival. A large portion of this knowledge must come from hands-on training; it cannot be accomplished by simply reading a chapter in a book, or even by

reading a complete text dedicated to safety and survival.

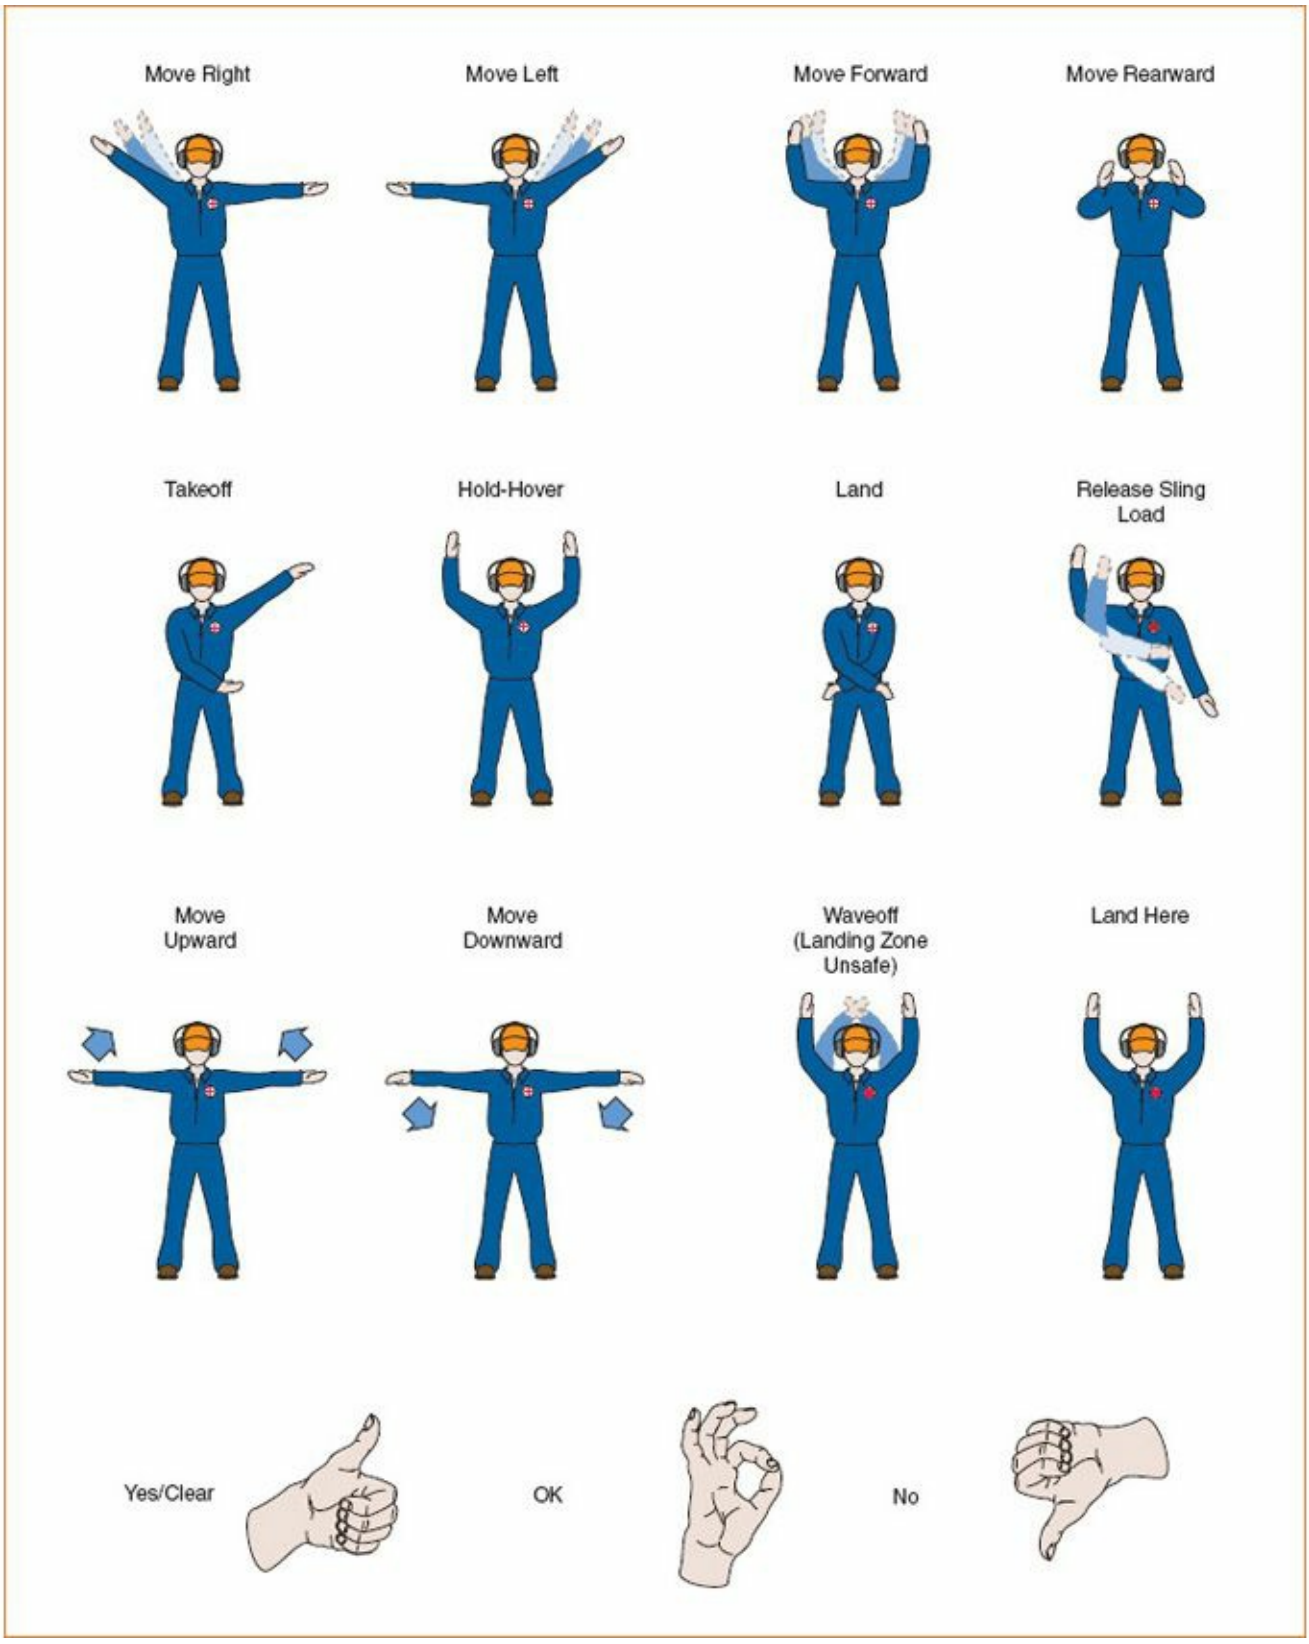

Figure 3-18 Helicopter hand signals.

Safety Training

All flight team members must have initial training on aircraft safety and survival, and then undergo refresher training annually. Every member of the flight team must be familiar with the different types of aircraft that are operated by the program. It is also useful for flight team members to be familiar with the different types of aircraft that are used by programs located in nearby areas in case they operate on a dual

mission and need to assist with loading or offloading patients. Also, if flight team members are hospital based, they will routinely assist with aircraft loading and unloading on their hospital's helipad.

A comprehensive safety training program needs to address the following issues:

- Aircraft familiarity
- Behavioral characteristics of aircraft during hard landing sequence/crash landing
- Equipment storage
- Personal protective equipment
- Egress training

For example, flight team personnel need to routinely train on evacuating the aircraft while blindfolded to simulate a smoke-filled environment. During training, personnel should be instructed to use aircraft exits that they normally would not use, so as to simulate blocked or jammed doors. Programs that fly over water should also incorporate water egress training using a simulator called an aircraft dunker.

Daily Safety Briefing

To protect patients and all members of the critical care transport team, it is imperative to be familiar with the inherent occupational safety risks. Critical care transport teams should hold **daily safety briefings** at the beginning of each scheduled shift. These briefings should include the daily plan, crew member duties, equipment and aircraft issues, weather expectations, and emergency situations **Figure 3-19**.

Although crew members share in all aspects of each mission, individual crew members often agree to assume primary responsibility for certain duties during the shift. For example, one crew member may agree to manage blood products, and the other may be responsible for medications. Even though one crew member may take primary responsibility for a task, the overall responsibility of all aspects of the shift is shared. Other issues that are usually addressed include reminders of general safety issues such as maintaining two pairs of hands on the stretcher, no storage of medical equipment on a step or skid, and crew comfort level.

During the daily safety briefing, the pilot in command also briefs crew members on weather forecasts and determines if the crew will be ready to respond or if a weather check is needed before making a "go or no go" transport decision.

Figure 3-19 Before each shift, the pilot gives the daily safety briefing.

Crashes and Hard Landing Operations

Several circumstances may result in unscheduled landings or hard landings. An unscheduled landing may

be a normal landing but occurs at a point other than the intended landing site. A **hard landing** is when the aircraft contacts the ground harder than normal, possibly resulting in injury or aircraft damage. Unscheduled landings are primarily due to either unexpected weather (IFR situations with a VFR-rated pilot or aircraft) or a non–life-threatening mechanical problem with the aircraft. Hard landings can result from any of the following:

- Engine failure
- Mechanical failure
- Wire strike
- Pilot error
- Incapacitated pilot

Use of Radios and Emergency Locator Transmitters

In the event of an aircraft emergency, medical flight crew members may be required to switch VHF radio frequencies to the international mayday frequency of 121.5 MHz. This frequency is always monitored by air traffic controllers, military agencies, and search-and-rescue groups.

Most aircraft today carry an **emergency locator transmitter (ELT)** on board; indeed, most aircraft operators are mandated by the FAA to have an ELT on board **Figure 3-20**. ELTs are designed to activate with 4g of force in the event of a crash. The ELTs transmit a distress radiobeacon to satellites in geostationary and low-altitude earth orbits. These satellites then transmit the signal to distress radiobeacons, which are monitored at ground receiving stations referred to as local user terminals. These terminals receive and process the satellite downlink, allowing rescue agencies to coordinate search-and-rescue missions.

Preparing for a Crash or Hard Landing

Crew members may only have seconds to react if a hard landing or crash landing is going to occur. If the crew realizes that the aircraft will impact the ground, the oxygen needs to be immediately shut off. If there is a patient on board, the head of the stretcher should be elevated to 30°, or per manufacturer's instructions for a hard landing. Crew members should also make sure their seatbelts are tight and their helmet straps are secured. They should ensure that they are free from entanglement hazards such as the communication system or monitor cables and cords. Crew members should brace for impact, ideally maintaining one hand on the aircraft door to maintain a point of reference for exit after the crash.

Figure 3-20 An emergency locator transmitter.

The best time to prepare for a crash is before it happens. CCTPs must be physically and mentally

prepared to survive **Figure 3-21**. The following rules should be practiced until they become instinctive:

- Never exit a crashed helicopter until the blades stop turning. After a crash, blades may not function properly and could cause grave injuries if they come into contact with a person.
- After exiting the helicopter, all crew members should meet at the 12 o'clock position, which is directly off the nose of the aircraft (shown in Figure 3-16), *before* attempting to rescue crew members or patients still in the aircraft. Individual safety comes *first*. If there is fire or debris at the 12 o'clock position, crew members should assemble at a safe location nearby.
- If the pilot is incapacitated, crew members should be proficient in operating throttle, fuel, and battery switches to decrease the likelihood of fire and explosions.
- In the event of a crash into water, the helicopter will likely flip because it is top heavy. Crew members should place one hand on the ceiling of the aircraft to use as a reference point. Doing so enables them to reference up and down and in and out directions. The general rule is to follow your bubbles as they always lead to the surface. Reference points should also be used in darkness and when smoke is present.

Figure 3-21 After a crash, CCTPs must properly exit the aircraft and avoid exposure to fire.

Dealing With the Aftermath of a Hard Landing

If the aircraft experiences a hard landing, several important steps must be followed. Upon landing, the flight team must ensure that all motion of the aircraft has stopped before attempting to exit. This is especially important in the rotor-wing environment, where the blades may still be spinning after the aircraft has landed. A good rule of thumb is to slowly count to five after the aircraft comes to a complete stop before attempting to exit. Once flight team members have exited the aircraft, their next priority is to attempt the immediate rescue of the other flight team members. If they are unable to extricate the other crew members or if a fire prevents such rescue, flight team members must proceed to a safe distance from the aircraft and assemble at a predesignated location. Unless otherwise stated by a specific program, the predesignated meeting point is at the 12 o'clock location in front of the aircraft. Once the flight team has assembled at this location, they can begin treating any injured persons and make plans for a rescue attempt for the patient in the aircraft if one was onboard.

Once the aircraft has cooled down and the immediate threat of fire has been resolved, the flight team needs to develop a plan of action. This plan must include the salvage of survival gear from the aircraft along with any usable pieces of the wreckage that may be used for shelter or signaling.

Safety and Survival After a Crash

As with a crash, the best time to prepare for survival is before the need to survive. Preparation and education in survival techniques increase the likelihood of a positive outcome and should be included in every critical care transport program.

At a minimum, the following elements should be included in survival training programs:

- Location and contents of the aircraft survival bag. Crew members need to be intimately familiar with each piece of survival equipment and its intended use.
- Directions for construction of a temporary shelter to protect crew members and patients from the elements. This training should include evaluation of a suitable location free from future dangers, the basic parts (roof, floor, and walls), and assembly of temporary shelter using limited resources.
- Survival priorities. This training should prepare crew members to prioritize their basic physiologic needs, using the **rule of 3s**, which prioritizes the basic physiologic needs for survival as follows: The average person can survive 3 minutes without oxygen, 3 hours without shelter, 3 days without water, and 3 weeks without food.

Upon exiting the aircraft after a crash, crew members must size up the situation, the available equipment, and the number and severity of everyone's injuries. Unless help is immediately visible, it is good practice to stay within close vicinity of the aircraft. It is much easier for rescuers to locate the wreckage of an aircraft than it is to find individual crew members. By staying near the aircraft, the team members also are able to salvage and use most of the parts of the aircraft for survival **Table 3-6**.

Previous rehearsal of emergency procedures usually results in automatic action on the part of the individual during a crisis. Through such training, you will also learn your own limitations. By knowing yourself, you can anticipate the fears you are likely to experience. The anticipation of fear can help you avoid panic, which is deadly. It is important to maintain a realistic, yet positive, attitude and remember what is at stake.

Air medical crews must be proficient in safety and survival operations. They need to routinely practice egress operations from the aircraft and activities after the crash. People will act in accordance with how they are trained. Proper, frequent training saves lives in the event of an aircraft emergency.

Increasing the Survival Odds

There are six important tips for increasing survival:

1. Conserve strength, fluid, and heat by moving as little as possible and as slowly as possible.
2. Prepare emergency signals, make shelter, inventory supplies, and ration all food.
3. Guard against infections and intestinal disorders.

TABLE 3-6 Aircraft Parts List and Usage

Aircraft Part	Potential Use
Battery	Signal lights, communication, fire starter
Cowlings	Signal panels, water collection, fire pit, shelter
Doors	Shelter, windbreak, signal panel
Engine oil and fuel	Fire starter, signal fire
Fuselage	Shelter
Seats	Insulation, fire material, signal material

Tires	Black smoke signal

4. Do not travel in adverse weather if injured or confused. If you stay put, eventually someone will find you. Numerous searches have found that search parties were inadvertently moving in concert with the victims, often within hundreds of yards of each other without realizing it.
5. Stay with the downed aircraft. The wreckage is easily spotted from the air, and it is the first place where the search will begin. Determine your location, and scout the immediate area for shelter, water, and food.
6. If you must travel, do not separate parties. Mark your path, leave messages behind, and keep a log.

The ability to signal is vitally important in increasing survivability. The first rule of signaling is to increase your visibility—whether by staying near the aircraft wreckage or moving to a nearby clearing or higher elevation. It is important to carefully consider the decision to leave the wreckage, as it is one of the first places where rescue crews will begin their search.

Hydration is of paramount importance following a crash. In survival operations, finding potable water is the immediate priority after shelter has been obtained. A person who uses thirst as a guide drinks only two thirds of his or her daily water requirement. To prevent dehydration, use the following guide:

- At temperatures below 100°F (38°C), drink 0.5 L of water every hour.
- At temperatures above 100°F (38°C), drink 1 L of water every hour.

Crash survivors must also guard against despair and protect themselves from pain, cold, thirst, fatigue, boredom, loneliness, and fear or panic. The number one killer of crash survival victims is panic. The four most common causes of death in the survival setting are panic, carelessness, faulty and inadequate equipment, and incorrect survival behavior. Powerlessness and despair increase fear and must be overcome. Decrease fear as follows through:

- Training
- Faith in your equipment
- Faith in the technical knowledge of the immediate superior
- Concentration on the task to accomplish
- Trust in providence/God

One of the most critical elements in ensuring survival is also the easiest to manage. Immediately after the crash, once you are in a safe area and have rescued all survivors, stop and sit down. Lean back against a tree or a boulder and relax. Force yourself to take six slow deep breaths. Think about your situation and plan out exactly what you need to do. This begins conservation of your physical and mental resources. By taking these steps, you have increased your survival chance by 50%!

Water Ditching

A recent NTSB report indicated that of 63 pilots who died after a crash into water (**water ditching**), 78% were located inside the aircraft and died of drowning; only 20% died as a result of their injuries or because of nonfatal incapacitation. Every year, approximately 30 to 40 general aviation ditchings occur in US coastal or inland waters. Most crew members will have less than 15 seconds' notice that the aircraft is going to ditch. If ditching is imminent, immediately assume the crash position and disconnect your headset to prevent an entanglement hazard. If there is time, tighten your seatbelt, turn off the oxygen, lay the patient flat, and secure all items.

Airplanes and helicopters act differently in water. Airplanes will usually float for several minutes before sinking. By contrast, after the helicopter makes contact with the water, it will usually capsize because it is top-heavy, which results from the weight of the engines and transmissions.

Once the aircraft makes contact with the water, four important steps need to be followed to successfully egress the aircraft.

First, resist the urge to exit the aircraft immediately; instead, sit and count to five to ensure that all motion of the aircraft has stopped. The rotor blades may continue to turn after the aircraft has hit the water, and counting to five will prevent crew members from exiting the aircraft and running into the path of spinning blades.

Second, identify and open your exit using the deliberate offset method **Figure 3-22**. To find the exit handle, put your hand on your knee, with your knee against the cabin wall. Start low and feel your way up until you find something you recognize, such as the armrest or a door seam. From there, work your way up to the exit handle. This exit may be jammed shut or blocked, so always know an alternate exit.

Third, grab hold of a reference point that you are familiar with in the direction of your exit. Do not release your belt until you have a secure grip on a reference point. If the aircraft is inverted, under water, or dark, you can become disoriented as soon as you release your seatbelt. Using the hand-over-hand method, you should always maintain one hand on a reference point and not let go of it until you grip another reference point.

Figure 3-22 The deliberate offset method. **A.** Put your hand on your knee, with your knee against the cabin wall. **B.** Starting low, feel your way up until you find something you recognize. **C.** From there, work your way up to the exit handle.

Fourth, once the exit is open, keep a hold on that reference point, release your seatbelt with the other hand, and pull yourself through your exit. As you exit the aircraft, do not kick; you could get stuck in wires or debris. If you become stuck, don't panic: Try backing up a bit and rotating a little before proceeding. Be prepared to encounter aviation fuel in the water, which can blind you. Also, remember to continually exhale as you ascend to the surface to prevent barotrauma. If you become disoriented in water as to the direction of the surface, you can follow your bubbles or swim opposite of the direction that causes pressure to build in your ears.

Summary

The air medical environment is a complex mix of aircraft operations and treatment of the critically ill and injured. Medical crew personnel must have a strong knowledge both in aircraft operations and in critical care treatment. Working in the air medical environment is filled with risks, and providers must take every step possible to limit their exposure to danger. Many different agencies are actively working to reduce the

risk of aircraft crashes, and flight team personnel are encouraged to become involved and aggressively work to make the industry safer. The air medical transport industry continues to grow, and flight team personnel must be ready to meet the myriad of challenges that they will inevitably face as air medical transport professionals.

Case Study

AT 3:25 AM ON A SUNDAY MORNING, you and your crew are fast asleep at your flight base. Your flight tones sound, alerting you and your crew of a pending flight.

Dispatch: Air One, Air One, you are requested for a scene flight. Coordinates and landing zone information will follow with acceptance of flight.

You and your crew jump out of bed, don your flight suits, and head for the aircraft. The pilot checks the weather to ensure that the ceiling and visibility are within night weather limitations. He gives the thumbs ups and alerts dispatch that the flight is a go. Before liftoff, the flight crew performs their walk-around of the aircraft.

The flight crew load into the aircraft, donning their flight helmets and seatbelts. The pilot asks, "Flight crew ready?" You respond, "Ready on right," and your partner responds, "Ready on left." The radio communication continues.

Dispatch: Air One is off the ground and en route to scene.

Dispatch: Air One, Air One, ready to copy coordinates.

Pilot: Dispatch, Air One is ready to copy coordinates.

Dispatch: Air One, your coordinates are 34° 3′ 5′ N, 118° 14′ 57′ W You will be landing in a parking lot, which has a 100′ × 100′ area cleared of all obstructions and hazards. The fire department is on scene and will be coordinating the landing zone. The fire department will be on frequency 15 for further communication.

Dispatch: Air One medical crew, ready to copy patient information.

Air One Medical Crew: Dispatch, Air One medical crew is ready to copy patient information.

Dispatch: You are responding to a two-vehicle motor vehicle collision. Your patient is a 25-year-old male with major head trauma, distended abdomen, and a deformed right femur. Vital signs are blood pressure 90 by palpation, pulse of 132 beats/min, respiratory rate of 28 breaths/min.

Air One Medical Crew: Copy patient information.

Air One Medical Crew: Local fire department, this is Air One, we have a 5-minute ETA to the scene. Can you provide us with updated landing zone information?

Local Fire Department: Air One, you will be landing in a parking lot that has been cleared of all vehicles. Local law enforcement has secured the scene to prevent any vehicles from entering into the landing zone. The landing zone is 100′ × 100′. Power lines are on the north side of the landing zone. Power lines will be marked with a police vehicle under the lines with its running lights on. The landing surface is level and absent of further obstructions and hazards.

Air One Medical Crew: Copy landing zone information, we have an ETA of 2 minutes. Because of the patient's condition, we will be remaining hot once we land. Do you have a landing zone coordinator who will be maintaining a secure and safe landing zone after we exit the aircraft?"

Local Fire Department: Roger that, we will ensure that bystanders are kept away from the aircraft.

The scene becomes visible to Air One. The pilot performs a high reconnaissance of the landing zone. The pilot and crew all agree that the landing zone is adequate and safe to land. The pilot makes a slow approach into the landing zone; the flight crew is looking out the right and left windows. You state "clear right" and your partner states "clear left." The pilot brings the aircraft in slowly and touches down. The flight crew awaits permission from the pilot to exit the aircraft.

The crew members exit the aircraft and are instructed on the location of the patient. They are informed that the patient is located in ambulance 32. The flight crew approaches the ambulance and enters through the rear door of the ambulance. They receive an updated report on the patient. The medic on the scene reports that the patient needs to be intubated, but is "clamped down" and was unable to be intubated without the use of rapid-sequence intubation. The flight crew performs a rapid trauma assessment, attaches the patient to transport monitors, and prepares to perform rapid-sequence intubation. The patient is successfully intubated and packaged for transport. He is transported to the aircraft via stretcher.

As the flight crew approaches the aircraft, they provide a quick debrief of the safety around the aircraft. They inform the ground crew that they will approach the aircraft from the front, once the pilot gives the go-ahead. They ensure that all loose objects are secure and that the ground crew has eye and hearing protection. Once the flight crew has ensured that it is safe to approach the aircraft, they enter into the landing zone from the front of the aircraft, maintaining eye contact with the pilot. Once the flight crew and ground crew reach the aircraft, your partner climbs into the aircraft to assist with loading. You remain on the outside of the aircraft to assist the ground crew. The patient is lifted off the stretcher via the backboard and loaded into the aircraft.

All of a sudden you hear a loud crash, and debris of metal is flying everywhere. Everyone is ducking and taking cover. The pilot immediately shuts down the aircraft. It becomes apparent that the ambulance stretcher rolled into the tail rotor, causing major damage to the tail rotor. Luckily, no one on the scene was injured. The pilot informs dispatch of the incident and states that they are "grounded" and requires the aircraft mechanic to report to the scene. The flight crew informs the ground crew that the patient needs to be transported by ground. The patient is unloaded from the aircraft, transferred to another ambulance, and transported by ground to a local Level I trauma center, with the flight crew on board.

1. What is the purpose of performing a walk-around of the aircraft?
2. What is the specific reason for responding "ready on right" and "ready on left"?
3. What is the purpose of high reconnaissance?
4. What went wrong?
5. Could they have flown the patient if there was minimal damage to the aircraft, especially since the patient's condition was critical?
6. Was it necessary for the flight crew to accompany the patient to the hospital with the ground crew?

Analysis

The tail rotor is one of the most dangerous areas in rotor operations. Contact with an operating tail rotor is usually serious or fatal. This scenario illustrates the importance of assigning a tail rotor guard and ensuring that all personnel and equipment are kept away from the tail rotor.

During a hot load, the aircraft remains running and the pilot maintains the aircraft. Hot loads may be necessary when a patient's condition is critical, but they impose several safety risks, including walking into the rotor, dipping rotor blades, and debris blowing into the rotor blades. A landing zone coordinator must be assigned and is responsible for ensuring that no one approaches the aircraft. He or she also

minimizes other hazards, for example by ensuring that hats are removed, no one carries anything over the head, and everyone is aware of the danger zones.

A cold load occurs when the aircraft is completely shut down during loading of the patient. This is the safest type of load.

Regardless of the type of load being performed, no one should approach the aircraft during start up or shut down. The aircraft should not be started until the landing zone is clear of all personnel.

Walk-arounds are performed to ensure that all doors, bolts, and hatches are secure, to prevent any doors from opening during flight, and to ensure that there are no loose bolts or hatches that could loosen in flight and damage the aircraft.

The statement "ready on right" or "ready on left" informs the pilot that the flight crew is ready for take-off and that they are looking out the side windows for other aircrafts or obstructions that may not be visible to the pilot. This is part of crew resource management, which holds the entire crew responsible for the safety of the crew and aircraft.

The purpose of the high reconnaissance is to allow the pilot and crew to view the scene and to identify potential hazards that the ground crew may not have identified. At this time, the pilot ensures that the landing zone is adequate.

This incident could have been prevented if the ground and flight crews had assigned someone to maintain the stretcher. Any incident that can cause possible damage to the aircraft requires the aircraft mechanic to inspect the aircraft and repair any damage that has occurred, including bird strikes, unusual noises, or vibration. Safety always comes first in air medical transport.

Once the flight crew accepted the patient and "took over care" they had to maintain that patient care. Flight medical crews are often considered a higher level of care than ground medical crews. Therefore, if they fail to accompany the transport, it would be considered abandonment.

Prep Kit

Ready for Review

- The CCTP needs to be familiar with both rotor-wing (helicopter) and fixed-wing (airplane) operations. Aircraft safety and operations are the primary concern.
- Critically ill or injured patients and those who would have a negative outcome with prolonged transport by ground units benefit most from air medical transport.
- Evaluate the benefits vs risks before transporting a patient via air. Consider the potential effects of altitude on the patient and the terrain, weather, and geographic location of the closest facility.
- VFRs are used when there is generally very good visibility and minimal cloud cover.
- IFRs apply when adverse weather conditions exist, visibility is poor, or the cloud cover is low.
- An authorized ATC facility may provide flight following to aircraft flying VFR, in which the controller notifies the aircraft about traffic in the area.
- If a pilot flying VFR in a helicopter decides not to flight follow with ATC, real-time radio contact with a communications center must occur every 15 minutes.
- During fixed-wing operations, when a flight plan has not been filed, the pilot in command must make contact with ATC or a communications center every 30 minutes.
- While transporting a patient in a ground unit, communication lapse must not exceed 45 minutes.
- There are two types of air medical transport: rotor wing (helicopter) and fixed wing (airplane). Rotor-

wing transport is used most commonly. Fixed-wing transport is typically used for flights of 200 nautical miles (300 miles) or greater, international transports, and transports that cannot occur by rotor wing because of weather conditions.

- Advantages of rotor-wing transport include vertical takeoff and landing (ability to access areas where other vehicles cannot) and ability to maneuver.
- Disadvantages of rotor-wing transport include weather limitations (must fly VFR), interior space limitations, weight limitations, and cost.
- Advantages of fixed-wing transport include that it is generally safer than rotor wing, ability to fly IFR, ability to fly at high speeds, ability to travel great distances, ability to carry multiple patients, and no weight limitations.
- Disadvantages of fixed-wing transport include high cost for operating the aircraft, performing maintenance work, and maintaining a hanger for housing the aircraft.
- One of the benefits of air medical transport is specialty. A flight crew's protocols may allow a higher level of care than even a critical care transport ground crew's protocols.
- Hazards of air medical transport relate primarily to rotor-wing hazards, such as moving tail rotors.
- The cost of air medical transport is generally high. There must be solid justification for helicopter use in order for insurance companies and/or Medicare to reimburse flight programs.
- Most air medical providers do not routinely transport patients in active cardiac arrest.
- Patients who will not benefit from air transport include those with terminal illnesses, do not resuscitate orders, and arrest without return of spontaneous circulation; and those whose conditions will overwhelm the capabilities of the crew.
- Relative contraindications to air medical transport include severe anemia, hemoglobinopathy, myocardial infarction within 10 days or complications in the 5 days before the flight, uncontrolled arrhythmia, pregnancies past 24 weeks' gestation, recent eye surgery affecting the globe, and non-acute hypovolemia.
- Helicopter EMS is one of the most dangerous forms of aviation with a very high accident rate compared with other sectors of aviation.
- Aircraft crashes are never caused by one single event, but rather by a series of factors. Human error is the number one cause, and weather is the main contributing factor.
- Crew resource management was developed to address communication issues that resulted in fatal crashes.
- All members of the crew should hold equal empowerment regarding whether to accept a mission. If any crew member does not feel comfortable with a mission, the mission should be aborted.
- Two FAA guidelines apply to air medical operations: Title 14 CFR Part 91 and Title 14 CFR Part 135. The guidelines for 14 CFR Part 135 operations are much stricter than those for 14 CFR Part 91 aircraft and apply to almost all air medical operators.
- The FAA requires that air medical transport programs designate someone for the position of operational control. This is the person who has the ultimate authority to initiate, conduct, and terminate the EMS mission, and has ultimate authority over all of the flight operations for the program.
- A weather decline is when an air medical provider refuses a mission because the weather does not meet established company or FAA guidelines for flight operations.
- CAMTS publishes safety standards to which CCTPs and pilots should adhere. They have also

established weather guidelines that exceed FAA requirements and have been accepted by many air medical providers.

- The most common crew configuration in the air medical environment is flight nurse/flight paramedic. Other configurations include nurse/respiratory therapist, nurse/nurse, and paramedic/paramedic. Some services may include a perfusionist on the flight team.
- A standby is when an HEMS provider is notified of a potential need for air medical transport. While on standby, the air medical crew determines whether to accept the mission, prepares for the call, and awaits confirmation or cancellation.
- Some programs have an auto launch protocol, in which the aircraft launches en route to the scene when placed on standby instead of waiting for the formal launch request.
- Landing a helicopter can be very dangerous if the landing zone is not properly established.
- Landing zone personnel must use proper hand signals and must wear proper eye and ear protection at all times. No personnel should ever operate near the tail rotor.
- When loading patients into the aircraft, no one should approach the aircraft unless directed by the flight crew.
- One member of the flight team should be assigned as tail rotor guard to ensure that no one approaches the tail rotor.
- All flight team members must have training in aircraft safety and survival. Training should also include aircraft familiarity, hard landing sequence/crash landing, equipment storage, personal protective equipment, and egress training.
- Critical care transport teams should hold daily safety briefings at the beginning of each scheduled shift, covering the daily plan, crew member duties, equipment and aircraft issues, weather expectations, and emergency situations.
- A hard landing is when the aircraft contacts the ground harder than normal, possibly resulting in injury or aircraft damage.
- The best time to prepare for a crash is before it happens. Crash safety procedures should be practiced until they become instinct.
- Preparation and education in survival techniques should be included in every critical care transport program.
- Air medical crew should receive crash survival training, including location and contents of the aircraft survival bag, construction of a temporary shelter, and survival priorities.
- Be familiar with how to improve your odds of survival. It is crucial to avoid panic and anticipate your fears. Know how to signal, stay with the downed craft, and find potable water in order to stay hydrated.
- Water ditching is the term for crashing into water. Helicopters usually capsize because they are top heavy.

Vital Vocabulary

Air Medical Physician Association (AMPA) An organization of physicians and air medical professionals that promotes safe patient transport.

auto launch A protocol that launches an aircraft at the time it is placed on standby rather than waiting for

the formal launch request. An auto launch is frequently activated when the distance to be covered for the response is greater than 30 nautical miles.

Commission on Accreditation of Air Medical Transport Services (CAMTS) An organization dedicated to improving the quality of patient care and safety of the transport environment for both rotor-wing and fixed-wing providers. CAMTS also provides voluntary accreditation of critical care transport agencies.

crew resource management A system that originated as the result of a NASA workshop in 1979 as a means to improve air safety. It incorporates equipment, procedures, and crew concerns to make the best decision during flight operations, focusing on interpersonal communication, leadership, and decision making.

daily safety briefing A meeting held at the beginning of each critical care transport shift, in which the daily plan, crew member duties, equipment and aircraft issues, weather expectations, and emergency situations are reviewed.

emergency locator transmitter (ELT) A device that activates upon the crash of an aircraft and broadcasts a signal that rescuers can use to locate the downed aircraft.

Federal Aviation Administration (FAA) A US governmental agency within the Department of Transportation that regulates and oversees civil aviation within the United States; established and enforces the Title 14 CFR that govern aircraft operation within the United States.

flight following The practice of maintaining constant contact with other local traffic and air traffic controllers.

hard landing An excessively firm contact with the ground, potentially resulting in injury or aircraft damage.

helicopter emergency medical service (HEMS) Use of a rotor-wing aircraft to deliver air medical service, for which the goals are to rapidly transport CCTPs to a patient, stabilize the patient's condition, and rapidly transport that patient to a tertiary care center.

helicopter shopping The practice of making sequential calls to numerous air medical providers in an attempt to find a service that will accept a mission request that has been declined by other services based on safety factors such as poor weather, limited landing zone availability, exceptional distances, or other factors.

hot loading Loading a patient into a helicopter while the helicopter is running.

instrument flight rules (IFR) A mode of flight used when adverse weather conditions exist, visibility is poor, or cloud cover is low. The pilot may not be able to see outside the aircraft, must rely on instruments, and must be in constant contact with an air traffic controller who assists in maintaining proper separation from other air traffic.

instrument meteorological conditions (IMC) Weather conditions (eg, cloudiness or low visibility) in which a pilot must fly under instrument flight rules, depending on instruments to guide the aircraft.

International Civil Aviation Organization (ICAO) An agency of the United Nations that defines standards for international air navigation and, as part of its role in developing safe practices, requires crew resource management.

National Transportation Safety Board (NTSB) An independent federal agency that promotes transportation safety, including aviation, railroad, highway, maritime, pipeline, and hazardous materials safety; investigates transportation crashes to identify the cause and make safety recommendations.

operational control The person who has the ultimate authority to initiate, conduct, and terminate the EMS mission; in an air medical program, usually the chief pilot or operational manager.

overtriage Considering a patient to be in more serious condition than he or she actually is.

rule of 3s A means of prioritizing the basic physiologic needs for survival: The average person can survive 3 minutes without oxygen, 3 hours without shelter, 3 days without water, and 3 weeks without food.

somatogravic illusion An error in perception that occurs with acceleration, as the otolith organs are displaced rearward, similar to when a person is looking up. This perception of a nose-up altitude may cause the pilot to push the nose of the aircraft down inappropriately at night or in unlit terrain.

spatial disorientation An error in perception that may result from a person's inability to determine his or her position, altitude, and motion in relation to the surface of the earth or to a significant fixed object during flight.

standby The situation in which an HEMS provider is notified of a potentially life-threatening emergency call and makes preparations to respond to the call. During standby, the flight crew checks weather data, obtains landing coordinates, and conducts a preflight inspection of the aircraft.

sterile cockpit The time when unnecessary communication that could distract the pilot is banned in the cockpit—usually during takeoffs, landings, and any other critical phase of flight at the discretion of the pilot in command.

Title 14 Code of Federal Regulations (CFR) Part 91 Established by the FAA, this guideline governs the operation of all aircraft within the United States, including the waters within 3 nautical miles of the US coast.

Title 14 Code of Federal Regulations (CFR) Part 135 Established by the FAA, this guideline governs the operations of all commuter or on-demand commercial operations.

undertriage Considering a patient to be in less serious condition than he or she actually is.

visual flight rules (VFR) A mode of flight used when weather conditions are good, meaning there is generally very good visibility and minimal cloud cover; the pilot is responsible for maintaining separation from other aircraft.

water ditching Crashing into water.

weather decline A situation in which an air medical provider is requested, but the pilot and the flight team determine that the weather does not meet established FAA guidelines and therefore decline to make the flight.

AIR MEDICAL CREW

Flight Physiology

Authors

Mike Clumpner, BS, MBA, CHS, NREMT-P, CCEMT-P, PNCCT, EMT-T, FP-C

Objectives

1. Describe the composition of the atmosphere (p 70).
2. List the three physiologic zones in the atmosphere (p 71).
3. Discuss the seven primary gas laws affecting flight physiology (p 72–75).
4. Define the four types of hypoxia (p 76–77).
5. Describe the four stages of hypoxia as they relate to altitude (p 78).
6. Recognize the signs and symptoms of altitude-induced hypoxia and the appropriate treatment (p 80).
7. Summarize the advantages and disadvantages of pressurized and nonpressurized aircraft (p 80–81).
8. Recognize the physical and physiologic effects of rapid cabin decompression (p 81).
9. Define the effective performance time and the time of useful consciousness (p 76).
10. Describe the primary forces that act on an aircraft (p 81).
11. List the primary stressors of flight and their physiologic impacts (p 82–89).
12. Define the factors affecting tolerance of the stressors of flight (p 89–90).
13. Identify different dysbarisms and trapped gas disorders (p 90–91).
14. Describe assorted exacerbations of medical conditions due to altitude (p 75, 90).

Introduction

CCTPs must have a thorough understanding of flight physiology and the implications for their patients and for themselves. Critical care transport frequently involves air and ground transportation. Critical care providers who are solely ground based must still have a comprehensive knowledge of flight physiology because frequently they will prepare patients for air transport and will receive patients who have been flown in. Knowledge of flight physiology involves not only recognition of barometric maladies, but also, more important, the prevention of such problems.

The air medical environment is complex and extremely dynamic. Critical care providers frequently encounter comorbidities or multitrauma patients who are already in a severely compromised condition. Many conditions will be exacerbated by changes in the barometric pressure. Likewise, the forces experienced during flight can have significant impact on disease pathophysiology. Therefore, CCTPs must have a strong understanding of the effects of altitude on the body.

This chapter discusses the various gas laws that are pertinent to flight medicine and several common problems that can occur as the result of changes in barometric pressure. Related to barometric pressure, this chapter also discusses the advantages and disadvantages of pressurized and nonpressurized aircraft and the impact of decompression at altitude. CCTPs must have a solid understanding of the potential catastrophic consequences that can be experienced with rapid cabin decompression.

CCTPs must also be aware of the primary stressors of flight and the factors that can affect tolerance toward the stressors. Aircrew members need to also be familiar with different illusions of flight and spatial disorientation that can have disastrous impacts on flight operations. Some spatial disorientation can also have negative effects on patients and can precipitate serious medical conditions. A thorough

knowledge of flight physiology is essential to keep the flight crew airworthy and to prevent complications in the transport of critically ill and injured patients.

The Atmosphere

In his book *Basic Flight Physiology,* **flight surgeon** Richard Reinhart defines three distinct parts to flight: the aircraft, the flight crew, and the environment (the **atmosphere**). All three maintain a relationship of balance; however, the atmosphere directly affects the aircraft and the flight crew. The atmosphere is likened to an ocean of gases with defined layers of stratification.

The atmosphere extends from the surface of the earth to 348 miles (560 km), which is the beginning of space **Figure 4-1**. This chapter primarily discusses the components of the lower atmosphere in which all aviation occurs with the exception of space exploration. The atmosphere varies with time of day, season of the year, and latitude. Because of these variables, only averages are discussed in this chapter.

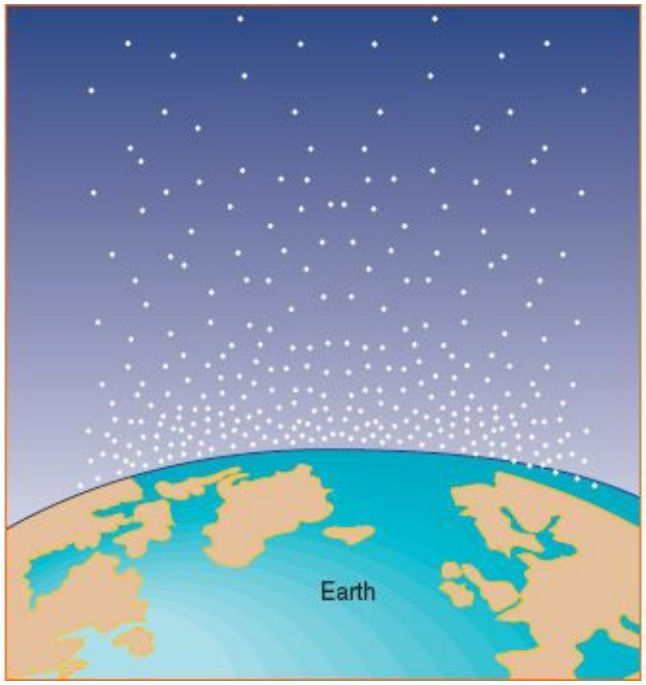

Figure 4-1 The density of the atmosphere decreases the farther you are from sea level.

Atmospheric Composition

The composition of the atmosphere is constant and is defined as a percentage of gases instead of absolute amounts. Although the percentage of gases is constant, the density of the gases varies with the altitude. Three gases constitute almost 99% of the atmosphere, which remains constant from the surface to altitudes of 250,000′. Oxygen constitutes 21% of the atmosphere. A by-product of photosynthesis, oxygen is the most critical gas needed to sustain life. Nitrogen is the most abundant gas in the atmosphere, accounting for 78% of the total volume. Nitrogen is responsible for the majority of the composition of the atmosphere and is an inert gas that is odorless, colorless, and tasteless. This gas is not readily used by humans; however, it is a critical element for life. Nitrogen is present in the human body in abundant quantities and can be responsible for evolved gas disorders at altitude or after rapid ascent while scuba diving. Argon constitutes approximately 0.93% of the atmosphere. The other trace gases that are found include carbon dioxide, neon, helium, methane, krypton, and hydrogen. No matter what the altitude, the percentage of oxygen will always be about 21%. During ascent in altitude, the molecules of oxygen spread out and become less numerous in each breath. This is why it can be difficult for human beings to breathe at high altitudes, such as at the top of Mount Everest.

Layers of the Atmosphere

There are several distinct layers of stratification of the atmosphere. Gravity holds the layers of the atmosphere in place. Five distinct layers have been identified using thermal characteristics (temperature changes), chemical composition, movement, and density. The density of the atmosphere decreases with height because the weight of the molecules actually compresses the gas near the earth's surface.

The first layer is called the **troposphere**. The troposphere extends from sea level to about 26,405′ over the poles and nearly 52,810′ above the equator. Virtually all weather occurs in the troposphere because of the presence of water vapor and strong vertical currents. In this layer, clouds form, rain falls, wind blows, and humidity varies depending on the climate. Winds in the troposphere become stronger westerly with increasing west to east winds at altitudes higher than 35,000′. The strong jet stream is located above 35,000′, and maximum winds in the jet stream average 200 mph at about 30° latitude north or south.

The troposphere is the densest portion of the atmosphere. Temperature varies from 62.6°F (17°C) to –68.8°F (–56°C) and decreases proportionately with increases in altitude. The **tropopause** is the layer between the troposphere and the stratosphere, which is the next layer. The tropopause ranges in height from 30,000′ at the poles to more than 60,000′ at the equator. More solar energy is received by the earth near the equator, causing the air to heat and expand. This expansion of rising air increases the height of the tropopause. Conversely, the cool air at the poles results in contraction and shrinkage of the air, resulting in a lesser height of the tropopause. The tropopause and the troposphere are known as the lower atmosphere.

The layers above the tropopause include the stratosphere, stratopause, mesosphere, thermosphere, and exosphere, in that order. Critical care transports would not usually occur at these altitudes. **Figure 4-2** shows the layers of the atmosphere and how they compare with the zones of the atmosphere, to be discussed next.

Physiological Zones of the Atmosphere

The atmosphere is divided into three distinct zones that directly correlate to a human's response to hypoxia. These zones are the **physiological zone**, the **physiologically deficient zone**, and the **space equivalent zone**.

Physiologic Zone

The physiologic zone is the area of the atmosphere that contains the oxygen and barometric pressure needed for a normal, healthy person to live. This zone extends from sea level to 10,000′. In this zone, the barometric pressure falls from 760 mm Hg at sea level to 523 mm Hg at 10,000′. The pressure at 10,000′ is still enough to maintain an adequate **partial pressure of oxygen (arterial) (Pa_{O_2})** without the use of supplemental oxygen, pressurization, or protective equipment. However, it is important for CCTPs to realize that at 10,000′, many healthy people will begin to experience very mild effects of hypoxia, such as a mild headache, and almost all patients with comorbidities will be hypoxic at this altitude. Part 135.89 of the Federal Aviation Regulations (FAR) states that commercial pilots must use supplemental oxygen when flying above 10,000′.

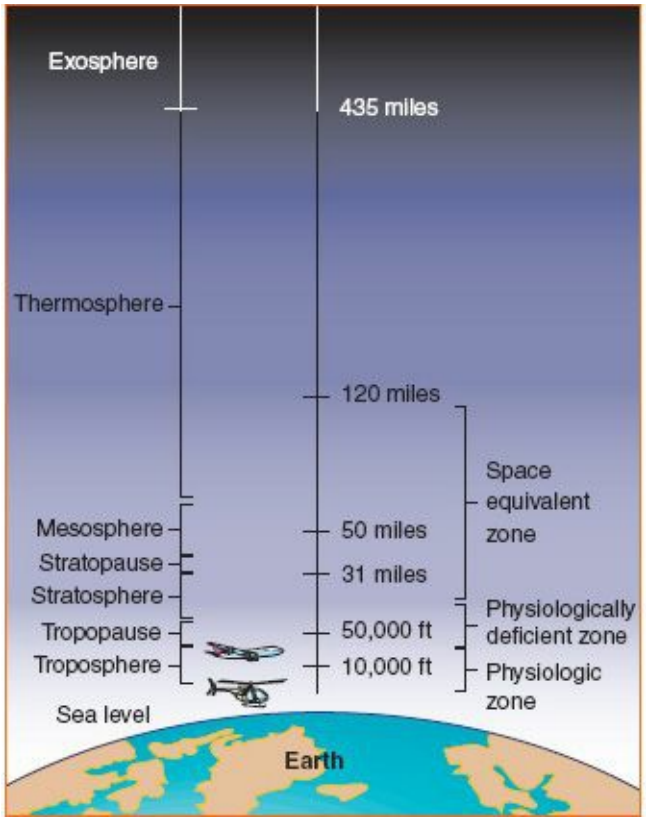

Figure 4-2 The layers and zones of the atmosphere.

Rapid changes in altitude at this level can produce trapped gas conditions such as ear or sinus problems; however, these problems are considered relatively minor compared with the physical impairments that occur at higher altitudes. Altitudes above 5,000′ can also affect night vision unless supplemental oxygen is used.

Physiologically Deficient Zone

The area from 10,000′ to 50,000′ is called the physiologically deficient zone. Above 10,000′, barometric pressure begins to decrease to levels that will result in hypoxic hypoxia, which is discussed later in this chapter. Barometric pressure at this level ranges from 523 mm Hg at 10,000′ to 87 mm Hg at 50,000′. At these altitudes, the effects of trapped gases become more pronounced, and protective equipment, supplemental oxygen, and pressurized aircraft are necessary.

Space Equivalent Zone

The space equivalent zone extends from 50,000′ to 120 miles. At this point in the atmosphere, 100% supplemental oxygen is no longer adequate because of the inadequate barometric pressure. Pressure suits and sealed cabins are also required. Two additional hazards can be present. Exposure to atmospheric conditions could result in the boiling of body fluids as the fluids turn to a vapor. Personnel may also be exposed to increased levels of radiation from the sun in this zone. Currently, no commercial aircraft used for air medical transport operate in this zone.

Barometric Pressure

Barometric pressure, also called atmospheric pressure, is a direct result of the weight of air. Barometric pressure varies with location and time because the amount and weight of air above the earth vary with time and location. Barometric pressure is also related to the density of the air, which is related to air temperature and height above the earth's surface. Thus, **barometric pressure** is the weight per unit area of all of the molecules of the gas above the point at which the measurement was taken, with temperature

and humidity as variables. Barometric pressure is also related to weather and is one of the most important factors that determine weather.

Barometric pressure is reported in different measurements, most commonly inches of mercury in the United States, but millibars are used in most countries that use the metric system, such as in most of Europe. There are different scientific definitions of the atmosphere. The two most prevalent definitions are the US Standard Atmosphere and the International Standard Atmosphere. The US Standard Atmosphere has been recognized for the longest time; however, the International Standard is now more widely recognized across the globe.

Gas Laws

It is critically important that CCTPs have a thorough knowledge of the assorted gas laws as they relate to both flight and hyperbaric medicine. The various gas laws have an important role not only in patient care, but also in the overall safety of the flight crew. There are seven gas laws that are integral to flight physiology, some of which are interdependent.

Boyle's Law

Robert Boyle studied the relationship between the volume of a dry gas and its pressure. To study the relationship of volume and pressure, he fixed the amount of gas and its temperature. Boyle found that when he increased the volume of the gas, the pressure decreased. Likewise, a decrease in volume resulted in an increase in pressure. **Boyle's law** can be remembered by the saying, "Boil Very Prudently," where Boyle = Volume (Very) × Pressure (Prudently). A practical example is that as altitude increases, the atmospheric pressure decreases. This means there is less outside pressure on gas molecules holding them close together. As a result, the gas molecules expand, or drift apart. For example, a bag of unopened chips on a commercial air flight expands as the altitude of the aircraft increases. During descent, the bag of chips shrinks back to its original size.

Boyle's law has numerous implications in aviation medicine. Any gas trapped in the chest, such as in a pneumothorax, will expand approximately 35% when going from sea level to 8,000′ **Figure 4-3**. At 18,000′, a given volume of gas will expand to twice its size. The key to minimizing the effects of altitude is to maintain the lowest possible cabin pressure during flight. As a general rule-of-thumb, altitude will not become a significant factor until 3,000′ above ground level. Most people, except people with significant respiratory disorders, tolerate altitudes of 5,000′ with minimal disturbances. However, below 10,000′—even as low as 3,500′—there can be significant effects on unhealthy people. Partly because of these facts, most helicopter transports are conducted at or below 3,000′ above ground level.

Several disease processes can have a drastic effect with increasing altitude. An injury such as a pneumothorax can quickly become a tension pneumothorax as altitude increases. Patients with an open skull fracture are at risk for pneumocephalus because air becomes trapped inside the skull and expands with altitude, causing a significant increase in intracranial pressure. Patients with **pneumoperitoneum** (the collection of air within the peritoneum) or **pneumomediastinum** (the collection of air within the mediastinum) are also susceptible to the changes in altitude. Although these disease processes might not cause a high-tension event within the body, they cause significant discomfort.

Boyle's law also applies to the expansion of any trapped gas within the body in such places as the middle ear, sinuses, stomach, and intestines. There are also many pieces of medical equipment that are exquisitely sensitive to an increase or decrease in barometric pressure. The cuffed balloon on endotracheal tubes can double in size from 5,000′ to 10,000′, causing the balloon to rupture or cause tissue necrosis if allowed to remain hyperinflated for a length of time. Therefore, cuffed balloons should

be filled with saline before flights planned for above 6,000′, or cuff pressure should be monitored and adjusted.

IV fluids also are sensitive to changes in barometric pressure. The rate of flow of fluids in a glass bottle, such as nitroglycerin, will increase because of the changes in altitude and the inability of the bottle to expand or contract. The rate of fluids that are allowed to free flow can increase drastically at altitude as pressure causes expansion inside the bag. Because of the short height of aircraft cabins, most IV fluids are unable to flow readily and can frequently back up in the IV tubing. Therefore, the use of pressure infusers to administer fluids is recommended. The use of a "dial-a-flow" to administer IV fluids is not considered reliable, and IV infusion pumps should be used instead.

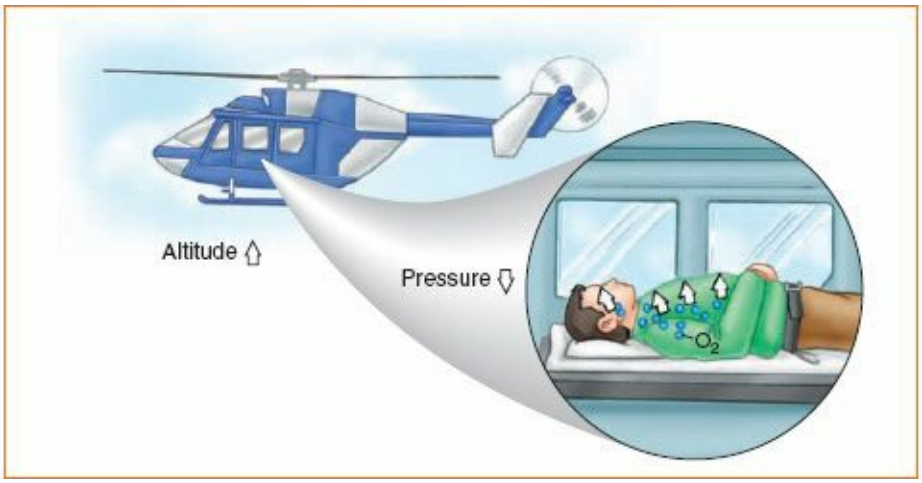

Figure 4-3 Boyle's law. As altitude increases, atmospheric pressure decreases, and gases inside the body expand.

Although most services do not use pneumatic antishock garments (PASGs) and their use is no longer routinely recommended, providers must still be aware of the dangers of PASGs at altitude. If a patient is flown wearing PASGs, CCTPs must give close attention to the PASGs, and as soon as the Velcro begins to "pop off," the relief valve must be opened or the PASGs will come apart. The same concept applies to air splints at altitude. Some models of air splints have pressure relief valves that will activate, but other models do not and must be adjusted manually.

All patients who have a nasogastric or orogastric tube inserted should be transported with the tube open or frequently vented. Patients with colostomy bags should frequently have the built-up gas "burped" to prevent overpressurization and failure of the colostomy bag.

Charles' Law

Discovered in 1787 by Jacques Charles, **Charles' law** states that the volume of a gas is directly proportional to the temperature, with the pressure remaining constant. The practical application is that as the air heats up, the volume increases, allowing the molecules to spread out, making the air less dense. It is easier for a helicopter to fly in cold weather because the gas molecules are more compressed and allow more lift as the rotor blades spin. In hot weather, gas molecules are farther apart and provide less lift. There are fewer molecules for the blades to "push off of." For this reason, the amount of weight a helicopter or airplane can carry is less on a hot, humid day than on a cold, dry day.

Charles' law can be remembered by the phrase "Charles' cold" or "Charles Celsius." Charles' law is significant in flight medicine because aircraft cabins get very, very cold at altitude without supplemental heat **Figure 4-4**. This cold temperature puts patients and crew at significant risk for hypothermia. CCTPs need to take measures to keep themselves and their patients warm.

Dalton's Law

In 1800, John Dalton postulated **Dalton's law**, which states that the total pressure of a gas mixture is the sum of the individual pressures. Simply put, all of the parts equal the whole. He discovered that in a gas mixture, gas molecules are unaffected by each others' motion because there is so much space between the molecules. This law is also referred to as the law of partial pressure. The partial pressure is the pressure of a single gas in the mixture.

Dalton's law illustrates that increasing altitude results in a proportional decrease of partial pressures of gases found in the atmosphere. Although the percentage concentration of gases remains stable with increasing altitude, partial pressure decreases in direct proportion to the total barometric pressure.

Even though the percentage of oxygen is a constant, the partial pressure will decrease proportionately as atmospheric pressure decreases, or vice versa. Pressure is required to facilitate the passing of oxygen from blood to the cells. A decrease in pressure can lead to hypoxia in the body. Although the proportion of oxygen remains about 21% in the atmosphere, there are fewer molecules that the body can use. Dalton's law is extremely important in critical care medicine because when supplemental oxygen is given, Dalton's law can be used to calculate the expected partial pressure of oxygen (P_{O_2}) that should be obtained when arterial blood gas values are checked. Dalton's law can be remembered by the phrase "Dalton's gang," because oxygen molecules that were "ganged up" at lower altitudes spread apart at higher altitudes, making less oxygen available for breathing **Figure 4-5**.

Fick's Law

Fick's law was first established in 1855 by Adolph Fick. This law states that the diffusion rate of a gas is proportional to the difference in partial pressure, proportional to the area of the membrane, and inversely proportional to the thickness of the membrane. In practical terms, the rate of diffusion is affected by atmospheric pressures, the surface area of the membrane, and the thickness of the membrane. This is the primary gas law for the diffusion of oxygen across the alveolar membrane. For example, an elderly patient with chronic obstructive pulmonary disease (COPD) who also has pneumonia will have decreased gas exchange at altitude because of decreased atmospheric pressure, decreased surface area of alveoli, and increased membrane thickness, from the long-standing COPD and the exudate from the pneumonia **Figure 4-6**.

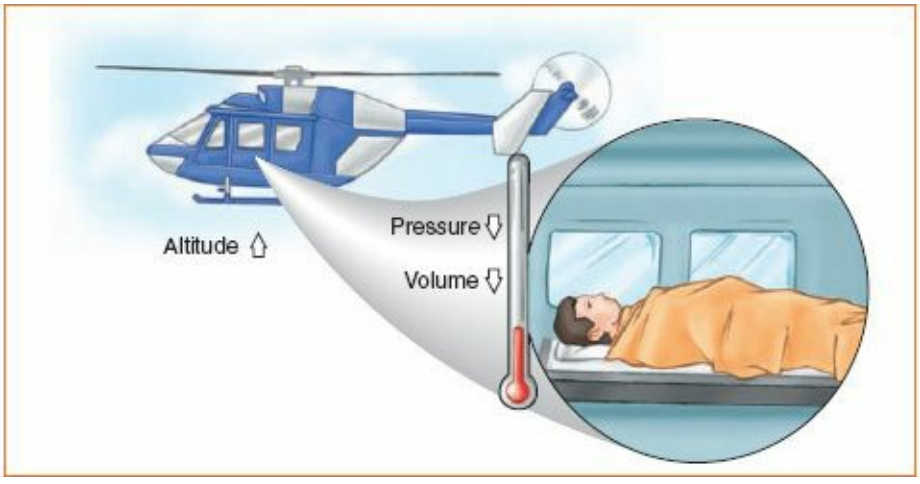

Figure 4-4 Charles' law. The volume of a gas is directly proportional to the temperature, with the pressure remaining constant.

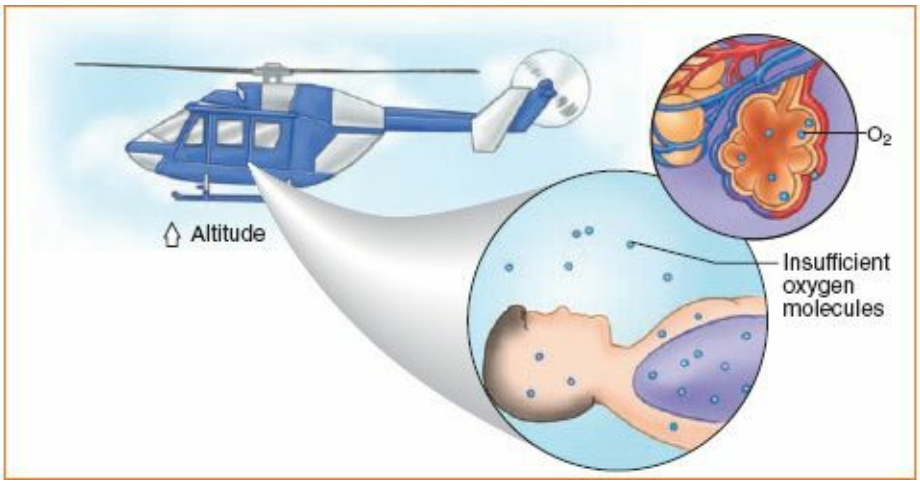

Figure 4-5 Dalton's law. The total pressure of a gas mixture is the sum of the individual pressures. Insufficient oxygen molecules can lead to hypoxia.

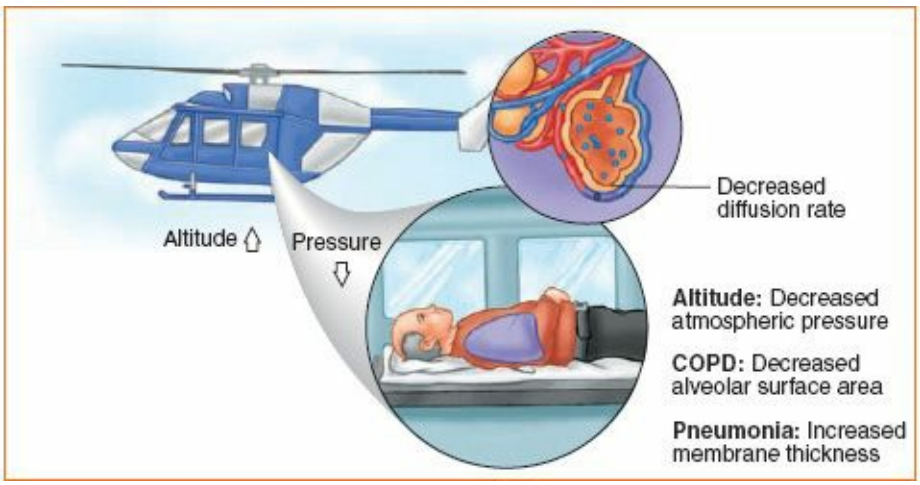

Figure 4-6 Fick's law. The diffusion rate of a gas is affected by atmospheric pressures, the surface area of the membrane, and the thickness of the membrane. A patient with COPD and pneumonia will have decreased gas exchange.

Henry's Law

In 1800, J.W. Henry postulated **Henry's law**, which states that the amount of a gas in a solution varies directly with the partial pressure of a gas over the solution. In other words, as the pressure of a gas over a liquid decreases, the amount of gas dissolved in the liquid will also decrease. As more pressure is applied over the liquid, more gas can be dissolved in the liquid. In practical terms, this law states that molecules of a gas can be dissolved in a liquid and remain in the liquid as long as the liquid is in a pressurized, closed container.

All carbonated beverages are an example of Henry's law. Carbon dioxide is dissolved in a liquid to produce carbonation. The beverage will remain carbonated as long as the bottle or can remains sealed. Once the beverage is opened, the pressure above the liquid falls, and carbon dioxide will begin to leave the solution, producing bubbles in the beverage.

The effect of Henry's law is evidenced in the body by decompression sickness, which is discussed later in this chapter. In this case, inert gases in the body tissue (primarily nitrogen) are maintained in equilibrium with the partial pressure of the same gases in the atmosphere. As barometric pressure decreases, the partial pressure of nitrogen in the atmosphere decreases as well. This decrease in barometric pressure leaves the tissues saturated with nitrogen at a higher pressure than the ambient

barometric pressure. As the body attempts to establish a new equilibrium, nitrogen comes out of solution in the form of gas bubbles and travels in the venous blood system to the lungs **Figure 4-7**.

Universal Gas Law

The **universal gas law** is also known as the ideal gas law because it states how a hypothetical gas should act if there are no variables affecting it. It states that a change in density is directly related to a change in temperature and pressure. Many gases have properties similar to the universal gas law at ambient temperature and pressure.

Gay-Lussac's Law

In 1809, French chemist Joseph Louis Gay-Lussac found that there is a correlation between the pressure and the temperature when volume is constant. **Gay-Lussac's law** can be expressed as a ratio; for example, if pressure increases, temperature increases, and vice versa **Figure 4-8**. Think of a room full of people (molecules); as the room gets smaller (pressure increases), the people will bump into each other, creating friction that will generate heat. As the room gets larger (pressure decreases), the people will not bump into each other and no heat is generated; thus, the room is cooler.

Graham's Law

Graham's law was formulated by Scottish physical chemist Thomas Graham. His law, also known as Graham's law of effusion, states that the rate at which a gas moves through a small hole, avoiding interaction with other particles along the way, is related inversely to the square root of the mass of one mole of its molecules. Thus, if the molecular weight of one gas is four times that of another, it would diffuse through a porous plug or escape through a small pinhole in a vessel at a rate half that of the smaller molecule.

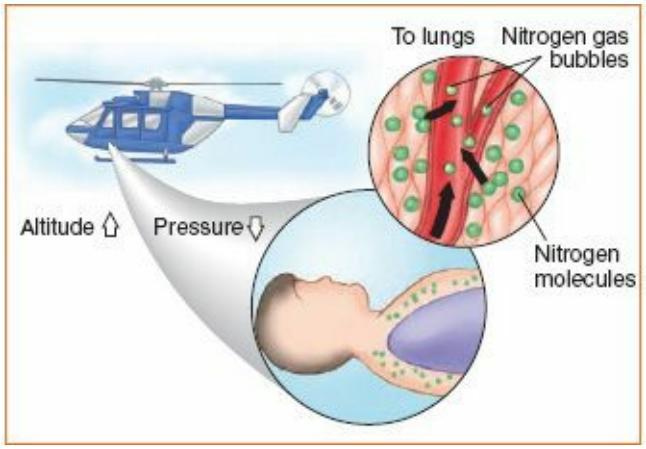

Figure 4-7 Henry's law. As the pressure of gas over a liquid decreases, the amount of gas dissolved in the liquid will also decrease. In decompression sickness, nitrogen saturates the tissues, then forms gas bubbles that travel to the lungs.

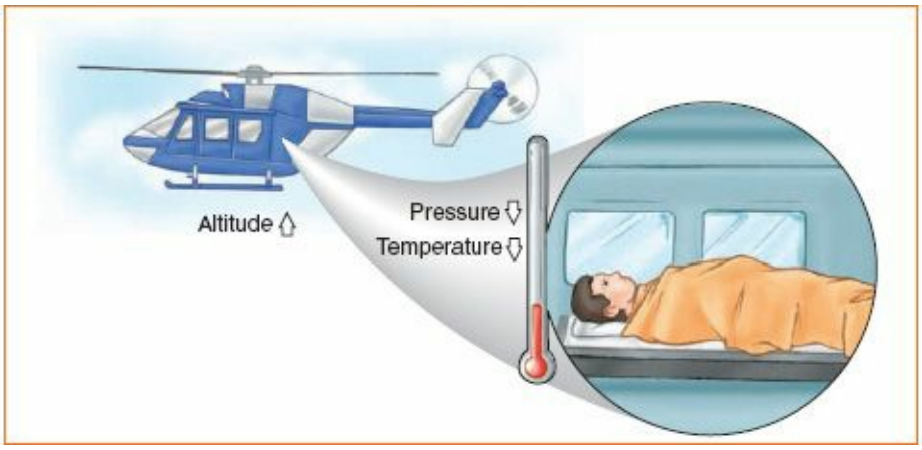

Figure 4-8 Gay-Lussac's law. As pressure decreases, temperature decreases. Remember to keep your patients warm.

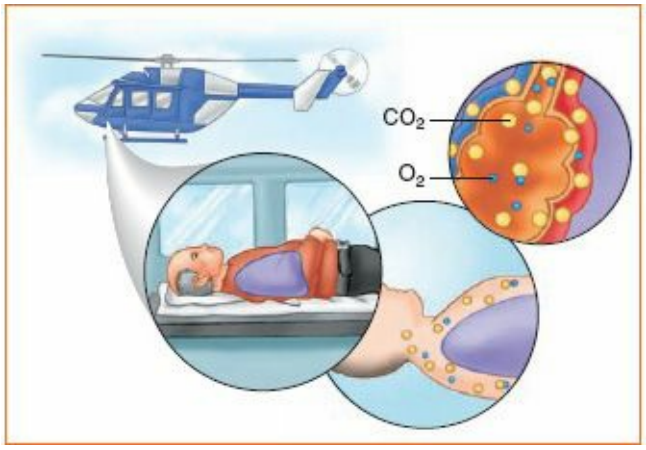

Figure 4-9 Graham's law. The rate at which a gas moves through a small hole is related inversely to the square root of the mass of one mole of its molecules. Carbon dioxide diffuses more readily into the bloodstream than does oxygen.

A practical example of this law is the ongoing process of the diffusion of oxygen and carbon dioxide in the blood and the transfer of oxygen from blood into the cells. Carbon dioxide molecules are much more massive than oxygen molecules, and carbon dioxide also has 22 times the solubility of oxygen; thus, the diffusion rate is much quicker than that of oxygen **Figure 4-9**.

Formulas Based on the Seven Gas Laws

The following formula, based on Henry's law, is used to determine how much additional oxygen will be needed to compensate for the altitude and barometric pressure changes:

$$\frac{\text{Initial } F_{IO_2} \times \text{Initial Barometric Pressure}}{\text{Barometric Pressure at Cruising Altitude}} = \text{Adjusted } F_{IO_2}$$

(F_{IO_2} is the fraction of inspired oxygen)

If the barometric pressure is 760 mm Hg at sea level and 600 mm Hg at 6,000′ above sea level and the patient's initial F_{IO_2} is 70%, with this formula, the adjusted F_{IO_2} would be:

$$\frac{70\% \text{ Initial } F_{IO_2} \times 760 \text{ mm Hg}}{600 \text{ mm Hg}} = 88.7\% \text{ Adjusted } F_{IO_2}$$

To ensure that the patient continues to receive 70% FIO_2, the ventilator would need to be adjusted to 88% FIO_2.

Types of Hypoxia

Hypoxia, a main hazard in aviation, can have catastrophic results. This physiologic effect can occur in otherwise healthy people at altitudes less than 10,000′, but can greatly affect patients with impaired pulmonary function at much lower altitudes.

With all of the advances in aircraft technology, the US military still reports 8 to 10 incidents of hypoxia during flight every year. Most of these incidents are attributed to a failure in cabin pressure with a concurrent failure in the oxygen delivery system. In most of these incidents, the pilots were able to recognize the situation and take immediate corrective action to avoid catastrophe.

A common misconception in aviation is the belief that one can recognize the early signs of hypoxia and take immediate corrective actions. This misconception is deadly and dangerous. One of the earliest effects of hypoxia is impaired judgment. This impaired judgment can limit the aviator's ability to recognize hypoxia and, consequently, his or her ability to take immediate corrective actions. Numerous aircraft crashes have documented aircrews responding to hypoxic events with inappropriate and dangerous actions. Also, early hypoxia mimics fatigue and hypoglycemia, making it difficult to recognize. Fatigue and hunger contribute to hypoxia as well.

TABLE 4-1 Relationship Betweeen Effective Performance Time and Altitude

Altitude	Effective Performance Time (Standard Ascent Rate)	Effective Performance Time (After Sldden Decompression)
18,000′	20-30 min	10-15 min
22,000′	8-10 min	5 min
25,000′	4-6 min	1.5-3.5 min
35,000′	30-60 s	15-30 s
43,000′	9-12 s	5 s
> 50,000′	9-12 s	5 s

Data source: Federal Aviation Administration.

Effective Performance Time and Time of Useful Consciousness

There is a limit to how long a person can function with an inadequate level of oxygen. This limited time is called **elleclive perlormance lime** Table 4-1, and the **time of useful consciousness** is the period between a person's sudden deprivation of oxygen at a given altitude and the onset of physical or mental impairment to the point at which deliberate function is lost.

It is important to realize that the times in Table 4-1 were obtained by using healthy military volunteers in a standard altitude chamber. The effective performance time and time of useful consciousness vary with each person and are dependent on individual tolerances, the method of hypoxia induction, and the environment before hypoxia. Any exercise will reduce these times considerably. For example, on exposure to hypoxia at 25,000′, the average person has a time of useful consciousness of 3 to

5 minutes. The same person after performing 10 deep knee bends will have a time of useful consciousness in the range of 1 to 1.5 minutes. Also, an aircrew member who was breathing 100% oxygen before the onset of hypoxia will have a longer period of compensation than an aircrew member who was breathing ambient air. Rapid cabin depressurization also dramatically affects the effective performance time and the time of useful consciousness. When aircraft cabin decompression occurs above 33,000′, there is an immediate reversal in oxygen flow in the alveoli. A higher Pa_{O_2} in the pulmonary capillaries occurs, causing the oxygen reserves in the blood to be depleted, reducing the effective performance time by up to half.

The time of useful consciousness varies from 5 minutes to 1 minute; however, if the crew is subjected to rapid depressurization, this time can be only a matter of seconds. A **rapid decompression** can reduce the time of useful consciousness by up to 50% because of the forced exhalation of the lungs during decompression and during an extremely rapid ascent.

Another common misconception regarding hypoxia is the belief that those living at higher altitudes do not require supplemental oxygen in order to reach more extreme heights. Although there is some truth to this notion, it does not afford the protection that most assume. Living at higher altitudes causes the body to produce red blood cells at a faster rate, facilitating oxygen transport. A slight physiologic advantage exists; however, an aircrew member who, for example, lives at 5,000′ may be able to fly 1,000′ to 2,000′ above the 10,000′ recommended ceiling without ill effects, but tolerance is not extended an additional 5,000′.

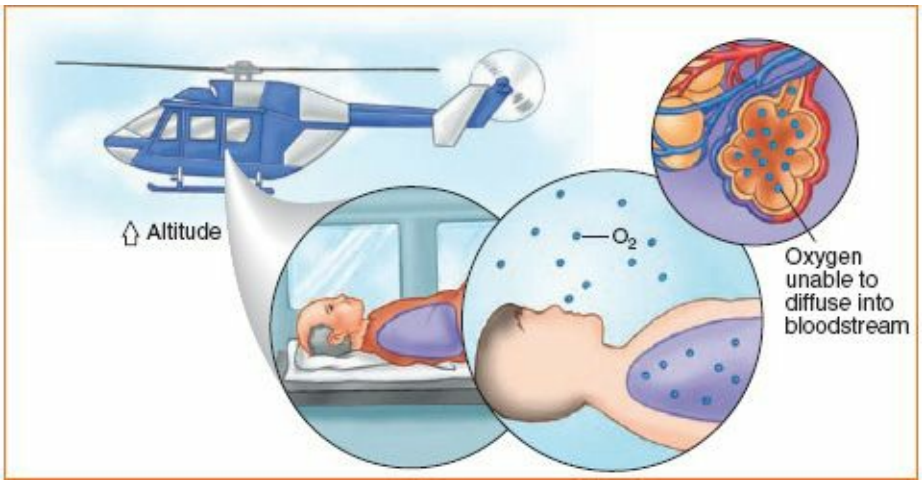

Figure 4-10 Hypoxic hypoxia results from a lack of oxygen or an inability of oxygen to diffuse into the bloodstream.

Hypoxic Hypoxia

Hypoxic hypoxia (also referred to as altitude hypoxia) results from inadequate ventilation or a reduction in the Po_2 and is characterized by a lack of oxygen entering the blood **Figure 4-10**. Hypoxic hypoxia can occur from a variety of causes, including lung disease, right-to-left shunt in the heart, airway obstruction, a reduction in gas exchange area in the alveoli, and a low Po_2. Increased altitude also leads to hypoxic hypoxia.

In the air medical environment, personnel will most likely encounter this condition as a result of reduced atmospheric pressure that causes a reduced alveolar Pa_{O_2}. Simply put, there is not enough oxygen available in an inspired breath at higher altitudes owing to decreased levels of Po_2 oxygen. (Remember Dalton's law: oxygen molecules are further apart, so less oxygen is available.) Diffusion of oxygen is directly dependent on the Po_2. As oxygenated blood flows through the capillaries, the Po_2 level

decreases. The part of the capillaries farthest from the lungs requires at least 1 mm Hg of pressure for diffusion of oxygen to the cells. As altitude increases, the pressure decreases below 1 mm Hg, and aerobic metabolism is inhibited. As metabolism becomes depressed, cellular death begins. Clinical hypoxia actually starts to develop within a few hundred feet from the ground; however, symptoms do not begin to manifest themselves until heights above 5,000′.

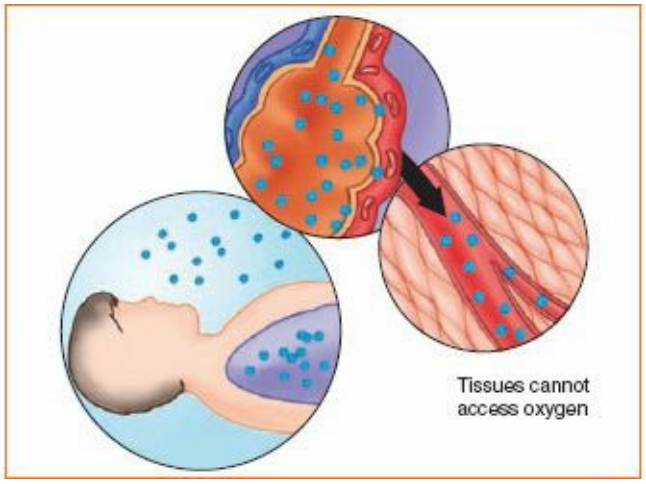

Figure 4-11 In histotoxic hypoxia, plenty of oxygen is available, and it can bind to the hemoglobin, but the tissues cannot access it.

Histotoxic Hypoxia

Histotoxic hypoxia is the cell's inability to adequately use oxygen. Plenty of oxygen is available, but tissues cannot accept it, or oxygen cannot offload from the hemoglobin **Figure 4-11**. During histotoxic hypoxia, the venous hemoglobin oxygen saturation is higher than normal because the oxygen is not being unloaded to the tissues because the tissues are unable to metabolize the delivered oxygen. Histotoxic hypoxia is a result of poisoning, such as by cyanide, which is one of the major toxins generated by housefires. This condition is also exacerbated by the use of narcotics, chewing tobacco, and alcohol.

Stagnant Hypoxia

Stagnant hypoxia occurs when there is failure to transport oxygenated blood. This form of hypoxia occurs when there is a reduction in the flow of blood, but not necessarily a complete stoppage **Figure 4-12**. Outside of the aviation environment, this condition is frequently seen in heart failure and major myocardial infarctions. In flight medicine, stagnant hypoxia can result from venous pooling in the patient during accelerated maneuvers, such as steep turns and other maneuvers that increase the gravitational load on the aircraft. Another practical example is blood pooling in the lower extremities of patients and crew members who sit in an aircraft for extended periods.

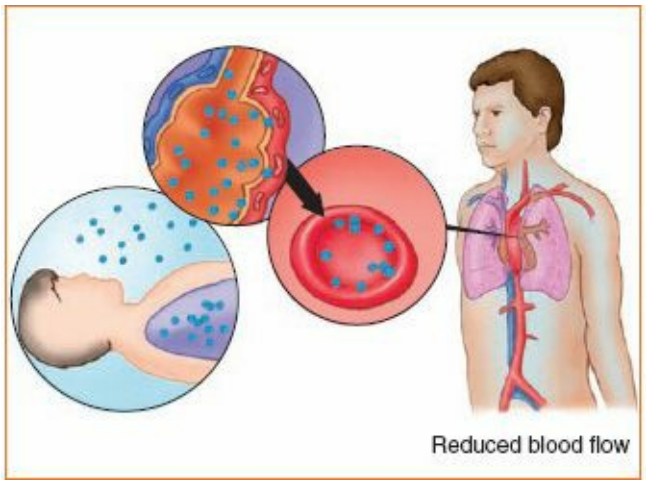

Figure 4-12 In stagnant hypoxia, there is a failure to transport oxygenated blood.

Hypemic Hypoxia

Hypemic hypoxia (also known as anemic hypoxia) occurs when a lack of hemoglobin molecules are present (as seen with exposure to chemicals such as carbon monoxide) or a lack of red blood cells (as seen with hemorrhage or anemia) causes a reduction in the ability of the blood to carry oxygen to the tissues **Figure 4-13**. Oxygen is abundant; however, it is unable to bind to hemoglobin because the amount of hemoglobin is insufficient. Blood loss and anemia are the two most common causes of this condition. Excessive smoking is a major cause as well: smokers are susceptible to hypoxia at lower altitudes than nonsmokers. At sea level, a smoker's apparent altitude is approximately 7,000′. There are several other causes, including carbon monoxide poisoning, the use of nitrite and sulfa drugs, and sickle cell disease, that reduce the amount of hemoglobin available to transport oxygen. Normally, 1 g of hemoglobin carries 1.34 mL of oxygen. In a healthy adult, hemoglobin has the ability to transport 20 mL of oxygen in 100 mL of blood. A reduction of hemoglobin by half reduces the body's transport ability by half. The blood may be completely saturated with oxygen; however, it is insufficient to meet the metabolic demands of the body.

Special Populations

When transporting a pregnant patient by air, oxygen supplementation should always be considered. Even if a pregnant woman's oxygen saturation is 100% (by pulse oximetry), the fetus may still be compromised. The pregnant patient's circulatory system will shunt all richly oxygenated blood to her own vital organs, robbing the fetus and placenta of much-needed oxygen. A normal fetal Pa_{O_2} level is around 45 mm Hg (in a pregnant patient with 90% to 100% Pa_{O_2}). If a pregnant patient's Pa_{O_2} level decreases as a result of hypoxia, the oxygen status of the fetus can quickly become compromised because the fetus has limited reserves.

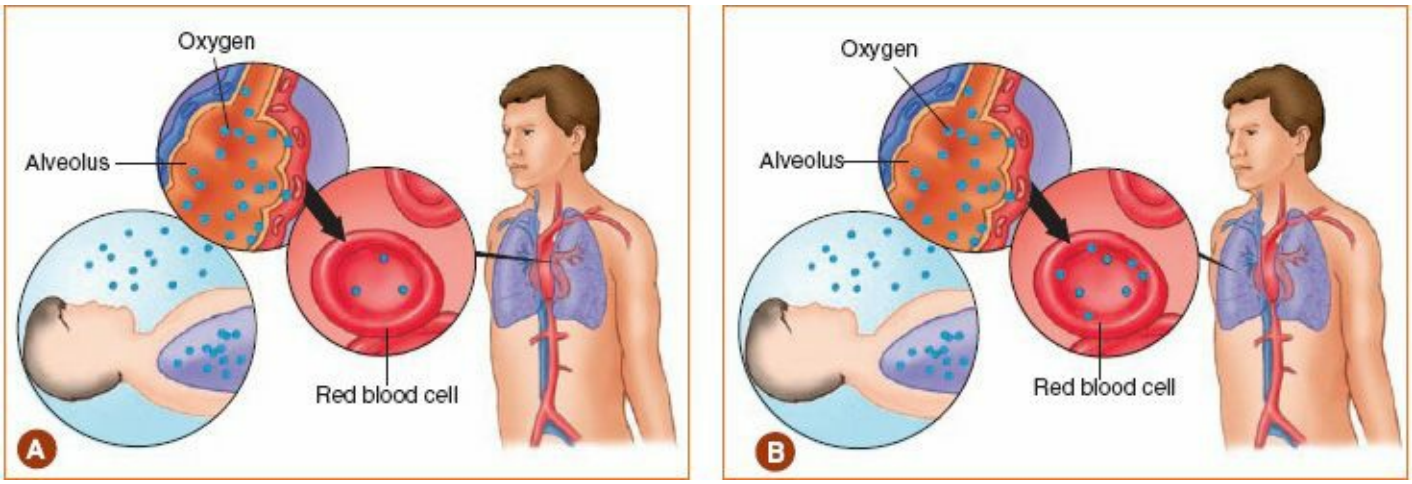

Figure 4-13 With hypemic hypoxia, there is a reduced ability of the blood to carry oxygen to the tissues. **A.** Impaired attachment of oxygen to hemoglobin. **B.** Reduced number of red blood cells.

Four Stages of Hypoxia as They Relate to Altitude

The symptoms of hypoxia can be divided into stages directly related to the altitude, approximate barometric pressure, and the oxygen saturation of the blood. These stages can be divided into the **indifferent stage**, **compensatory stage**, **disturbance stage**, and **critical stage**. Symptoms of hypoxia are listed in **Table 4-2**.

Indifferent Stage

This stage is experienced between sea level and 10,000′; however, the indifferent stage may manifest itself at altitudes as low as 5,000′. Mild hypoxia can cause night vision to deteriorate at altitudes above 5,000′. The military has recognized this problem and requires fighter pilots to breathe oxygen from the ground up during night-flight operations. Physiologically, electrocardiographic changes have been known to occur at altitudes as low as 5,000′. Tachycardia is common, and there is also a slight increase in alveolar ventilation noted during this stage. Oxygen saturation in this stage varies from 98% to 87%. This stage is referred to as the indifferent stage because of the minor physiological effects on the body.

Compensatory Stage

The second stage is called the compensatory stage. As the name implies, the body is able to provide short-term physiologic compensation against the effects of hypoxia. The compensation is dependent on the physical shape of the flight crew member, the physical activity level, and the duration of exposure. In this stage, the respiratory rate and depth may increase and cardiac output increases. This stage is experienced between 10,000′ and 15,000′ (between 39,000′ and 42,000′ if breathing 100% oxygen). Hemoglobin saturation in this stage varies from 87% to 80%.

TABLE 4-2 Symptoms of Hypoxia
Confusion/altered mental status Fatigue
Headache
Changes in vision acuity • Tunnel vision • Blurred vision and/or inability to focus

• Difficulty focusing from near to far • Loss of night vision
Euphoria
Tingling in the hands and feet
Feelings of air hunger Tachypnea
Cyanosis of the skin Irregular heart rhythms
Short-term memory loss
Decreased muscular coordination
Loss of hearing
Diminished sense of pain
Diminished sense of touch and feel
Difficulty speaking; stammering
Loss of self-criticism
Overconfidence
Overly aggressive behavior

Disturbance Stage

In the disturbance stage, tissue can no longer depend upon the physiologic compensatory mechanisms for sufficient oxygen supply. This stage is characterized by subjective and objective symptoms of hypoxia **Table 4-3**. During altitude testing, some subjects did not experience the subjective symptoms before becoming unconscious from hypoxia. The following can be affected by hypoxia: respiratory system, senses, mental processes, manifestations of personality, and psychomotor functions.

TABLE 4-3 Stages of Hypoxia

	Indifferent Stage	Compensatory Stage	Disturbance Stage	Critical Stage
Altitude	0′-10,000′	10,000′-15,000′	15,000′-20,000′	20,000′-25,000′
Oxygen saturation (%)	98-90	89-80	79-70	69-60
Symptoms	Decrease in night vision	Drowsiness Poor judgment Impaired coordination Impaired efficiency	Impaired flight control Impaired handwriting Impaired speech	Circulatory failure

Senses

Vision, hearing, and sense of touch are affected during the disturbance stage. Visual ability decreases as the eye muscles become weak and uncoordinated. Sensations of touch and pain become diminished and eventually are lost. Weakness and loss of muscular coordination are experienced and become worse with the degree of hypoxia. This loss of muscle coordination, in conjunction with confusion, quickly becomes a deadly combination. Accurate communication in the aircraft environment is imperative to the overall safety and success of the mission. Although hearing is one of the last senses to be impaired, loss of hearing from hypoxia will further confound the safety and success of the mission.

If a medical crew member is having difficulty following simple commands or performing simple tasks, the crew member and the other members of the medical and flight team should consider hypoxia. At times, crew members cannot recognize hypoxia in themselves but can recognize it in others.

Cognition

One of the most dangerous hallmarks of hypoxia is the early impairment of intellect that makes it impossible for people to comprehend their own disability. As the cerebrum becomes hypoxic, the victim loses his or her ability to make coherent judgments and calculations. Reaction time becomes slower, and the short-term memory is severely impaired. All of these impairments prevent the person from recognizing the ongoing effects of hypoxia.

A common misconception among flight crews is that they can learn all of the early signs of hypoxia and be able to take immediate corrective action. Unfortunately, because one of the earliest effects of hypoxia is impaired judgment, the flight crew can recognize hypoxia but may take inappropriate corrective actions. Aviators have been known to have adequately recognized hypoxia but, in an attempt to correct the problem, immediately disconnect themselves from their only oxygen supply.

Personality Manifestations

Hypoxia can cause the emergence of symptoms similar to those a person may exhibit while under the influence of alcohol. These symptoms include the following:

- Aggressiveness
- Euphoria
- Irritability
- Overconfidence
- Depression

Psychomotor Functions

As hypoxia is induced, muscular coordination decreases. When the partial pressure of alveolar carbon dioxide falls below 25 mm Hg, muscular coordination deteriorates. As the partial pressure continues to fall, muscle coordination deteriorates to levels that are incompatible with coordinated activity. The first resulting problems are speech difficulty, illegible handwriting, and poor coordination in flying the aircraft. As the degree of hypoxia increases, delicate and fine muscular movements become impossible, and gross motor movements become significantly impaired. It is interesting to note that stammering and illegible handwriting are two of the hallmark signs of typical hypoxic impairment.

Critical Stage

The last stage of hypoxia is called the critical stage. This stage occurs at 20,000′ and above (44,800′ and above with the use of 100% oxygen). Within 3 to 5 minutes of hypoxygenation, judgment and coordination deteriorate to the point of inadequate or inappropriate function. In this stage, mental confusion is quickly followed by incapacitation, unconsciousness, and death, if uncorrected. Hemoglobin saturation in the critical stage drops to less than 65%.

Hyperventilation

Hyperventilation symptoms mimic those of hypoxia, so it is critical that flight crew members first address the possibility of hypoxia before assuming that the problem is caused by hyperventilation. Hyperventilation *and* hypoxia result in confusion, poor judgment, and inappropriate corrective maneuvers.

Hyperventilation is caused by the subconscious reaction to a stressful situation. This reaction is

manifested by an abnormal increase in the volume of inspiratory and expiratory air and by tachypnea, which results in respiratory alkalosis as the carbon dioxide is blown off. This aberration in blood gases can have serious consequences. The lack of carbon dioxide also affects the automation of respiration. Normal control of respiration is mediated reflexively through the chemoreceptors in the aorta and the carotid artery by arterial oxygen deficiencies. In healthy people without a hypoxic drive, ventilation rate and depth are controlled by carbon dioxide and acid-base balance of blood circulating through the respiratory center in the medulla. Excessive elimination of carbon dioxide with hyperventilation results in a rapid decline in sodium bicarbonate in the blood. This decline causes an elevation in the pH of the blood. Cellular activity is dependent on proper acid-base balance. When the pH of the blood falls out of normal range, homeostasis is interrupted in the cell, and cellular activity quickly declines or stops.

Hyperventilation leads to several important physiologic changes that begin a cascade of events. As minute volume (tidal volume × rate) increases, the partial pressure of carbon dioxide decreases, which results in an increase in the pH of the blood. The cerebral blood vessels respond to the decrease in carbon dioxide by vasodilation. This vasodilation causes blood to shunt to various parts of the body while starving other areas. Oxygen is used up in the areas with pooled blood, whereas immediate cellular hypoxia and anoxia occur in the areas with decreased circulation, which is why routine hyperventilation of head-injured patients is no longer recommended. Unconsciousness quickly follows the induction of prolonged or significant hypoxia into cerebral tissue.

Hyperventilation can cause assorted symptoms, including the following:

- Light-headedness
- Feelings of suffocation
- Drowsiness
- Tingling in the extremities
- Painful muscle spasms
- Ataxia
- Disorientation
- Unconsciousness

One of the most disastrous effects of hyperventilation is that it promulgates panic. Maintaining control is one of the few remedies to prevent or overcome panic. Hyperventilation contributes to the overwhelming sense of panic. If a flight crew member is unable to control his or her hyperventilation, panic may ensue related to progressive hypoxia.

Recognition and Treatment of Altitude-Induced Hypoxia

The key to recognition of altitude-induced hypoxia is a thorough knowledge and understanding of basic flight physiology. As previously mentioned, many aviators have erroneously believed that they can recognize hypoxia as it is occurring and immediately correct the problem. Recovery from hypoxia is rapid when sufficient oxygen is supplied. People who are on the precipice of unconsciousness can regain full mental abilities within 15 seconds after receiving high-flow oxygen. In fact, studies show that a hypoxic person who rapidly breathes in 100% oxygen may experience sudden dizziness, which is quickly resolved, followed by complete restoration of function. This condition is sometimes referred to as the **oxygen paradox**.

Prevention is the key to treatment, and avoidance of hypoxia is the key to safety. If hypoxia is detected, the flight crew must immediately use supplemental oxygen and descend to below 10,000′. Hypoxic crew members are a valid reason to declare an emergency with air traffic control.

Supplemental Oxygen Requirements

As discussed in Chapter 3, air medical transport providers are subject to one of two rules, part 91 or part 135 of the FAR. The FAR part 135.89 governs the use of supplemental oxygen by pilots and provides rules for pressurized and nonpressurized aircraft. In nonpressurized aircraft (helicopters included), at altitudes from 10,000′ through 12,000′, each pilot must use oxygen continuously if the duration of flight at this altitude is longer than 30 minutes. Pilots must use oxygen at all times above 12,000′. In a pressurized aircraft when the cabin altitude exceeds 10,000′, the same rule applies. At altitudes from 25,000′ through 35,000′, each pilot must use continuous oxygen unless the aircraft is equipped with an approved quick-donning-type mask. Pilots must wear an oxygen mask continuously above 35,000′. The more stringent rules regarding oxygen use as altitude increases are because of the dramatic decrease in time of useful consciousness as altitude increases; above 35,000′, pilots will have mere seconds to respond to a sudden loss of cabin pressure.

Passengers will be provided supplemental oxygen as well, in accordance with FAR part 91.211. At cabin altitudes above 15,000′, all occupants will be provided with supplemental oxygen. In a pressurized aircraft, there must be a 10-minute supply of oxygen available for each occupant if the aircraft is to be operated above 25,000′. These rules for supplemental oxygen are for crew and nonpatient passengers only. A sick or injured patient will likely need supplemental oxygen at all altitudes to prevent hypoxia.

Pressurized and Nonpressurized Aircraft

The most effective method to protect people from the physiologic effects of reduced barometric pressure is by pressurizing the aircraft. This pressurization is accomplished by increasing the barometric pressure in the aircraft above the ambient pressure outside the aircraft. The higher the differential pressure required between the aircraft cabin and the ambient pressure, the stronger and heavier the fuselage construction must be. A higher differential pressure also requires a greater capacity of the pressurization system. Aircraft pressurization requirements increase engineering and maintenance costs of the aircraft and require more power.

There are two primary methods used for pressurizing aircraft: the isobaric system and the differential control method for pressurization. The majority of civilian and military aircraft use isobaric systems for pressurization. The differential control (also known as conventional or isobaric-differential) method is designed primarily for military aircraft and has an aircraft cabin pressure that fluctuates with altitude.

Isobaric Control System

The **isobaric pressurization system** is the most frequently used method for pressurizing aircraft. This system is designed to maintain the aircraft cabin at a constant pressure (usually between 5,000′ and 8,000′) despite falling barometric pressure outside the aircraft. This system is designed to maximize the comfort of the crew and passengers and does not require the use of supplemental oxygen as long as the system is working properly. This type of system also minimizes the effects of fatigue on the crew and passengers and allows for maximum mobility of the crew and passengers.

The drawback of the isobaric system is that it requires a heavier fuselage and airframe to keep the higher pressure inside the aircraft cabin. It also adds more weight to the aircraft because of the equipment needed to pressurize the aircraft, along with the heavier fuselage. Another drawback is the explosive rate of decompression (see rapid decompression discussed in “Aircraft Depressurization”) that can occur when pressure inside the aircraft cabin is much greater than the ambient outside pressure.

Differential Control Method

A differential control system is used primarily by tactical military aircraft. The differential system is used by aircraft that fly above the designed and engineered limits of the isobaric system. This system does not maintain a constant cabin altitude. Instead, it is designed to ensure that the cabin pressure does not exceed the outside pressure by a predetermined amount, for example 5 psi. As altitude varies, so does the internal cabin pressure. The rate of pressure change, however, is less drastic than that of the outside pressure and is designed to slowly adjust pressures within the predetermined ratio. Most differential controls maintain the cabin pressure at a pressure the same as at 8,000′ until the aircraft climbs above 23,000′. At that point, the differential control maintains the cabin at a 5-psi difference from the outside pressure.

The drawback to the differential control method is that supplemental oxygen and pressure suits must be available and used at certain altitudes. However, advantage is gained in a lightweight aircraft fuselage and less of a risk of explosive decompression. Any military aircraft that can potentially take gunfire uses the pressure differential system. Therefore, if there is penetration into the aircraft cabin, the rate of depressurization is less than if the aircraft cabin were maintained at a higher cabin altitude and there is less risk for catastrophic failure of the aircraft.

Aircraft Depressurization

Decompression at altitude is categorized as "slow" or "rapid." Rapid cabin depressurizations are dramatic events. With a loud explosion and numerous master caution warning horns sounding in the cockpit, it is quickly obvious to everyone that a major emergency has occurred. When rapid cabin depressurization occurs, the occupants of the aircraft are immediately exposed to the dangers of hypoxia, decompression sickness, gastrointestinal expansion, and hypothermia. In addition, the cyclonic winds may lead to the loss of personnel or passengers through the aircraft opening that caused the depressurization, and a dense fog and icy temperatures quickly fill the cabin. The dissipation rate of the fog is dependent on the size of the aircraft. Larger aircraft will take longer to clear the fog. All commercial pilots are extensively trained and tested on rapid decompression and emergency descent procedures.

A slow decompression can occur when a small leak develops in a pressurized aircraft. This type of decompression is dangerous because of the insidious onset and undetectable loss of oxygen leading to hypoxia and death if uncorrected. In 1999, golf legend Payne Stewart died when his Lear 35 jet aircraft developed a small leak at 45,000′ and everyone onboard the aircraft died of hypoxia. The aircraft flew for 3 hours with all of the crew presumed dead before it crashed. Military chase planes observed frost built up on the inside of the windows, indicating that the aircraft was depressurized.

A review of data collected by the National Aeronautics and Space Administration shows that of all decompression events reported worldwide each year, generally 40 to 50 will be classified as rapid decompression. Of these, approximately 70% will occur above 30,000′. If a loss of cabin pressure occurs, a descent must be made immediately to a level at which cabin altitude can be maintained at or below 10,000′ and oxygen will be used by all occupants until the flight crew indicate it is no longer necessary. As previously mentioned, rapid cabin depressurization also dramatically affects the effective performance time and the time of useful consciousness—reducing these times by up to half.

Primary Forces That Act on an Aircraft

There are four primary forces that constantly act on an aircraft in flight: **lift**, **thrust**, **weight** (gravity), and **drag** **Figure 4-14**. Lift counteracts weight, and thrust opposes drag. Essentially, greater amounts of thrust and lift allow an aircraft to take off. Conversely, greater amounts of drag and weight must exist for an aircraft to land. In straight and level flight, thrust equals drag and lift equals weight. The forces of flight and how they relate to flight medicine were discussed in Chapter 3.

Primary Stressors of Flight

There are many stressors that flight crew members will experience during their career; however, some stressors may cause catastrophic outcomes. When flying in an airplane or a rotor-wing aircraft, rapid altitude changes are frequently experienced. When the body is exposed to significant altitude changes without the proper precautions, adverse outcomes may result as the body attempts to maintain homeostasis. As the body is exposed to altitudes of 8,000′ and above, the atmospheric pressure continuously decreases, making it more difficult to breathe. The difficulty in breathing is a direct result of a decrease in the amount of oxygen that is available in one breath. If the proper precautions are not taken, CCTPs, other crew, and patients may become hypoxic and begin to experience symptoms such as confusion, fatigue, visual impairment, headache, nausea, and euphoria.

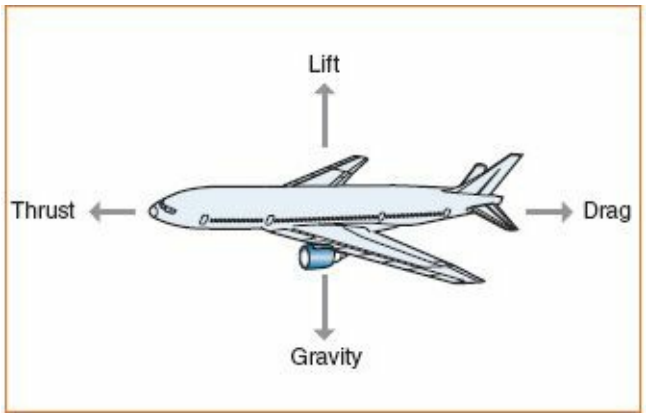

Figure 4-14 The forces of flight: weight, lift, drag, and thrust.

Decreased Levels of P_{O_2}

As mentioned previously in this chapter, decreased levels of P_{O_2} can quickly cause hypoxia in flight crew and passengers. At 15,000′, the barometric pressure is 429 mm Hg, and average values for a healthy patient would include an oxygen saturation of 80% (the body requires 87% to 97%) and a Pa_{O_2} of 44 mm Hg (the body requires 60 to 100 mm Hg) **Table 4-4**. Remember that these values are averages for a healthy person; they are not representative of critical care patients.

Barometric Pressure Changes

The greatest pressure change in an aircraft takes place from sea level to 5,000′. Therefore, problems associated with pressure must be considered even in nonpressurized aircraft that are not flying at altitudes requiring supplemental oxygen or cabin pressurization. During daylight hours for nonpressurized aircraft, 10,000′ of altitude is the ceiling at which crew members must begin to use oxygen. Because the loss of night vision is one of the first symptoms of hypoxia, the ceiling drops to 8,000′ for nighttime flight operations that exceed one hour in length. The alveolar P_{O_2} at 10,000′ is approximately 61 mm Hg, which produces the maximum acceptable degree of hypoxia allowed. The upper limit for the indifferent stage of hypoxia is 10,000′. However, deviation by a few thousand feet for a short time will have little difference. For this reason, certain military operations are allowed at 13,000′ as long as the duration of the flight is less than 3 hours. In addition to causing hypoxia and malfunctioning pacemakers, ambient pressures and increasing altitudes can cause discomfort in air-trapped organs and sinuses (for example, the ears and gastrointestinal system).

Thermal Changes

Flight crew members are subjected to a variety of thermal extremes ranging from the very cold to the very hot. These extremes in temperature affect the metabolic rate and demands on the body. Temperature changes increase the oxygen demands on the body and make the body less tolerant of the effects of hypoxia. Temperature changes can result in the effects of hypoxia at lower altitudes than normally expected.

Temperature declines with increases in altitude. Temperature decreases by 3°F to 5°F (1°C to 2°C) per 1,000′ gain in altitude, depending on humidity. (At altitudes from 35,000′ to 99,000′, the temperature remains relatively constant at –32°F [–50°C].) In helicopters, pilots often take advantage of the decline in temperature at higher altitudes during the summer to assist with cooling the aircraft cabin. If the air conditioner cannot keep the cabin cool because of high ambient temperatures, the aircraft can ascend and take advantage of the cooler temperatures at higher altitudes.

The flight crew is also subjected to hot temperatures because they frequently must operate outside at emergency scenes for extended durations during summer months. The flight crew must then work aggressively in the tight, hot confines of the aircraft to provide medical care to a patient in critical condition. Most flight crews wear fire-retardant flight suits **Figure 4-15**, which are an added weight and do not allow heat to rapidly dissipate. In addition, most rotor-wing flight personnel wear helmets, which do not facilitate cooling and can lead to increases in the core body temperature.

Table 4-4 Partial Pressures of Oxygen at Various Altitudes

Altitude	Atmospheric Pressure (mm Hg)	Pa_{O_2} (mm Hg)*	Pv_{O_2} (mm Hg)	Pressure Differential (mm Hg)	Blood Saturation (%)*
Sea level	760	100	40	60	98
10,000′	523	60	31	29	87
18,000′	380	38	26	12	72
22,000′	321	30	22	8	60
25,000′	282	7	4	3	9
35,000′	179	0	0	0	0

*These are average measurements for a healthy patient. Pa_{O_2}, partial pressure of oxygen (arterial); Pv_{O_2}, peak oxygen consumption (the highest amount of oxygen consumption during an exercise period).

Figure 4-15 A fire-retardant flight suit (Nomex).

Another problem encountered is that flight personnel are subjected to a wide range of ambient temperatures because of the range of their aircraft. Flight crew assigned to rotor-wing aircraft may experience a temperature of 80°F (26.7°C) at their base but fly less than an hour into mountainous areas where the temperatures can be less than 40°F (4.4°C). Flight crews assigned to fixed-wing aircraft may see an even broader range of temperatures as they start in a northern climate in the snow and end in the hot sun in a southern climate. A secondary hazard also is the greenhouse effect, which can result in an increase in the temperature by 50°F (10°C) to 59°F (15°C) in the cockpit or cabin of a small aircraft simply because of radiant solar heat.

Flight crews must be cognizant of the potential for heat stress. Core body temperatures that exceed 100°F (37.8°C) result in decreased short-term memory, degradation of motor skills, and a general decrease in performance. Heat stress also causes increased irritability and poor judgment, increases the propensity for motion sickness and hypoxia and potentiates the effects of gravitational forces, which are discussed later in this chapter.

Vibration

Vibration is noted in all helicopters, most propeller-driven aircraft, and, minimally, jet-engine aircraft. Studies have found that vibrations between 1 and 12 Hz can cause significant effects on the body. The low-frequency vibrations can cause several untoward effects, including body discomfort, pain (usually in the abdomen or chest), decreased vision, and, most notably, fatigue. Excess vibration is an issue that must be addressed with aircraft mechanics and manufacturers. However, there are some modifications that can be made to reduce the effects of vibration. Increasing the cushioning on seats is one of the most important modifications, as is proper use of shoulder and lap belts, which reduces the transmission of vibrations.

Prolonged effects of vibration can increase the core body temperature as the body constantly tries to fight the effects of vibration and movement. As mentioned, one of the most noted effects of vibration is fatigue. As the body becomes fatigued with prolonged exposure to vibration, it becomes more susceptible to the effects of vibration and, thus, continues in an unbroken cycle.

To combat crew fatigue due to vibration, there are restrictions regarding the amount of time a crew is allowed to fly on any given shift before resting. Preventive measures include prohibiting medical crew members from leaning against the airframe (to decrease vibration) and providing extra padding for patients so they are not leaning against the airframe.

Decreased Humidity

Humidity is the degree of moisture (water vapor) in the air and is expressed as a percentage. Humidity is relative to temperature. As temperature increases, so does humidity. Conversely, as temperature falls, so does the relative humidity. Because temperature falls with altitude, so does humidity. Because of the relatively low levels at which they fly, humidity levels in rotor-wing and propeller aircraft are higher than those of jet aircraft. Jet aircraft fly at high altitudes where there is low humidity. Any humidity in the air is quickly used on inspiration by the flight crew and passengers. Any other humidity that was trapped in the aircraft from wet clothes or perspiration is also used quickly until all of the moisture is lost. The air in a pressurized jet aircraft is constantly being recirculated through filters, and any moisture is drawn off by the system. In highspeed, high-altitude, long-range flights, less than 5% humidity remains after 2 hours of flight and less than 1% remains after 4 hours of flight.

During a long flight, the dry air can cause dry, cracked mucous membranes, chapped lips, and sore throats and can lead to dehydration. This lack of humidity is why many people feel fatigued or jet-lagged

after a long commercial flight. These problems can further be compounded in injured or ill patients, so it is important to ensure that patients are properly hydrated before and during the flight **Figure 4-16**. Patients who are receiving supplemental oxygen are at twice the risk of becoming dehydrated because oxygen causes moisture to dry up in the respiratory system. If available, humidified oxygen should be used during air transports. The dry air in the aircraft can also cause drying of the cornea in unconscious or intubated patients if their eyes are not protected by taping or using artificial tears. In addition, owing to the relatively dry environment, consideration should be given to increasing the rate of IV fluids or providing additional oral hydration, if possible. To combat the effects of decreased humidity, crew members are encouraged to increase their fluid intake.

Figure 4-16 Proper hydration for all air transport patients should be provided.

Noise

Noise is defined as any unwanted sound. Long exposure to noise can damage the soft tissue of the inner ear. The cells and nerves in the inner ear may be completely destroyed by continuous exposure to loud sounds. If enough cells are damaged, hearing is permanently damaged.

To determine how noise will affect hearing, three factors must be considered: loudness, pitch, and duration of exposure. The results of loudness and duration are inversely proportional. The louder the sound, the less time before damage occurs. One of the biggest problems with damage caused by noise involves the subtle symptoms of hearing loss. Hearing loss usually manifests as feelings of pressure or fullness in the ears, muffled speech, or ringing in the ears. These symptoms may go away within minutes, hours, or days after the exposure or, depending on the damage, may never go away. It was once thought that only extremely high sound levels create hearing loss; however, cumulative exposure to levels around 70 dBA without protection have been shown to lead to irreversible hearing loss **Table 4-5**. Sound at 140 dB causes pain and indicates danger of immediate hearing loss.

There are several proven negative consequences to exposure to noise. Noise causes a release of epinephrine, which causes increased myocardial oxygen demand, increased respiratory rate, and vasoconstriction. This vasoconstriction can cause a significant increase in blood pressure, especially in people who are susceptible to hypertension. High levels of noise are also proven to cause headaches, stomach ulcers, feelings of apathy, and feelings of a “headrush.” The US Environmental Protection Agency has established a link between exposure to high levels of noise for an extended period and low-birth-weight neonates and fetal birth defects. A study in Japan showed that a developing fetus is most susceptible to loud noises 14 to 60 days after conception. Because of the difficulty of studying fetuses in utero, research on the exact amount of noise and the duration to noise is questionable. Psychological effects of noise include sleep disturbance, increase in aggressive behavior, and overall increases in chronic stress levels. Noise has also been found to intensify the adverse effects of carbon monoxide and hypoxia, both of which are prevalent in the aircraft environment. Prolonged exposure to noise is also a

significant factor in causing fatigue.

TABLE 4-5 Noise Exposure Without Hearing Protection That Leads to Irreversible Hearing Loss

Sound	Decibel Level (dBA)*	Time of Exposure
Whispering	20	No limit
Normal conversation	60	No limit
Car	70	No limit
Diesel truck	100	2 h
Jackhammer	100	2 h
Helicopter	105	1 h
Live rock music	90-130	30 min to 8 h
Propeller aircraft	120	7 min
Jet aircraft	140	Imminent hearing loss at any length of exposure

*dBA refers to noise levels from A-weighted noise-monitoring equipment, used in noise studies to filter noises so that they are more similar to how they would be interpreted by the human ear.

Noise in the cabin of the aircraft can make it difficult for patients and care providers to communicate, which can lead to patient anxiety. The noise also makes it difficult for CCTPs to assess heart and lung sounds. Many monitoring errors and malfunctions can be attributed to the noise and vibrations associated with air medical transport. Pulse oximetry and hemodynamic monitoring are two technological advances that can help lessen these negative effects and permit early recognition of complications. To preserve the hearing of patients and accompanying family members, CCTPs must remember to provide them with appropriate hearing protection for the flight. In addition, CCTPs and flight crew members must protect their hearing. Many employers require aircraft personnel to wear hearing protection to limit the effects of noise in the aircraft.

A recent study showed that noise causes apathy and that people will instinctively attempt to get away from noise, even if it means ignoring the obvious. An example in the aircraft environment can be seen when loading or unloading a patient when the aircraft is running. Because of a desire to get away from the sound of the aircraft during loading, there may be a tendency to hurry and load the patient while omitting safety features such as fastening all seatbelts on the stretcher. This is a well-documented phenomenon of which flight personnel must be aware, especially when monitoring a patient.

There are several ways to prevent hearing loss in the critical care transport environment. One way is to make equipment modifications that reduce noise exposure. Several such modifications have been made to sirens in the ground transport environment to minimize the effects of the noise on the crew members, while maximizing the effect of the siren on traffic. Previously, siren speakers were mounted on the roofs of ambulances, but are now mounted in the front of the truck above the bumper. This modification was made to decrease the amount of noise to which the crew was exposed, and to also place the siren speaker closer to traffic level. Crew members who are frequently exposed to siren noise should also wear noise-attenuating headsets or ear plugs when the siren is in use. Many ambulances now are equipped with headsets that allow the crew to communicate while protecting them from the external noise of the siren.

Crew members who work in the aircraft environment must be very attentive to the potential for hearing loss. Crew members should be required to always wear hearing protection anytime that they are operating around an aircraft that is running. All crew members working inside a rotor-wing aircraft should always wear hearing protection. Often times this is accomplished by wearing a helmet with an internal communication system. Many crew members elect to wear soft hearing protection under their helmets as a secondary means of protection. For those rotor-wing programs that do not utilize helmets, the use of headsets should always be required. Not only do the helmets and headsets protect from noise, they also facilitate communication between crew members.

Crew members who operate on fixed-wing aircraft may or may not be required to have hearing protection inside the aircraft. Hearing protection is dependent on the type of aircraft (propeller vs jet) and the individual aircraft design. Generally speaking, larger aircraft will have better sound insulation and will not require the use of hearing protection inside the aircraft.

Fatigue

Fatigue is much more than simply the lack of sleep; however, the lack of sleep is the foundation for fatigue. Most physiologic problems encountered in the flight environment can cause significant fatigue. These physiologic problems can quickly become cumulative when combined with the lack of restful sleep. Many flight crew members begin their shift already tired. Studies have shown that greater than 50% of flight personnel are chronically fatigued because of long work hours. Studies conducted by the FAA and the National Transportation Safety Board find that crew fatigue is often times a mitigating factor in aviation accidents and near misses. Air medical crew members most commonly work 12- or 24-hour shifts. However, most pilots are limited by federal regulations to a maximum of 8 flight hours in any 24-hour period and are required to have at least 8 hours of uninterrupted rest. Most companies and flight crews do not rely on government agencies to police their duty time; instead, they impose more stringent requirements on themselves. In addition to lack of sleep, three other factors contribute to crew fatigue: jet lag, vibration of the aircraft, and poor diet, which often includes missed meals due to the very nature of air medical transport.

In the fixed-wing environment, jet lag becomes another fatigue factor. When flight crew travel across time zones, their bodies require time to adjust to the new time zone. Studies have shown that it takes 1 day for each hour of difference from the original time zone to reset the body's own circadian rhythm.

It is not uncommon for CCTPs to experience fatigue while flying, but the challenge arises when CCTPs are required to maintain competency while caring for critically ill or injured patients. Fatigue causes delayed reaction time, thus increasing vulnerability to error. The Commission on Accreditation of Medical Transport Services, discussed in Chapter 1, emphasizes crew rest and ensuring that duty days do not exceed 16 hours. To avoid beginning another flight in a fatigued state, CCTPs should immediately request "crew rest" as soon as they feel fatigued. This request must be granted and typically lasts for 4 hours, occurring between flights. At the end of the 4 hours, a CCTP is reassessed to determine fitness for duty.

The constant vibration that aircrew members experience during flight also leads to fatigue. In order to combat the fatigue from vibration that is often experienced during flight, crew members must be in good physical shape. Crew members can also gradually become resistant to vibration fatigue by increased flight time and the body's ability to compensate with repeated exposure.

The fourth contributing factor to crew fatigue is the 24-hour operational nature of air medical transport. Most air medical programs operate around the clock, and flight crews work varied shift schedules ranging from 8-hour shifts to 24-hour shifts. Crew members may work a varied shift schedule that frequently rotates between day shifts and night shifts, which does not allow for crew members to establish a natural circadian rhythm. There has been an increased focus within the air medical industry to

limit shifts to a maximum of 12 hours in length in order to prevent medical crew fatigue. Air medical programs are encouraged to allow crew members the ability to have crew rest periods incorporated into shifts in order to minimize fatigue.

Gravitational Forces

The body's response to **gravitational forces** is affected by the intensity of the impact of acceleration, its direction, the length of time the body is subjected to stress, the time it takes for gravity's effects to appear, and the individual's unique physical makeup. Although termed gravitational force, it is actually rapid acceleration or deceleration, not gravity, that affects the body. One unit of gravitational force (informally referred to as g force or as 10*g*, for example) is equal to the weight of the object. The gravitational force experienced is multiplied by the weight to determine the actual force on the body. For example, a 100-lb person who experiences 10*g* will have 1,000 lb of force on his or her body.

There are two types of gravitational forces that can be experienced. Negative gravitational forces result from a steep dive in an aircraft. Positive gravitational forces result from high-speed acceleration, climbs, or high-speed turns. Positive gravitational forces push blood away from the brain, whereas negative gravitational forces push blood toward the brain. Most humans can survive a positive gravitational force of 9*g* but are only able to tolerate a negative gravitational force of 2*g* or 3*g*. Most humans will become unconscious around gravitational forces of 6*g* to 8*g*.

Physiologic response to gravitational forces is influenced by the length of time a person feels the effects of acceleration. Acceleration "pushes" that last fewer than 0.2 seconds can be tolerated at a relatively high gravitational force as long as the duration is brief. People who are in car crashes can reach a gravitational force up to 12*g*, but very quickly. A person who experiences a sustained gravitational force of 12*g* will have a greater physiologic impact on the body as a result of the force. Exposure to a gravitational force that lasts longer than 0.2 seconds is considered sustained or prolonged. During prolonged exposure, organs shift and third spacing (discussed later in this chapter) can occur.

Gravitational forces can have significant impacts on the human body. The first physiologic sensation of gravitational force is the feeling of being pushed down in a seat or feeling weightless, depending on whether the aircraft is accelerating or decelerating. As the gravitational force increases, breathing becomes labored. Acceleration compresses the rib cage and lungs, making it difficult to draw in air or exhale. This can result in exhaustion and air hunger. Hypoxia arises when gravitational force causes blood to leave the brain (for example, during a high-speed acceleration or turn) and transfer to the lower extremities. The body must then work much harder to circulate blood to the brain. Hypoxia can result in a loss of peripheral vision, when the body is subjected to gravitational forces of 5*g* to 6*g*. As the gravitational force continues, tunnel vision develops, and, eventually, vision becomes gray (loss of color perception). Further exposure to acceleration stress will cause a person to experience blackout—a loss of all vision. During this time, the organs are displaced downward, significantly affecting blood flow. If the gravitational force continues, the flight crew member will lose consciousness (also called gravitational force loss of consciousness, or gravitational force–induced loss of consciousness). Other signs and symptoms include petechiae, rashes, and bruising; loss of consciousness with accompanying seizures, amnesia, and confusion; and cardiac arrhythmias (tachycardia and bradycardia), heart blocks, and stress cardiomyopathy.

Several factors affect tolerance to sustained exposure to gravitational force. The response is dependent on the person's conditioning, psychological stress level, and amount of muscular straining while experiencing the gravitational force. Because of these factors, military pilots are given extensive training in gravitational force maneuvers to improve their tolerance.

Several other factors are known to decrease tolerance to positive gravitational force during

acceleration. Age can play an important role in determining the extent to which a person may be affected by acceleration. People older than 60 years, for example, have a diminished tolerance to gravitational forces. Infection and illness, resulting in fever and dehydration, also increase the body's susceptibility to the effects of gravitational forces. A person with hypoglycemia will lose consciousness, under acceleration stress, 0.5*g* earlier than someone with a higher, normal blood glucose level. Alcohol consumption will cause a person to feel effects 0.1*g* to 0.4*g* sooner.

Hypoxia and heat stress, conditions that often arise during periods of acceleration, also alter the body's response to gravitational force. Heat stress causes the body's temperature to rise, resulting in a loss of moisture. A person suffering heat stress is more immediately at risk of blacking out. Hypoxia describes a decrease in oxygen levels within the blood, which in turn inhibits blood flow to the brain and eyes. This condition also decreases physical tolerance to positive gravitational force during acceleration. Furthermore, the stress of a situation may cause a person to hyperventilate, a physical response that will reduce the body's resistance to the effects of acceleration.

Spatial Disorientation and Illusions of Flight

Particular movements or situations in flight can make it difficult for a person to keep track of his or her orientation in relation to surroundings. This concept, spatial orientation, is important in studying flight physiology. In flight, a person may not be able to trust his or her senses to orient himself or herself. When this happens, a person experiences **spatial disorientation**—a condition in which he or she has an incorrect understanding of the body's position with respect to earth.

To maintain spatial orientation on the ground, there are three key components. Effective perception, integration, and interpretation of visual, **vestibular**, and **proprioceptive** sensory information are all essential to maintaining orientation. (Vestibular sensory information comes from the organs of equilibrium located in the inner ear. Proprioceptive sensory information comes from the skin, muscles, tendons, and joints.) The brain recognizes changes in linear acceleration, angular acceleration, and gravity and attempts to relate them with visual input. Spatial orientation in flight is difficult to achieve because of conflicting sensory input. When visual, vestibular, and proprioceptive sensory stimuli provide conflicting information, a sensory mismatch occurs and results in illusions and spatial disorientation. Of all of these senses and stimuli, visual reference provides approximately 90% of the information to maintain spatial orientation. Visual reference is a dominant source of input that will overpower conflicting sensations from other systems, and people seldom realize when the brain has received contradictory information. Learning not to rely on visual reference is an important factor for pilots who are flying by instruments. In fact, a great deal of time during instrument training is spent convincing students to trust the instruments and not their senses. Of note, even birds (with the exception of bats) must have vision to maintain orientation and safe flight. Like humans, birds become disoriented in clouds or in fog and are susceptible to spatial disorientation. Senses provide invalid information because the brain is convinced that "down" is the bottom of the aircraft, no matter the actual position or angle of the aircraft.

It is important to note that because all of the illusions discussed in this section result from vestibular ear disorders, these illusions can also cause significant nausea and vomiting, further debilitating the flight crew. Spatial disorientation is responsible for 5% to 10% of all general aviation accidents, and most of the time (90%), accidents resulting from spatial disorientation are fatal.

Types of Spatial Disorientation

Spatial disorientation has been studied for many years by military and civilian organizations. Spatial disorientation is divided into three types: type I, type II, and type III.

Type I

Type I spatial disorientation occurs when the pilot does not notice that spatial disorientation exists because the senses confirm that the pilot's experience is real. If a flight crew member does not sense danger, he or she will not respond to the disorientation. This is a potentially deadly type of disorientation, because it can lead to a crash. A pilot experiencing type I spatial disorientation may fly directly toward the earth without realizing that is where he or she is headed.

Type II

Type II spatial disorientation occurs when the pilot does not realize that he or she is experiencing spatial disorientation, but senses that something is wrong. Usually the pilot will misinterpret the problem as a malfunction of the controls and trust his or her own senses instead of relying on the instruments. For example, during gradual banking and descent, the pilot may sense the descent but not the bank and may attempt to gain altitude. The attempt to gain altitude actually increases the rate of the bank until the aircraft spirals out of control. This is called the graveyard spiral, but it is a rare occurrence.

Type III

Type III spatial disorientation occurs when the pilot is affected by the illusion of intense movement and is unable to reorient himself or herself. Usually when one person is affected this way, the other generally is not, and the correctly oriented person (the copilot) can steer to safety.

Since the John F. Kennedy, Jr, crash in 1999, the FAA has revised several rules regarding recognition of and training for spatial disorientation. Currently, even initial private pilot applicants must receive at least 3 hours of instrument training and be taught recovery techniques, and most instructors include the topic of spatial disorientation during recurrent training.

Visual Illusions

The visual system can give deceptive signals to the brain, especially during instrument meteorological conditions, such as when flying in clouds or low visibility. These illusions can lead to the misperceptions about location, altitude, distance away from other aircrafts or objects, the rate of speed as the aircraft closes in on other objects, and attitude. Flight crew members need to have a good understanding of assorted visual spatial disorientation illusions to prevent and recognize potentially disastrous situations. These situations are potentially lethal but extremely rare.

Third Spacing

Third spacing became a factor in aviation at the end of World War II. Third spacing is the loss of fluids from the intravascular space into the tissues. The German Luftwaffe encountered this phenomenon after they developed the first jet-powered aircraft. It became evident that the human body was not designed for rapid acceleration and deceleration or for high-speed turns. Third spacing became a factor during high-speed turns because of the addition of centrifugal force in concert with the acceleration or deceleration of the aircraft. These forces actually began to push fluids (primarily plasma) from the intravascular into the extravascular space, causing hypovolemia and potentiating hypoxia.

To counteract the effects of third spacing, the "g-suit" or military antishock trousers (MAST pants) were developed. The first g-suits developed actually were tightly laced suits that were similar to corsets. The aviators put these suits on and then tightened the laces to help counteract third spacing. The newer suits recognized high-gravitational-force maneuvers and automatically inflated to help prevent plasma from leaching into the extravascular space. Today, in most aircraft that will experience high-gravitational-force maneuvers, the flight team is equipped with pressure suits and is trained in techniques to prevent them from experiencing third spacing.

Flicker Vertigo

Flicker vertigo is defined by the Flight Safety Foundation as "an imbalance in brain cell activity caused by exposure to low-frequency flickering or flashing of a relative bright light." The effects of flicker vertigo may include nausea, vomiting, seizures, or fainting. These symptoms are usually mild and stop as soon as the source of the flickering is removed. This condition can be brought about by any bright light flickering at a frequency of 4 to 20 cycles per second (Hz). Helicopter personnel are most often affected by flicker vertigo when natural light or reflections of anticollision strobe lights are distorted by rotor blades. This same phenomenon is possible in fixed-wing propeller aircrafts. A rotating beacon can also cause flicker vertigo. If the propellers are the cause of flicker vertigo, simply changing the revolutions per minute of the engine can often eliminate the symptoms; if strobe lights while in clouds are the cause, they can be turned off until the aircraft is in clear skies.

Flicker vertigo can also manifest in patients who are susceptible to external noxious stimuli. For example, a patient with a severe head injury is being prepared for helicopter transport. As the medical crew loads the patient in to the aircraft, the pilot begins to increase the revolutions per minute of the engine. As the engine is warming up, the patient has a seizure. The medical crew instructs the pilot to delay departure so that they can manage the seizure. The patient is given an appropriate dose of an antiepileptic medication and the seizure stops. The medical crew advises the pilot that they are ready for departure. As the pilot speeds up the aircraft engine, the patient has another seizure. The flight crew quickly realizes that the patient's eyes are uncovered and the sunlight coming through the rotors is producing a strobelike effect, causing the seizure. The patient's eyes are covered and there is no more seizure activity during the flight.

Fuel Vapors

Flight crew members and patients are exposed to the noxious odors of fuel vapors. Most of the exposure occurs when the flight crew is loading or unloading a patient. The jet fuel odors can cause headaches and precipitate feelings of nausea, if prolonged. The flight crew is more susceptible to the effects than is the patient, because the crew undergoes more prolonged exposure.

Weather

Weather can be an additional stressor. For example, rapidly worsening conditions or inadvertent flight into conditions that require the use of instrument flight rules (IFRs) cause stress. Transport programs that operate by visual flight rules (VFRs) fly only in conditions that meet a visibility minimum of 3 miles and appropriate clearance from clouds. Transport programs rated for IFRs can fly in all but the worst of weather. The vast majority of rotor-wing programs operate under VFRs only because the pilots often must land the aircraft at unimproved sites (sites that are not paved). Pilots undergo extensive training to quickly handle changing weather conditions.

Anxiety

Anxiety has a pivotal role in flight operations but is rarely addressed or discussed; it is often assumed to have been covered in initial crew training. Several factors can cause anxiety. Numerous studies have shown catecholamine release in flight crew members and patients in rotor-wing operations. Even among experienced flight crew members, there is still a significant release of adrenaline, which is a catecholamine. This release of catecholamines can be advantageous to performance if it occurs in small quantities but detrimental if the release is in large quantities.

The experience and confidence of flight crew members helps determine the amount of adrenaline released. Critical care flight medicine is very different from critical care medicine within the confines of

a hospital. First, providers must realize that the patient always comes second. The safety of the flight crew and the operations of the aircraft always take precedence. Especially during takeoffs and landings, the pilot might require the assistance of medical crew members, and they must divert their attention from the patient. Second, medical flight crew members must not only learn to deal with a wide range of injuries and illnesses in critical care patients, but also must become intimately familiar with the safe operations of the aircraft and how to function as integral members of the aircrew. An excellent critical care practitioner may quickly be overwhelmed by the additional challenges of the flight environment.

There is an exceptionally steep learning curve for new flight nurses and paramedics. They must be adept at treating patients in the most critical of conditions—traumatic and medical—and ranging in age from birth to old age. Initially, all new flight crew members can be expected to have a high level of anxiety until they have gained experience transporting patients with a range of conditions during different types of flights.

Another stressor that can lead to anxiety is the confines of the aircraft cabin. Especially in rotor-wing aircraft, cabins are very small and usually filled with equipment and crew **Figure 4-17**. Even people who do not consider themselves claustrophobic may feel as though they are in a space that is simply too small. Flight crew members are trained in numerous advanced life-saving techniques but may quickly become frustrated when they realize that the confines of the aircraft prevent them from being able to use all of the needed skills.

Anxiety can occur in patients as well as the crew. Patients who express concern about the tight confines of the aircraft may be pretreated with antianxiolitics. Administration is based on individual protocols and patient presentation.

Figure 4-17 Aircraft cabins are very small, which can lead to anxiety on the part of patients and CCTPs.

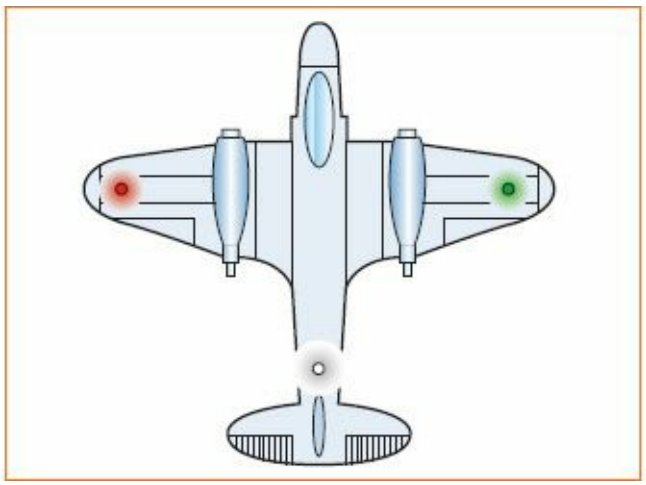

Figure 4-18 An aircraft's lights are set up in a standard format that makes it possible to determine the aircraft's direction of flight.

Night Flying

Crew members must be vigilant in assisting the pilot's scan for other aircraft when able, at night and during the day. Fortunately, due to lighting, aircraft are often easier to spot at night. Lights on airplanes indicate the direction of flight: from the seat of the aircraft being flown, the green light is on the right wing, the red light is on the left wing, and a white light is displayed to the rear. Because the position of lighting on all aircraft is standard, it is easy to determine the direction of flight at night **Figure 4-18**. For example, if a pilot in an aircraft sees another aircraft with a red light on the left, a green light on the right, and a white light in the middle, he or she knows that the aircraft is moving away. A crew member who identifies aircraft traffic on a potential converging course should notify the pilot at once.

Crew members should reduce use of white light that may affect the pilot's night vision. Red lighting inside the aircraft is preferred. The pilot and crew have various advantages and disadvantages. The crew has no outside visibility. The pilot has the following disadvantages:

- Limited field of vision (reduced 40% due to night-vision goggles, if used)
- Added weight stress from helmet
- Loss of depth perception
- Monochromatic vision
- A reduced sense of speed

Factors Affecting Tolerance of the Physiologic Stressors of Flight

The primary human factors affecting tolerance of the stressors of flight can be remembered by the mnemonic IM SAFE, which stands for Illness, Medication, Stress, Alcohol, Fatigue, and Emotion. In flight medicine, there are two "types" of altitude: physical altitude, which is represented in feet above ground, and physiologic altitude, which is the altitude *perceived* by the body. Although incapacitation to altitude does not begin to manifest until 10,000′, the body may perceive being at 14,000′ because of human factors.

Illness

Many illnesses, even a common cold, can significantly impair a crew member's performance. Nasal congestion can lead to severe headaches, vertigo, or nausea during pressure changes, such as during a rapid descent. All flight crew members should be cleared to fly by a physician during any period of illness.

Medications

The use of medications affects the tolerance of hypoxia. Over-the-counter (OTC) medications, although frequently considered benign, can result in incapacitation when their effects are combined with the effects of hypoxia. In addition, an underlying problem might go untreated because OTC medications can mask the problem. All flight crew members should follow approved lists for OTC medications before they fly or consult with a flight surgeon or a physician knowledgeable in flight medicine, such as an aviation medical examiner, before taking any medications when they are scheduled to work.

The FAA has a list of approved prescription and OTC medications that flight crew members are permitted to use. The FAA states in FAR part 61 that pilots assume responsibility for all medications that

they take and that if there is any doubt about the effect of the medication on the ability to fly, they must consult with a flight surgeon before flying. All flight crew members should be strongly cautioned against taking a medication for the first time when they are working because they are unaware of how the body will react to the medication.

Stimulants such as caffeine are frequently used and have a high potential for abuse. Caffeine can cause tachycardia, hypertension, increased urine production, increased excretion, and dehydration. Intake of caffeine greater than 250 mg (about two and a half cups of coffee) can cause problems in most of the population. Caffeine is also a strong diuretic: 1 cup of coffee can result in the elimination of 2 cups of water through urination. Tea has an additional diuretic (theophylline) that can cause an even greater loss of water by urination. Stimulants can also cause insomnia, tremors, indigestion, and nervousness.

Stress

Most pilots and flight crew cannot simply "leave stress on the ground." Everyday stresses such as work, financial, and family issues can affect performance negatively and can lead to distraction and poor judgment. If crew members are experiencing high levels of stress, they should be encouraged to discuss this with members of management at their program. High levels of stress can cause inattentiveness and may have adverse effects on performance, including catastrophic effects in the aviation environment. If crew members recognize high levels of stress in their coworkers, they should take action to ensure the safety and effective operation of the program.

Alcohol

Alcohol can be a toxin in the body and can result in histotoxic hypoxia, inhibiting the use of available oxygen by hemoglobin and delaying metabolism at the cellular level. Research indicates that the intake of 1 oz of alcohol is equivalent to 2,000′ of physiologic altitude. Simply drinking two beers can add between 4,000′ and 8,000′ of physiologic altitude. Alcohol works by depressing the central nervous system and inhibiting judgment and coordination, further amplifying the effects of altitude. Alcohol is also a potent diuretic and can lead to dehydration in the early stages of drinking. As the blood alcohol level increases nearing intoxication, the kidneys begin to produce less urine, actually leading to significant fluid retention. Some studies indicate that part of the reason for hangovers is the significant amount of dehydration followed by rapid fluid retention. FAR part 91 clearly addresses the topic of alcohol. It reads as follows:

a. No person may act or attempt to act as a crewmember of a civil aircraft—

(1) Within 8 hours after the consumption of any alcoholic beverage;

(2) While under the influence of alcohol;

(3) While using any drug that affects the person's faculties in any way contrary to safety; or

(4) While having an alcohol concentration of 0.04 or greater in a blood or breath specimen. Alcohol concentration means grams of alcohol per deciliter of blood or grams of alcohol per 210 liters of breath.

Most aviation companies have a 12-hour "bottle to throttle" policy; however, all policies are underscored by the caveat that people who feel under the influence of alcohol, regardless of the time from the last drink, should not fly. FAR parts 91 and 135 also state that all flight crew members are subject to random drug and alcohol tests at any time while on duty.

Regardless of maintaining 8 or 12 hours between drinking alcohol and flying, another significant hazard is the hangover, or postalcohol impairment, associated with drinking. The symptoms of hangovers include tremors, thirst, nausea and vomiting, diarrhea, sweating, heartburn, dizziness, and headaches.

Physical and mental performance are still markedly reduced 14 to 24 hours after the blood alcohol level has returned to zero. One of the most dangerous problems during the hangover phase is the propensity for hypoglycemia and significant fatigue. Despite the frequent claims made about OTC medications, there is no simple remedy for hangovers. Coffee, cold showers, and breathing 100% oxygen will not speed up the metabolism of alcohol.

Fatigue

Exhaustion and fatigue have an important role in one's ability to tolerate the effects of hypoxia. Flight crew members who provide air medical transport must work all hours. Shift work causes a tremendous disruption in the circadian rhythm, making it difficult for crew members to regulate sleep at work and at home. Shift work can lead to crew members starting their shifts exhausted, predisposing them to the effects of hypoxia. Many air medical crew members also work second jobs during their off time and must use caution to allow for plenty of rest before the start of their flight shifts. Exhaustion can lead to judgment errors, narrowed attention, uncharacteristic behavior, and falling asleep at work. Crew members who find that they need to use pharmacological sleeping aids need to first have the medication approved by a flight surgeon. Frequent use of sleeping aids should be considered a flight safety issue and discussed in depth with a flight surgeon. The constant vibration that aircrew members experience during flight also leads to fatigue.

Emotion

Certain emotionally upsetting events, such as major arguments, a death in the family, and divorce, can significantly impair pilot and crew performance. Any pilot or crew member who experiences an intense emotional event should not fly until satisfactory resolution occurs.

Tobacco

An aviator who smokes risks the effects of hypemic hypoxia, because carbon monoxide is 50 to 300 times more attracted to hemoglobin than oxygen. Research studies have found that smoking three cigarettes in rapid succession or smoking 20 to 30 cigarettes in a 24-hour period can saturate 10% of the hemoglobin in the body. At sea level, a regular smoker has a starting physiologic altitude of 3,000′ to 8,000′. Smoking also affects night vision; a regular smoker has already lost 20% of the night vision, even at sea level.

Hypoglycemia

A nutritious diet allows flight crew members to be much more tolerant to the effects of hypoxia. Poor diet and low blood glucose levels can cause nausea, headache, dizziness, shakiness, nervousness, and judgment errors. Also, not eating or eating foods high in sugar and fat or cooked in grease can precipitate the effects of motion sickness. A good way to prevent the effects of motion sickness is to eat several small meals or regularly snack on healthy foods during the shift. A lack of food in the stomach can cause feelings of nausea and exacerbate the feelings of motion sickness. It is a good idea to keep healthy snack foods such as trail mix or granola bars on the aircraft for situations when eating a meal is not possible.

It is important for flight team members to maintain a healthy weight. Obesity can cause several problems in the flight environment and can be detrimental to the overall safety and performance of the overweight flight crew member. In addition, most rotor-wing flight programs have a weight limit for crew members. A flight crew member taking diet supplements must first have the supplements approved by a flight surgeon.

Additional Stressors

In addition to the aforementioned stressors, there are several others. Age is an important factor; as the body ages, its ability to compensate to stress is diminished. Good physical shape is also important for flight crew members. Physical exertion during flight significantly lowers the altitude at which evolved gas disorders occur. Physical exertion increases oxygen demand, increasing the risk for hypoxia. Maintaining good physical conditioning will help to increase this threshold.

Dysbarism and Evolved Gas Disorders

Various disorders are directly related to altitude. Barotrauma can result from gases expanding and contracting in the body, which causes pain, usually in the digestive tract, sinuses, teeth, middle ear, or lungs. Some illnesses, such as decompression sickness, are not fully understood. Other illnesses, such as **dysbarism**, are directly related to the effects of altitude as described by the various gas laws. A dysbarism is a syndrome resulting from a difference between the barometric pressure and the pressure of gases within the body. As gases expand at altitude, they can cause pain in closed cavities.

Barotitis Media

Barotitis media affects the middle ear and is one of the most common trapped-gas problems. A flight team member who flies with a head cold can experience substantial pain. Barotitis media results from failure of the middle ear space to equalize pressures when going from low to high atmospheric pressure. Pressure in the middle ear becomes increasingly negative and a partial vacuum is created. As the pressure increases, the tympanic membrane is depressed inward and becomes inflamed and a petechial hemorrhage develops. Blood and tissue fluids are drawn into the middle ear cavity. The eardrum may rupture if the pressure does not equalize.

As the barometric pressure in the aircraft cabin decreases during ascent, the air trapped in the middle ear begins to expand, pushing the eustachian tube open. Air escapes through the nasal passages, and the pressure is equalized **Figure 4-19**.

Normally, the eustachian tubes can be opened by swallowing, yawning, tensing the muscles in the throat, and pinching the nose and attempting to blow through the nostrils. On ascent, expanding trapped air usually escapes easily, with the eardrums equalizing pressure, which is usually felt as “popping” in the ears. On descent, it becomes much more difficult for the negative pressure inside the middle ear to equalize. As the negative pressure continues to build, loss of hearing and pain are noted. Any type of respiratory infection can make equalization in the eustachian tube difficult or impossible. If the eustachian tubes are unable to equalize pressure on descent, profound pain may be felt, along with the possible occurrence of hemorrhage, indicating that the eardrum is about to burst or has already ruptured. To relieve the symptoms, the pilot should ascend until the pain is relieved and equalized, then take a very slow descent so the ears can slowly equalize.

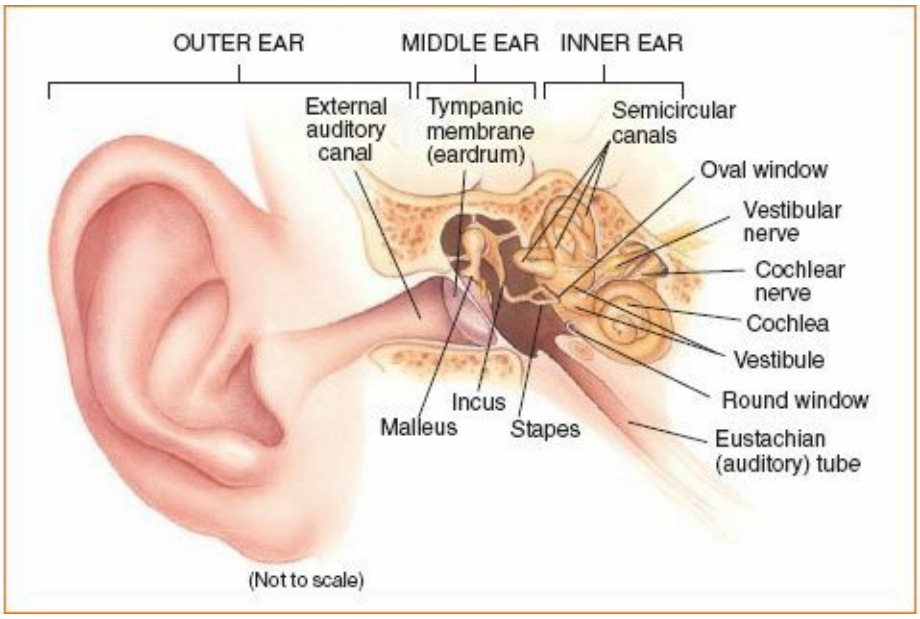

Figure 4-19 The inner ear, including the vestibular system. The otolith organs within the vestibular system are responsible for sensing equilibrium.

Decompression Sickness

Although **decompression sickness** is not the most frequent dysbarism, it is the most commonly known. Decompression sickness is explained by Henry's law and occurs by the formation of inert nitrogen gas bubbles at one or more locations in the body. The manifestation of symptoms depends on the location in the body in which the nitrogen bubbles form.

Normally, the tissue and fluid of the body contain from 1 to 1.5 L of dissolved nitrogen, depending on the barometric pressure of the atmosphere. As altitude decreases, nitrogen leaves the body in an attempt to reestablish equilibrium. Normally, the excess nitrogen diffuses into the capillaries in solution and is eliminated through venous circulation. If a human body is subjected to a rapid decrease in atmospheric pressure, the capillaries become supersaturated and nitrogen begins to leave as a gas instead of in a solution. Nitrogen bubbles begin forming in the tissue and in the blood. Fat is able to dissolve nitrogen five to six times more readily than blood, so tissues having the highest fat content are more likely to become saturated with nitrogen. Decompression sickness can cause circulation problems and, in severe cases, even death because of the potential for nitrogen bubbles in the arterial circulation causing an arterial gas embolism. Symptoms of decompression sickness are listed in **Table 4-6**.

TABLE 4-6 Symptoms of Decompression Sickness
Shortness of breath
Chest pain
Cough
Joint pain
Numbness and tingling of an arm or leg
Partial paralysis
Loss of speech
Loss of hearing

Vertigo
Visual disturbances (blind spots or the sensation of flashing or flickering lights)
Rashes
Itching of the skin

Summary

CCTPs must have a thorough knowledge of flight physiology, not only for their patients, but also for themselves and their fellow flight team members. Even if CCTPs are ground-based, they must still have a strong knowledge of the implications of flight because a large number of their patients will be prepared for flight or be received from a flight. Because the majority of patients that CCTPs will encounter have comorbid conditions or have multiple traumatic injuries, the effects of altitude will be far more pronounced. The most important aspect of flight medicine is safety. A thorough and comprehensive understanding of the implications of flight will help to keep the flight team members and their patients and passengers safe during the duration of the flight.

Case Study

YOU AND YOUR PARTNER ARE WORKING FOR A SMALL, RURAL AIR MEDICAL TRANSPORT SERVICE located in southeastern West Virginia that operates an American Eurocopter EC-135. The terrain that you are accustomed to is extremely mountainous with elevations more than 5,000′ above sea level. Owing to the geographic layout of your service area, many of the flight legs are completed in mountainous terrain with limited signs of human population.

It is 5:00 PM, and you are about half way through your 24-hour shift when you are dispatched to a small community hospital 45 nautical miles from your base. The requesting facility is asking your team to transport a patient via rotor-wing aircraft to a university hospital that is 2 hours away by ground and 25 minutes away by helicopter. Your pilot-in-command checks the local weather, and the decision is made to accept the flight. Once your pilot-in-command calls your operations center to confirm that you can accept the flight, you head to the aircraft and prepare for departure.

As soon as cruise altitude and speed are reached, your communications center informs you that your patient is a 64-year-old man with respiratory failure because of bilateral pneumonia and exacerbation of COPD. The patient was admitted to the hospital 2 days ago with acute shortness of breath and required immediate ventilatory support, including endotracheal intubation. The patient's condition has been stable during the hospital stay, but the family is requesting transport to the university hospital for a second opinion. The patient is receiving a propofol infusion for sedation, normal saline, and ceftriaxone. The patient is being mechanically ventilated with the following ventilator settings: tidal volume, 750 mL; synchronized intermittent mandatory ventilation rate, 12 breaths/min; and F_{IO_2}, 70%.

When you reach the patient in the outlying hospital intensive care unit, you are met by the staff nurse who provides you with a more detailed patient report. During this report, the nurse tells you that the local pulmonologist has been weaning the patient's ventilator settings with the goal of extubation. The results of recent laboratory studies, including blood gases, are reviewed by you and the staff nurse. The most recent set of vital signs are as follows: blood pressure, 124/64 mm Hg; pulse rate, 84 beats/min; respiratory rate, 16 breaths/min (patient is breathing 4 breaths/min on his own); and pulse oximetry, 94%. The nurse tells you that a copy of the patient's chest film and medical chart are in a folder for you to review and asks that you take them to the accepting hospital. Once the patient assessment has been completed and the

medications are transferred to your transport pumps, you secure the patient to your stretcher and prepare him for transport. You and your partner are concerned about his respiratory status owing to the bilateral pneumonia and are worried that he may not tolerate your transport ventilator as well as he did the hospital ventilator. You and your partner decide to perform a trial with the patient on your ventilator for at least 10 minutes before departing for your aircraft. The trial goes smoothly, and you proceed toward the aircraft.

During the initial phase of your flight to the university hospital, the patient remains adequately sedated and his vital signs remain unchanged. About 12 minutes into the flight, you notice that the patient's oxygen saturation readings are beginning to drop into the low 90% levels. After checking the patient and troubleshooting the ventilator and oxygen connections, you determine that ventilator settings are appropriate. You contact online medical command, provide a brief report, and ask permission to adjust the F_{IO_2}. Orders are received to increase the F_{IO_2} to 100% to maintain pulse oximetry readings of at least 97%. Within minutes of making this change, the pulse oximetry readings return to normal, at 99%. The remainder of the flight is unremarkable, and a full patient report is given to the nurse in the intensive care unit on your arrival at the university hospital.

1. What is the most likely cause of your patient's hypoxia that was experienced during flight?
2. What type of changes would you expect to see, as a result of the barometric pressure changes, with the IV solutions that you are infusing through the transport pump?
3. What are some common medical conditions that are typically worsened by altitude changes?

Analysis

It is important to first understand the critical state of a patient who has been diagnosed with bilateral pneumonia and has an underlying lung disease. Patients with these conditions often experience desaturation rather quickly with any change in position, altitude, or ventilator settings. In this particular case, flying at 6,000′ above sea level over very mountainous terrain was required to get to the university hospital. In situations like this one, it is very important to understand Henry's law, which states that the F_{IO_2} should be adjusted upward proportionate to the change in barometric pressure in the helicopter cabin. Because the barometric pressure in the hospital and the barometric pressure in the air are rarely available to CCTPs in advance, awareness is essential that increasing the F_{IO_2} en route may be necessary as altitude increases.

The second question asks what type of changes would be expected as a result of barometric changes when IV solutions are infused through the transport pump. The answer is none! As long as the infusions are being maintained on a pump, the barometric changes will not affect the flow rates. However, if the patient is receiving an infusion via gravity, the infusion rate will increase as the barometric pressure decreases, which occurs with increasing altitudes.

Pneumonia is one of the most common medical conditions that might require additional oxygen therapy to prevent worsening hypoxia. Other medical conditions that are adversely affected by altitude changes are COPD, asthma, coronary artery disease, pneumothorax, shock, and blood loss. Close attention should be given to patients with these conditions, and medical consultation should be obtained before departing the referring facility to discuss adaptive therapies that might be needed throughout the transport.

Prep Kit

Ready for Review

- CCTPs must have a thorough understanding of flight physiology and the implications for patients and for themselves because the medical environment during flight is complex and extremely dynamic and the changes in barometric pressures and the forces experienced in flight can have a significant impact on disease pathophysiology.
- There are several distinct layers of the atmosphere. The first layer is called the troposphere, followed by the tropopause (which together constitute the lower atmosphere). Above the tropopause are the stratosphere, stratopause, mesosphere, and thermosphere, respectively. Critical care transports would not usually fly above the tropopause.
- The atmosphere is divided into three distinct zones that directly correlate with a human's response to hypoxia. These zones are the physiologic zone (which extends from sea level to 10,000′ and contains the oxygen and has the barometric pressure needed for a healthy person to live), the physiologically deficient zone (from 10,000′ to 50,000′, where the barometric pressure begins to decrease and protective equipment, supplemental oxygen, and pressurized aircraft are necessary), and the space equivalent zone (from 50,000′ to 120 miles, where pressure suits and sealed cabins are required).
- Barometric pressure, also called atmospheric pressure, is a direct result of the weight of air and is also related to air density, air temperature, height above the earth's surface, and weather.
- CCTPs need to have a thorough knowledge of the seven gas laws, Boyle's law, Charles' law, Dalton's law, Fick's law, Gay-Lussac's law, Graham's law, and Henry's law, that have integral roles in aviation medicine and flight physiology.
- Boyle's law states that as altitude increases, atmospheric pressure decreases, and the gases inside the body expand. Boyle's law also applies to the expansion of any trapped gas within the body, in such places as the chest, skull, middle ear, sinus, stomach, and intestines, and increasing tension and pressure. Medical equipment and supplies can also be sensitive to an increase or decrease in barometric pressure, including IV fluids, nasogastric and orogastric tubes, and colostomy bags.
- Charles' law states that the higher the altitude, the lower the pressure and the colder it becomes, which puts patients and crew members at risk for hypothermia.
- Dalton's law states that the total pressure of a gas mixture is the sum of the pressures of the individual gases in the mixture, and at higher altitudes, oxygen molecules are less densely distributed, which means that at higher altitudes, an insufficient number of oxygen molecules can lead to hypoxia.
- Fick's law states that the rate of diffusion is affected by atmospheric pressures, the surface area, and the thickness of the membrane. This is the primary gas law for diffusion of oxygen across the alveolar membrane, which means that a patient with COPD and pneumonia will have decreased gas exchange.
- Gay-Lussac's law states that as pressure decreases, temperature decreases, and, therefore, it is important to keep patients warm.
- Graham's law states that if an existing permeable or semipermeable membrane separates regions of unequal pressure, the gas at higher pressure will diffuse through the membrane into the region of lower pressure, meaning that carbon dioxide will diffuse more readily into the bloodstream than oxygen.
- Henry's law states that as the pressure of gas over a liquid decreases, the amount of gas dissolved in the liquid will also decrease, meaning that as the barometric pressure decreases, nitrogen, which normally saturates the tissues, will form gas bubbles that travel to the lungs.
- A main hazard in aviation is hypoxia or oxygen deprivation. In addition to the fact that hypoxia mimics fatigue and hypoglycemia, making it difficult to recognize, one of the earliest effects of hypoxia is impaired judgment, which also limits an aviator's ability to recognize it.

- The length of time a person can function with an inadequate level of oxygen is called the effective performance time, with the time of useful consciousness defined as the period between an individual's sudden deprivation of oxygen at a given altitude and the onset of physical or mental impairment to the point at which deliberate function is lost.
- Hypoxic hypoxia, which can be due to increased altitude, results from a lack of oxygen or an inability of oxygen to diffuse into the bloodstream, symptoms of which begin to manifest at heights above 5,000′.
- Histotoxic hypoxia is the cell's inability to adequately use oxygen, even though there is plenty of oxygen available, because the tissues are not able to accept it or because the oxygen cannot offload from the hemoglobin.
- Stagnant hypoxia is the failure to transport oxygenated blood, and in flight medicine, the reduction in the flow of blood can result from venous pooling during acceleration maneuvers. Stagnant hypoxia, with blood pooling in the lower extremities of patients and crew members sitting in aircraft for extended periods, increases the risk of deep venous thrombosis.
- Hypemic hypoxia, also known as anemic hypoxia, occurs when there is a reduction in the ability of the blood to carry oxygen to the tissues due to a lack of hemoglobin or red blood cells.
- The symptoms of hypoxia are divided into stages (the indifferent stage, the compensatory stage, the disturbance stage, and the critical stage), which are directly related to the altitude, approximate barometric pressure, and the oxygen saturation of the blood.
- The indifferent stage is experienced between sea level and 10,000′ but can occur at altitudes as low as 5,000′. At this stage, night vision begins to deteriorate; electrocar-diographic changes, including tachycardia, are common; a slight increase in alveolar ventilation may be noted; and the oxygen saturation varies from 98% to 87%.
- In the compensatory stage, which occurs between 10,000′ and 15,000′, the body is able to provide short-term physiologic compensation against the effects of hypoxia, such that the respiratory rate and depth may increase and the cardiac output increases. At this stage, hemoglobin saturation varies from 87% to 80%.
- In the disturbance stage, which occurs between 15,000′ and 20,000′, the physiologic compensatory mechanisms are no longer able to provide adequate oxygenation to the tissue, and respirations, senses, mental processes, personality manifestations, and psychomotor functions may all be affected by hypoxia. At this stage, hemoglobin saturation varies from 79% to 70%.
- The critical stage, occurring above 20,000′, is the last stage of hypoxia. Within 3 to 5 minutes of hypo-oxygenation, judgment and coordination deteriorate, and mental confusion is quickly followed by incapacitation, unconsciousness, and death, if the hypoxia is not corrected. At this stage, hemoglobin saturation is less than 65%.
- Recovery from hypoxia is rapid, and full mental abilities can be recovered within 15 seconds after receiving high-flow oxygen. Prevention and avoidance of hypoxia are key to safety, but if hypoxia is detected, immediate use of supplemental oxygen and descent to below 10,000′ are necessary.
- Pressurizing an aircraft, which is accomplished by increasing the barometric pressure inside the aircraft above the ambient pressure outside, is the most effective method of protecting people from the physiologic effects of reduced barometric pressure. The two primary methods used for pressurizing an aircraft are the isobaric system (which is most frequently used and maintains the aircraft cabin at a constant pressure between 5,000′ and 80,000′) and the differential control method (which is used primarily by the military and does not maintain a constant cabin pressure, but varies the pressure with altitude; supplemental oxygen and pressure suits must be available and used at certain altitudes).

- Aircraft decompression at altitude is categorized as slow (as when a small leak develops) or rapid (a dramatic event that occurs with a loud explosion). As a result of decompression, the occupants of the aircraft are exposed to the dangers of hypoxia, decompression sickness, gastrointestinal expansion, and hypothermia.
- The four primary forces that act on an aircraft in flight are lift, thrust, weight (gravity), and drag, with lift counteracting gravity and thrust counteracting drag. In flight, thrust equals drag and lift equals weight, but to take off, a greater amount of thrust and lift are needed, whereas a greater amount of drag and weight are required to land.
- There are many stressors that can cause hypoxia in crew members, and if the proper precautions are not taken, CCTPs may begin to experience symptoms of hypoxia such as confusion, fatigue, visual impairment, headache, nausea, and euphoria.
- A decrease in the PO_2 can quickly cause hypoxia in flight crew members and passengers.
- The greatest change in barometric pressure occurs from sea level to 5,000′, and, therefore, problems associated with pressure must be considered, even in nonpressurized aircraft that are not flying at high altitudes at which supplemental oxygen or cabin pressurization is required.
- Flight crew members are subjected to a variety of extreme temperature changes, ranging from the very cold to the very hot as a result of changes in air temperature and altitude, which, therefore, affect the metabolic rate and the oxygen demands on the body, and at the same time make the body less tolerant of the effects of hypoxia. Temperature changes can cause the effects of hypoxia to be seen at lower altitudes than would normally be expected. Flight crews must be aware of the potential for heat stress and also the greenhouse effect, in which the temperature in the cockpit or cabin of a small aircraft is raised by 50°F (10°C) to 59°F (15°C) simply by radiant solar heat.
- Vibration is noted in all helicopters, in most turboprop aircraft, and, minimally, in jet-engine aircraft. As the body becomes fatigued with prolonged exposure to vibration, the person becomes more susceptible to pain, decreased vision, and fatigue. Preventive measures to decrease vibration include not leaning against the airframe and providing extra padding for the patient.
- Humidity is the degree of moisture in the air and is relative to temperature. Humidity is decreased during a long flight, and the dry air in the aircraft can cause cracked mucous membranes, chapped lips, and sore throats and can lead to dehydration. Crew members should increase fluid intake, and all patients should be properly hydrated.
- Noise in the cabin of an aircraft can make it difficult for patients and care providers to communicate and for CCTPs to assess heart and lung sounds. Monitoring errors and malfunctions can be attributed to the noise and vibrations associated with air medical transport; however, pulse oximetry and hemodynamic monitoring are two technological advances that can lessen these negative effects and help identify complications.
- Most physiologic problems encountered in the flight environment can cause significant fatigue and, coupled with the lack of restful sleep, quickly become cumulative. Jet lag in the fixed-wing environment becomes another fatigue factor. While caring for critically ill or injured patients, CCTPs should immediately request crew rest, typically 4 hours, the minute they feel fatigued.
- Gravitational forces can have a significant impact on the human body, including the feeling of being pushed down in the seat or feeling weightless, depending on whether the aircraft is accelerating or decelerating. As the gravitational force increases, other complications are difficulty breathing, hypoxia, loss of vision, loss of consciousness, petechiae, rashes, bruising, seizures, amnesia, confusion, and cardiac arrhythmias.

- Spatial disorientation is the state of having an incorrect understanding of the body's position in relation to earth and can cause significant nausea and vomiting. The three components to maintaining spatial orientation on the ground are effective perception, integration, and interpretation of visual, vestibular (from the organs of equilibrium in the inner ear), and proprioceptive (from the skin, muscles, tendons, and joints) sensory information.
- Third spacing is the loss of fluids from the intravascular space into the tissues, causing hypovolemia and potentially hypoxia, as a result of high-speed turns in conjunction with acceleration or deceleration of the aircraft.
- Flicker vertigo is defined as an imbalance in brain cell activity caused by exposure to low-frequency flickering or flashing or a relative bright light that occurs when sunlight flickers through the rotor blades or propeller, at night by the anticollision lights reflecting off the clouds, or by rotating beacons or strobe lights, resulting in nausea, vomiting, seizures, or unconsciousness.
- Exposure to the noxious odor of fuel vapors occurs mostly when the flight crew is loading or unloading a patient and can cause headaches and nausea if prolonged.
- Weather, reduced visibility, and night flying can be additional flight stressors.
- Additional factors affecting tolerance of the stressors of flight can be remembered by the mnemonic IM SAFE, which stands for Illness, Medication, Stress, Alcohol, Fatigue, and Emotion. Although incapacitation to altitude does not begin to manifest until 10,000′, the body may perceive being at 14,000′ because of these factors.
- Age and physical condition are additional factors related to one's ability to tolerate the effects of hypoxia.
- Illnesses such as dysbarism (a condition that results from the difference between the barometric pressure and the pressure of gases within the body) are directly related to the effects of altitude as described by various gas laws. As gases expand at altitude, they can cause pain in closed cavities. Barotrauma can result from gases expanding and contracting in the body. This expansion causes pain, usually in the digestive tract, sinuses, teeth, middle ear, or lungs.
- Barotitis media results from the failure of the middle ear space to equalize pressures when going from low to high atmospheric pressure. As the pressure increases, the tympanic membrane is depressed inward and becomes inflamed and petechial hemorrhage develops. Blood and tissue fluids are then drawn into the middle ear cavity, and the eardrum may rupture if the pressure does not equalize.
- Although decompression sickness is not the most frequent dysbarism, it is the most commonly known.

Vital Vocabulary

atmosphere Gases that extend from the earth's surface to space; composed primarily of nitrogen, oxygen, argon, and trace gases.

barometric pressure The weight per unit area of all of the molecules of the gases above the point at which the measurement was taken.

barotitis media Inflammation and possible petechial hemorrhage in the middle ear and possible rupture of the eardrum that results from the failure of the middle ear space to ventilate when going from low to high atmospheric pressure; also known as ear block.

Boyle's law States that the volume of a gas is inversely proportional to the pressure to which it is subjected. Gases trapped in body cavities will expand with increases in altitude and will contract with

decreases in altitude.

Charles' law States that when pressure is constant, the volume of a gas is very nearly proportional to its absolute temperature. Thus, the volume is directly proportional to the temperature when it is expressed on an absolute scale where all other factors remain constant.

compensatory stage A stage of hypoxia in which the physiologic adjustments that occur in the respiratory and circulatory systems are adequate to provide defense against the effects of hypoxia. Factors such as environmental stress and prolonged exercise can potentiate certain effects of hypoxia.

critical stage The stage of acute hypoxia in which there is almost complete mental and physical incapacitation, resulting in rapid loss of consciousness, seizures, respiratory arrest, and death.

Dalton's law States that the total pressure of a gas mixture is the sum of the individual or partial pressures of the gases in the mixture; also referred to as the law of partial pressure.

decompression sickness A condition resulting from exposure to low barometric pressure, causing inert gases normally dissolved in body fluids and tissue to come out of physical solution and form bubbles.

disturbance stage A stage of hypoxia in which physiologic responses are inadequate to compensate for the oxygen deficiency, and hypoxia is evident.

drag The resistance of an airplane to forward motion, directly opposed to thrust.

dysbarism A condition resulting from the effects (excluding hypoxia) of a pressure differential between the ambient barometric pressure and the pressure of gases within the body.

effective performance time The amount of time an individual is able to perform useful duties in an environment of inadequate oxygen; also known as expected performance time.

Fick's law States that the net diffusion rate of a gas across a fluid membrane is proportional to the difference in partial pressure, proportional to the area of the membrane, and inversely proportional to the thickness of the membrane.

flicker vertigo An imbalance in brain cell activity caused by exposure to low-frequency flickering or flashing light. Light flickering from 4 to 20 times per second can precipitate reactions, including nausea, migraines, unconsciousness, and seizures.

flight surgeon A physician who specializes in flight medicine and has been trained extensively in various aspects of aviation and the effects of flight on the human body; also specializes in working with pilots and flight crew members.

Gay-Lussac's law States that the pressure of a gas when volume is maintained constant is directly proportional to the absolute temperature for a constant amount of gas. Simply stated, as pressure increases, volume increases.

Graham's law States that the rate at which gases diffuse is related inversely to the square root of their densities.

gravitational forces Force changes that occur with acceleration and deceleration.

Henry's law States that the amount of gas dissolved in solution is directly proportional to the pressure of the gas over the solution.

histotoxic hypoxia Hypoxia caused by the inability of the tissues to use oxygen, usually as a result of poisoning by toxins such as carbon monoxide and cyanide.

humidity The degree of moisture in the air, expressed as a percentage.

hypemic hypoxia Hypoxia caused by a decrease in the oxygen-carrying capacity of the blood due to a

reduced amount of hemoglobin in the blood or a reduced number of red blood cells; also known as anemic hypoxia.

hypoxia A state of oxygen deficiency in the body, which is sufficient to cause an impairment of function. Hypoxia is caused by the reduction in partial pressure of oxygen, inadequate oxygen transport, or the inability of the tissues to use oxygen.

hypoxic hypoxia Hypoxia caused by a decrease in the amount of oxygen in the blood due to a reduction in oxygen pressure in the lungs, a reduced gas exchange area, exposure to high altitude, or lung disease.

indifferent stage The stage of altitude hypoxia in which the body is able to compensate for the hypoxia induced by low barometric pressures.

isobaric pressurization system A system in which the aircraft cabin is pressurized and the cabin altitude is maintained at a constant pressure even as ambient pressure decreases. This type of pressurization is found in most cargo planes and passenger aircraft.

lift The upward force created by the wings moving through the air, which sustains the airplane in flight.

oxygen paradox A condition that results when a hypoxic person rapidly breathes in 100% oxygen; he or she may experience sudden dizziness, which is quickly resolved followed by complete restoration of function. The condition is possibly due to the sudden constriction of dilated arteries in the brain.

partial pressure of oxygen (arterial) (Pa_{O_2}) The amount of the total pressure in the blood contributed by oxygen; a value measured when analyzing arterial blood gas level.

physiologically deficient zone The zone that extends from 10,000′ to 50,000′. Noticeable physiologic deficits occur above 10,000′. A decrease in barometric pressure results in oxygen deficiency, causing hypoxic hypoxia. In this zone, the manifestation of trapped and evolved gases occurs. The use of pressurized aircraft and/or supplemental oxygen is necessary in this zone.

physiologic zone The zone that extends from sea level to 10,000′ and is the area of the atmosphere to which humans are well adapted. The barometric pressure is sufficient in this zone to facilitate adequate oxygenation. The changes in pressure encountered with rapid ascents or descents within this zone can produce ear or sinus trapped-gas problems.

pneumomediastinum The collection of air within the mediastinum (the space within the chest that contains the heart, major blood vessels, vagus nerve, trachea, and esophagus; located between the two lungs).

pneumoperitoneum The collection of air within the peritoneum (the membrane in the abdomen encasing the liver, spleen, diaphragm, stomach, and transverse colon).

proprioceptive Referring to information that comes from receptors located in the skin, muscles, tendons, and joints; this information helps a person know the position of his or her body.

rapid decompression Occurs when a large leak or hole develops in a pressurized aircraft; can result in hypoxia and injury to people inside the aircraft and catastrophic failure of the aircraft.

space equivalent zone The zone that begins at 50,000′. In this zone, 100% oxygen is not sufficient to prevent hypoxia without the use of a pressurized aircraft or suit. Unprotected personnel may experience boiling of body fluids at a level above 66,500′.

spatial disorientation A state characterized by an erroneous sense of one's position and motion relative to the earth's surface. This condition results from a person's inability to determine his or her position, altitude, and motion in relation to the surface of the earth or to a significant fixed object during flight.

stagnant hypoxia Hypoxia caused by a malfunction of the circulatory system resulting in a decrease in

blood flow.

third spacing A loss of fluids from the intravascular space into the tissues caused by an increase in intravascular pressures and/or increased permeability of the cell membranes. Physical stressors of flight such as temperature, vibration, and changes in gravitational force can cause or aggravate this condition.

thrust The force exerted by the aircraft engine, which pushes air backward with the objective of causing a reaction of the airplane in the forward direction.

time of useful consciousness The time between a person's sudden deprivation of oxygen at a given altitude to the point at which deliberate function is lost. With the loss of effective performance during flight, a person is no longer capable of taking proper corrective or protective actions.

tropopause The space between the troposphere and the stratosphere. It rises to 60,000′ at the equator owing to heated air masses that expand and sinks to about 30,000′ at the poles owing to contracting cold air masses.

troposphere A portion of the earth's atmosphere that extends from the surface of the earth to 5 to 10 miles high depending on the relation to the equator and the poles. This layer is characterized by the presence of water vapors, a constant decrease in temperature with increasing altitude, and large-scale vertical currents.

Type I spatial disorientation The pilot is unaware of becoming disoriented.

Type II spatial disorientation The pilot realizes that a problem exists but does not recognize it as disorientation.

Type III spatial disorientation A sudden incapacitating form of loss of positional awareness.

universal gas law States how a hypothetical gas should act if there are no variables affecting it, such as temperature or pressure. Also known as the ideal gas law.

vestibular Describes organs of equilibrium located in the inner ear.

weight The downward force due to the weight (gravity) of the airplane and its load; directly opposed to lift.

Patient Assessment

Authors

Cathy Provins-Churbock, PhD, RN, MSN, CCRN, CCNS, CNA-BC

M. Allen McCullough, PhD, MPA, MSN, MS, APRN, ENP/FNP, NREMT-P

Mike McEvoy, PhD, RN, CCRN, REMT-P, CIC

Objectives

1. Understand the advantages and disadvantages of prehospital and in-hospital assessment models when used in the critical care transport setting (p 102).
2. Define differential diagnosis and how it is used in the critical care transport setting (p 102).
3. Compare assessment at a scene transport with assessment at an interfacility transport (p 103).
4. Describe the evaluation of assessment information and the process for assessment at a scene transport (p 103–104).
5. Discuss the considerations for packaging a patient at a scene transport (p 104).
6. Describe the evaluation of assessment information and the process for assessment at an interfacility transport (p 104).
7. Discuss the steps for packaging a patient at an interfacility transport (p 110).
8. List the components of a hospital transfer sheet (p 105–109).
9. Define normal and abnormal parameters of the critical care assessment (p 110–119).
10. Describe how to gather the necessary information for a critical care transport (p 103, 104, 105).
11. Describe and perform the assessments required for critical care transports, including the following:
    - General appearance
    - Cardiovascular assessment
    - Respiratory assessment
    - Neurologic assessment
    - Gastrointestinal assessment
    - Genitourinary assessment
    - Musculoskeletal assessment
    - Psychosocial and emotional assessment (p 110–119)
12. Discuss how to determine patient condition utilizing assessment skills (p 110–119).
13. Discuss transferring a patient to a receiving facility appropriately, including proper communication and documentation (p 120).
14. Understand how to interpret patient complaints, signs, and symptoms to determine patient condition and anticipate changes in condition (p 105, 110–119).

Introduction

Patient Assessment in the Critical Care Environment

Assessment of critical care patients presents unique challenges and, at times, dilemmas. During these

transports, patients with complex medical conditions are removed from the security of the intensive care unit, which may destabilize their condition.

Therefore, the need for a thorough understanding of the clinical scenario is a high priority for CCTPs, especially given that the time to obtain and absorb the data may be brief. CCTPs must, therefore, use sharp skills in clinical assessment. Interpersonal communications and diplomacy are also essential when relating to personnel at the sending and receiving hospitals and to patients. A balanced approach to assessment and treatment, applied in the light of modern critical care techniques, produces an effective blend of field and in-hospital principles.

As in all areas of health care practice, critical care intervention is based on the condition of the patient and response to therapy. For this reason, patient assessment is one of the most important processes for CCTPs to understand. Fortunately, nurses and paramedics are quite familiar with assessment processes through their initial training, their observation of other practitioners, independent reading, continuing education courses, and personal interactions and experiences with patients. Nevertheless, it is important to establish an assessment process that ensures the discovery and appropriate management of the patient's critical care needs to limit **morbidity** and **mortality** and improve patient outcomes.

Although we expect a patient in critical health status to have been assessed by prehospital care and hospital personnel in many cases, it is important to be familiar with the assessment process that established the initial care plan and also because critically ill patients change so quickly. Initial plans of care used in nursing and medicine are premised on a review of pertinent data, including assessments, laboratory and radio-logic studies, and other diagnostic tests, to arrive at one or more diagnoses. Paramedics use similar assessment skills and perform limited field diagnostic tests but often do not have the time or resources to achieve hemodynamic stability in a patient or the range of data needed to proceed any further than assembling a list of potential, or differential, diagnoses. When prehospital providers give initial care, they treat according to assessment findings and, using the limited data acquired, often formulate a **projected diagnosis**.

A useful tool mentioned throughout this book is the **differential diagnosis**. The differential diagnosis is a list of all possible diagnoses, aside from the projected diagnosis, that could be causing a patient's symptoms. The clinician, by using diagnostic testing and treatment, excludes or includes each differential diagnosis. In the critical care transport setting, it is useful for CCTPs to have an advanced understanding of pathophysiology and the full range of potential differential diagnoses for patients to assist in making treatment decisions and assessing the effects of treatments.

There are advantages and disadvantages to the paramedic and medical or nursing assessment models. Paramedics treat major problems as the symptoms are found, using a standardized assessment approach based on sequencing the most immediate threats to life and patient survival. The medical and nursing models of assessment are not always attuned to providing treatment during the assessment process. The wealth of information assembled using a medical or nursing model of assessment can be very beneficial to providers and patients by targeting treatment toward a known list of problems. Targeting treatment to underlying problems can be more effective than treating symptoms alone without knowing their causes. A combination of the paramedic and medical or nursing models of assessment is most ideal in the critical care transport environment.

Bridging Environments and Disciplines

The systems assessment presented later in this chapter comprises the detailed physical exam; however, if at any time the patient experiences a sudden deterioration in status, the CCTP should revert to the prehospital assessment and intervention strategies for short-term management (resuscitation).

The prehospital "find a life threat—fix a life threat" mindset is drastically different from the

problem-solving assessment more typically used in clinical practice. Although the prehospital assessment model works well in acute emergency care, it may not be the best choice for critical care. Fortunately, EMS practitioners need not reinvent the wheel. Critical care nursing and critical care medicine have for several decades developed and refined processes, techniques, and interventions unique to critical care patients that we can borrow and refine for use in the evolving field of critical care transport.

A critical care patient is usually being treated for problems involving one or more systems and frequently has interrelated, multisystem complications. CCTPs have for some time used a systems assessment approach for continuing patient evaluation, identifying subjective and objective criteria and performance indicators to measure physiologic status. This approach may be as simple as a neurologic assessment that notes a minor behavioral change or the more sophisticated measurement of intracranial pressure (ICP) with an ICP monitor.

Critical care is not solely driven by technology. Historically, the digital bells and whistles have received significant emphasis, but there has been a philosophical shift in the last decade, a return to bedside clinical care (that is, treating the patient, rather than the machine). The new approach involves looking at and listening to patients and families and making decisions and solving problems by balancing personal and clinical observations with technology. Astute assessment skills can provide data not given by machines or technology. Often, technology used in the hospital intensive care unit is unavailable in the field; therefore, excellent assessment skills are required in the transport setting. This chapter explores a systems approach using clinical observation and technological parameters for the continuing assessment of patients in critical condition.

Scene vs Interfacility Transport

Scene Transport

A CCTP called to an emergency scene will often need to interact with other providers caring for the patient, in some ways not unlike interactions needed on an interfacility transport. It is important to acknowledge and recognize the care provided before CCTP arrival and expeditiously assess, treat, package, and transport the patient to definitive care. Although paramedics may be accustomed to providing care and transport based only on a brief focused exam and limited diagnostic information, medical and nursing CCTPs need to be aware that more comprehensive assessment and sophisticated treatments are best deferred until the patient arrives at a definitive care facility.

Interfacility Transport

Unlike scene transports, voluminous patient information is sometimes available before arrival for interfacility transports. CCTPs should take the time to review all available data and patient information before arrival to reduce the need for referring staff to review or repeat information already transmitted when requesting the transport and to more intelligently interact with staff when receiving the patient for transport. In stark contrast with scene transports, CCTPs should gain a comprehensive, overall picture of the patient as much as possible before initiating transport. This activity includes performing any procedures or diagnostic tests necessary to reduce the likelihood of adverse events occurring during transport.

It is important for the transfer team to have a general understanding of the patient's situation. It can be challenging even for a health care provider to describe in 5 minutes conditions that may have been evolving for 15 days. When preparing for an interfacility transport, the hospital staff needs to understand that the service is not there just to transport the patient from point A to point B. In fact, this period of transfer of an acutely ill or injured patient may become the most critical point in the continuum of total care. An alert CCTP will prompt for and inquire about needed information. A professional manner should be exhibited to maintain good relations with hospital staff. The transport team should respect the nurse-

patient dynamics in the critical care unit because often they have developed a therapeutic relationship that can lead to separation anxiety and increased stress as a result of the transfer.

Anticipated transport time is a critical variable in differentiating "need to know" from "helpful to know" information. The longer the transfer, the more information that may be necessary to provide appropriate assessment and intervention.

The hospital medical record may not contain all the data listed in **Table 5-1**, but it typically includes several special sections based on the patient's diagnostic and medical care needs:

- Admission orders
- Advance directives
- Operative notes
- Postoperative notes
- Progress notes
- Consultation notes
- Preoperative notes
- Procedure notes
- Discharge summary
- Lab reports
- Medication administration records
- Nurses' notes and flow sheets

Scene Transports

Evaluating Available Information

At the beginning of a scene transport, in addition to eliciting patient assessment findings from scene personnel, it is important to ascertain details from the scene that might not be available to providers treating the patient at the receiving facility. These details include the same information that prehospital care providers routinely record and convey, including mechanism of injury details such as speed, distance of fall, type of weapon, and duration of environmental exposure **Figure 5-1**. CCTPs accustomed to practicing in the prehospital environment routinely observe and record pertinent details from the scene and may even include digital or instant photographic images with the patient record.

Current Interventions

Before leaving the scene, it is imperative to obtain as much detail as possible about interventions provided before arrival of the CCTP. These interventions include medications administered, procedures performed, and any other care provided.

Interventions provided on the scene and during transport are recorded using the data collection system of the transport service. At any given moment, a CCTP should be able to reference or immediately recall the total volume of fluids administered, the total doses of each medication administered, and the major procedures performed.

Figure 5-1 CCTPs should observe details from the scene when arriving at a scene transport.

Responses to Interventions

Patient outcomes are largely described by response to interventions. Intervals between reassessment vary and are based on patient acuity. Nevertheless, observing patient response to each intervention and recording these data cannot be overemphasized.

Patient Status

Numerous scoring systems and patient status descriptors have been developed and are in use in in-hospital and prehospital settings. The most useful terms for describing patient status in general are objective and measurable in nature. Subjective terms such as stable, unstable, no acute distress, mild distress, moderate distress, and in extremis are left to interpretation of the caregiver. The Glasgow Coma Scale (GCS) score is one prehospital scoring system that is useful and that facilitates communication between providers and with receiving facilities.

Process for Patient Assessment at the Scene

Patient assessment by CCTPs for scene transports is no different from patient assessment conducted as a field provider except that CCTPs may have available and use more sophisticated patient monitoring devices and technologies on scene and during transport **Figure 5-2**.

Patient Packaging for Transports

Packaging for on-scene transports is dependent on multiple variables, including the physical location of the patient, care in progress on arrival, temperature and weather conditions, and the type of CCTP transport vehicle. Often one CCTP will obtain a patient report while a second CCTP applies the monitoring equipment, conducts a cursory physical assessment, performs any necessary procedures such as obtaining venous access or securing the airway, and bundles the patient and equipment for transfer to the transport unit stretcher.

Figure 5-2 A critical care transport ambulance.

Local practice protocols and procedures dictate the sequence of packaging and moving the patient for transport and the methods used to secure lines, tubes, and equipment before and during transport. The most important component of patient packaging for scene transports is expediency. Delays are not in the best interests of patients, the credibility of CCTPs, or the reputation of the critical care transport service with the field providers on scene.

Interfacility Transports

Evaluating Available Information

Like a CCTP with extensive prehospital experience, a seasoned critical care transport nurse or physician can often scan the "scene" around a hospitalized critically ill patient and instantly gain considerable insight. Drips infusing, ventilator settings, numbers and types of lines, drains, and hemodynamic monitoring values all provide vital information about a patient's condition.

Although actual physical assessment of a patient is focused on the diagnosis or presenting problems following the outline later in this chapter, assessment of ventilator settings, medication infusions, and monitoring equipment in use must be detailed and thorough. Ventilator settings need to be replicated using the transport ventilator, drip fluids may need to be remixed or transferred to different infusion pumps, and monitoring devices and equipment need to be replaced with the critical care transport monitors. To ensure patient safety, CCTPs must assess each therapy before and after transfer to the transport equipment **Figure 5-3**.

Figure 5-3 Assess each therapy the patient is undergoing before and after making transfers to the transport equipment.

Current Interventions

Unlike scene responses, current and previous interventions on interfacility transports can be extensive. Although the history may be contributory, it is important to maintain a focus on the current problem necessitating the need for transport because subsequent care will be predicated on previous interventions. In addition to the therapies presently in place, CCTPs need to learn the other interventions initiated to address the problem at hand, when they were attempted, and their outcomes.

As at scene responses, CCTPs should continually maintain an awareness or be able to immediately access the total volume of fluids administered, including blood and blood products, total doses of each medication administered, and the major procedures performed within the previous 24 hours.

Responses to Interventions

Response to treatments in the interfacility arena tends to be more clear-cut than in the prehospital setting. Often, the reason for critical care transport is to access services not available at the current facility. This supports the principle of getting patients to the most appropriate facility from the beginning of their illness. Sometimes going to the closest in-territory facility actually adversely affects patient outcome.

It is extremely useful to inquire about treatments and interventions that had been tried previously (for example, a phenylephrine infusion administered yesterday that failed to increase the patient's blood pressure or repeated platelet transfusions that did not result in an increased platelet count). Such information is not always easily elicited from the medical record but can benefit patient care during transport and provide helpful information for the receiving facility. In addition, CCTPs should inquire about patient-specific responses to current treatments, recognizing that individuals respond differently to medications and treatments. A critical care nurse caring for a patient can likely provide the precise increment to increase or decrease a pressor infusion in response to changes in blood pressure. Nurses are also probably well versed in the precise amount and type of sedation and/or analgesia needed to manage breakthrough pain or agitation in a specific patient. Obtaining this information before assuming patient care promotes a safer and smoother transition of care.

Patient Status

Interfacility transports encounter patients in two types of conditions: stable and unstable. Standardized scoring systems (ie, APACHE [Acute Physiology and Chronic Health Evaluation]) and other tools to

describe patient status are helpful for charting, billing, and coding but have little value for hands-on patient care. Although much of the assessment information used during an interfacility transport is obtained from the medical record or verbal report from providers at the bedside, determination of patient status must be done by CCTPs.

As with patient responses to interventions, critical care providers at the bedside can be most helpful in outlining anticipated problems during transport. CCTPs should ask about known issues with equipment, specific patient behaviors, and suggested responses to problems that have previously been observed. Knowing, for example, that an endotracheal tube has a small cuff leak and requires 0.1 mL of air every 2 hours, that an intra-aortic balloon pump alarms rapid gas loss whenever the patient coughs, or that a patient's routine runs of ventricular tachycardia are readily converted with 50 J of biphasic energy can save considerable trial and error during transport and make the voyage safer for the patient.

One imperative before initiating any interfacility transport is learning whether there are any advance directives in place. If so, CCTPs should be certain of the specifics contained in these documents and have copies of them during the transport.

Process for Patient Assessment at the Transferring Facility

As with scene transports, CCTPs often split duties, with one provider obtaining report from the transferring facility staff and the other conducting a patient assessment and applying the transport unit monitors, infusion pumps, ventilators, and other equipment. Because substantial assessment data are obtained during report rather than direct assessment, it may be more appropriate in many situations for all CCTPs to listen to a bedside report or to receive report while simultaneously conducting an assessment and transfer of care. "Bedside report" is a national standard in hospitals to improve efficiency, decrease errors, decrease overlooked information, and include patients in the plan of care.

Assessment should begin on entry to the sending facility with an overview of the surroundings to ensure that hallways, elevators, and routes of travel will accommodate the patient, equipment, and personnel to the transport unit. After or while obtaining report from the bedside care providers, CCTPs transfer the patient's monitoring to the transport monitoring equipment, making certain that readings are reliable and replicate those previously observed on the hospital's monitors. By using the report received from the transferring staff, CCTPs conduct an appropriate assessment using the outline presented in Table 5-1. As previously mentioned, although CCTPs have the advantage of more available time for assessment during interfacility transports, it is never necessary to perform every assessment outlined; CCTPs should choose the assessments pertinent to the patient condition and reason for transport.

To better appreciate the balanced, holistic approach to the patient and the situation, when performing an interfacility transport it is best to begin with a general overview that includes items routinely noted in the medical record. Typically, CCTPs will receive this general patient overview from the primary critical care nurse during the patient transfer report and, perhaps, also in written form on the hospital transfer sheet. This brief synopsis should review applicable elements from the following categories:

- Admission data
- History
- Allergies

TABLE 5-1 General Patient Overview for Interfacility Transport

Category	Elements	Examples
Admission data	Name Date Time Admitting diagnosis Sex Age Height Weight Baseline vital signs Mode of arrival Location from which the patient was admitted Attending physician of record Family physician or primary care provider	N/A
History	Chief complaint History of present illness Family medical history Social history Past medical history Hospitalizations Past surgeries and dates	Diabetes Cancer Bleeding tendencies Heart disease Hypertension Stroke Seizures Lung disease Hepatic or renal disorders Other
Allergies	Medications Foods Dye Environment Latex Anesthesia • Prior experience • Any reactions Past blood transfusion • Reaction Types of reactions for all	N/A
Medications	Home In hospital Last use During transport Route, dosage, indication, actions, adverse effects, contraindications, and so forth	N/A
Radiologic films and findings, diagnostic reports	Recent chest film CT scans, cardiac catheterization films, MRI • Copies (printed or electronic) of pertinent CT scans and cardiac catheterization films for transport 12-lead electrocardiogram (copies in transfer record)	Confirms correct placement of ET tube, gastric tube, central lines, chest tubes Unusual ECG patterns
Laboratory and pathology findings	Electrolyte levels ABGs Complete blood cell count Pathology reports (copies in medical record)	Sodium, potassium, and glucose suitable for transport Stable ABG levels Potential transfusion or clotting factor needs
General health	Perception and maintenance patterns Description of general state of health (patient's words) Patient description of own mental and emotional state Greatest concerns and expectations Recent major life changes Cultural beliefs affecting health Anticipated length of hospitalization Tobacco use and amount Recreational drug use, types, and amounts	Medications Dressings and bandages Appliances (such as braces, artificial limbs, dentures, and hearing aids)
Activity	Bed rest (confined) Ambulatory • Independent • Requires assistance Chair Specialty care bed in use	Type of specialty care bed in use
Integumentary system	Wounds	

Integumentary system	Wounds Pressure ulcers or skin breakdown Description of each • Location • Appearance • Drainage (color, amount) Dressing (condition, for example, dry and intact)	N/A
Cognitive/perceptual status	Review of systems, physical assessment Affect and communication style and ability	GCS Alert Agitated Confused Oriented (person, place, and time) Restless Other Language other than English Interpreter
	Eyes: vision	Normal Blind Diplopia Other
	Pupils • Size in millimeters • Reaction to light	No reaction Brisk Sluggish Hippus
	Hearing	No difficulty Hearing impairment Deaf Pain Other
Cardiopulmonary status	Skin	Normal Jaundiced or pale Dry Cool Diaphoretic Warm Within normal limits Edematous or dehydrated Intact Broken
	Heart sounds	S_1 S_2 S_3 S_4 Clicks Murmurs Gallops
	Dyspnea	At rest On exertion Orthopnea
Cardiopulmonary status (continued)	Lung sounds	Clear and equal Crackles or rales Rhonchi Wheezes Stridor
	Chest pain	History

		Site Onset Severity Radiation of pain
	Respiration	Within normal limits Excursion Dyspnea Cheyne-Stokes Agonal
	Edema	Pattern Nonpitting Pitting
	Peripheral pulses	Dorsalis pedis, right and left Radial, right and left
Gastrointestinal and genitourinary status	Diet	Appetite New diagnosis of diabetes or renal or cardiac disease Diagnoses of malnutrition, eating disorder, multisystem trauma Need for nutritional education Need for tube feeding, enteral nutrition, or total parenteral nutrition 10-lb weight loss or gain in past month Dysphagia
	Bowel movement	Normal Last bowel movement Rectal bleeding (color)
	Urination	No difficulty Hematuria Catheter Frequency Urgency
	Female reproductive system	No difficulty Last menstrual period Birth control Hysterectomy Other
	Mouth	Moist Cracked mucosa Sores or lacerations Odors Other
	Bowel sounds	Present Absent Other
	Ostomy	Location
	Abdomen	Soft Firm Flat Distended Tenderness or pain and the location Radiation of pain
	Genitalia	Tender
Musculoskeletal system	Limitations in daily living Weakness and its location Gait, within normal limits, assistance devices, other Orthopaedic appliances History of pain and its location Deformity	N/A

	Deformity Contracture and the location Hand grasp, equal or other Fall prevention protocol	
Personal belongings	Eyeglasses Contact lenses, right and left Intraocular lenses Artificial eye Dentures, upper and lower Hearing aid Electrical appliance Jewelry Prosthesis Other	N/A
Advance directives	Patient and family understanding	State laws Living wills Durable power of attorney for health care Guardianship DNR (do not resuscitate)/DNI (do not intubate) Organ donor Consent form signed Medical order signed
Patient and family understanding and educational needs	Orientation to environment Disease process Diagnostic tests Medication Treatment and therapies Diet and nutritional screening Activity and exercise Equipment and special training Transfer reason Orientation to critical care transport Social service Rehabilitation Other	N/A

Abbreviations: ABG, arterial blood gases; CT, computed tomography; ECG, electrocardiographic; ET, endotracheal; GCS, Glasgow Coma Scale; MRI, magnetic resonance imaging; N/A, not applicable.

- Medications
- Radiologic films and findings, and diagnostic reports
- Laboratory and pathology findings
- Health perception and maintenance pattern
- Activity
- Integumentary system
- Cognitive-perceptual status
- Cardiopulmonary status
- Gastrointestinal and genitourinary status
- Musculoskeletal status
- Personal belongings
- Advance directives
- Patient and family understanding and educational needs

Table 5-1 provides a sample of elements from each of these categories. History taking and physical examination can be overdone, so the elements unique to the patient's needs should be used to develop an individualized critical care plan and documentation designed to meet those needs.

Institutions, critical care transport programs, and states all have varying policies with regard to the transfer of narcotic or controlled substance infusions from one facility or provider to another. It is important to be aware of these policies, if they exist; and to be flexible with regard to remixing, altering, or discontinuing sedation infusions if a hospital policy does not allow you to remove medication infusions from the facility. Involvement of the transferring or receiving physician and/or online medical control may be indicated for patients who will require significant changes in their sedative management for transfer.

Patient Packaging for Transports

Skill Drill 5-1 shows steps for packaging patients for interfacility transports, as follows:

1. Once monitoring equipment is in place, transfer any infusions to the transport unit infusion pumps **Step 1**.
2. Be certain to:
   - Read labels of bags **Step 2**.
   - Trace infusion tubings completely between the bag and the connection to the patient **Step 3**.
   - Label the distal end of the tubing with the infusion name **Step 4**.
3. Once all infusions have been transferred and are operational, reassess for hemodynamic stability and proceed to transfer the patient to the transport unit stretcher. Recheck the integrity of the endotracheal tube and other invasive lines after each transfer.
4. Once the patient is comfortably positioned on the transport stretcher, transfer any other necessary equipment (such as ventilators, continuous positive airway pressure units, and intra-aortic balloon pumps) **Step 5**. Ideal patient position may not be supine. It is important to consider variables such as cervical spine, pain, shortness of breath, and the presence of an endotracheal tube. If a patient is intubated, the ideal position is with the head of the stretcher elevated at least 30°. This helps prevent aspiration pneumonia.
5. Secure all equipment to the transport unit stretcher or carrier, bundle the patient as appropriate for weather conditions, and reassess to ensure that no changes in condition have occurred **Step 6**.
6. Before leaving the patient care area, be certain that all necessary equipment adapters and connectors are with the patient, ensure that family members have directions to the receiving facility, and provide transferring staff with contact information should they want to follow up on the transport of the patient. Show your appreciation for the care and assistance provided by the staff in packaging and transferring the patient to your care.

The Critical Care Systems Assessment

As previously stated, critical care assessment is typically systems based, using observational skills and clinical parameters of physiologic status. The need for technologic monitoring is to support observations or provide greater specificity and/or differentiation to the findings. With this in mind, the following sections review:

- General appearance
- Cardiovascular system assessment
- Respiratory system assessment
- Neurologic system assessment
- Gastrointestinal system assessment
- Genitourinary system assessment
- Musculoskeletal system assessment
- Psychosocial and emotional system assessment

The next sections are not absolute or exhaustive but simply provide a functional framework to

discuss the various elements of the critical care systems assessment. The depth of a systems assessment is dictated by the patient condition. For example, a patient with a subarachnoid hemorrhage would require a detailed neurologic exam at least hourly. Further, limitations of assessment during transfer (noise and turbulence) would lead a prudent CCTP to conduct the assessment prior to leaving the scene. This is especially true during flight transport.

It is important to note early on in the study of physical assessment that the assessment and the data obtained must be individualized to patients and their conditions. Generalization of assessment findings may lead a CCTP astray and impact patient care, as well as CCTP credibility. For example, a newborn with cyanosis of the lips should illicit a different response from a clinician than an adult with the same. The ability of CCTPs to obtain, interpret, and include or exclude data based on a patient's differential diagnoses is referred to as critical thinking. The basic premise of critical thinking can be taught, but only after many years of experience in application can the skill be honed.

In addition, providers must realize that the subjective information obtained from the patient and the family is as important, if not more important, than the objective information obtained during the actual exam. The subjective history includes chief complaint, review of systems, and history of past and present illnesses. These findings should be recorded in the patient's record as direct quotes from the patient and/or family. This information should guide the provider to ask other questions or to examine objective data to qualify the information.

Furthermore, what appears in the beginning of the assessment learning process to be cumbersome will with time occur without an intentional effort. With experience, much of the critical care assessment can be completed with just casual encounters with the patient. For example, if while being placed on a stretcher a patient asks for four pillows, an alert CCTP will inquire more about the need for the pillows. For example, the CCTP should identify orthopnea, or shortness of breath while lying flat, often because of left ventricular dysfunction. The CCTP may then ask, "How long have you been sleeping on four pillows?" in an attempt to ascertain worsening of the condition. This exploration of the system will lead to other assessment parameters such as shortness of breath with activity. Merely listening to patients and their families will provide a myriad of information that assists CCTPs in assessing and treating patients.

Skill Drill 5-1

Packaging Procedures for an Interfacility Transport

1 Once monitoring equipment is in place, transfer any infusions to the transport unit infusion pumps.

2 Be certain to read labels of bags.

3 Be certain to trace infusion tubings completely between the bag and the connection to the patient.

4 Label the distal end of the tubing with the infusion name. Once all infusions have been transferred and are operational, reassess for hemodynamic stability. Proceed to transfer the patient to the transport unit stretcher.

5 Once the patient is comfortably positioned on the transport stretcher, transfer any other necessary equipment.

6 Secure all equipment to the transport unit stretcher or carrier, bundle the patient as appropriate for weather conditions, and reassess to ensure that no changes in condition have occurred. Before leaving the patient care area, be certain that all necessary equipment adapters and connectors are with the patient. Ensure that family members have directions to the receiving facility. Provide transferring staff with contact information for follow-up. Show your appreciation for the care and assistance provided by the staff.

Assessment of General Appearance

The evaluation of general appearance includes an assessment of the patient's apparent health status based on data from the medical records and determination of parameters such as the apparent age relative to chronological age, the level of consciousness (LOC), and skin findings. CCTPs should also note the presence or absence of gross deformity, stature, posture, gait (if the patient is ambulatory), presence and degree of edema, skin lesions, and state of the fingertips and nail beds. Position of comfort is another piece of data that can be used to diagnose disease process. For example, the tripod position in toddlers can signify cardiovascular or respiratory disease. Whenever feasible, it is prudent to allow the patient to assume the position of comfort during transfer.

Skin temperature is another important factor to consider. A cool temperature may indicate vasoconstriction, and a warm or hot temperature may indicate fever. Whether the skin is wet or dry is also of interest. **Turgor**, rapid or sluggish, is an indicator of fluid status. Turgor should be assessed over the sternum or forehead. Use of the hand to assess turgor is often misleading, especially in elderly people and people with friable skin.

Cardiovascular Assessment

Inspection

A general overview or inspection of the patient provides data lending support to an acute diagnosis or gives a clue to a chronic health condition. Just by looking at the patient, an overall sense of the patient's baseline health can be surmised. Is he or she morbidly obese? Cachectic? The patient's skin color, central and peripheral, should be assessed. Either pallor or cyanosis can indicate hypoxia. Cyanosis of the nail beds may indicate acute oxygen insufficiency or, when combined with clubbing **Figure 5-4**, an angle of more than 160° between the nail and nail bed, may indicate long-term hypoxia such as associated with chronic obstructive lung disease.

Figure 5-4 Clubbing.

Special Populations

Peripheral vascular disease (PVD) affects 10% to 40% of the population and is more common in patients with diabetes and in older people. Although 70% to 80% of persons with PVD are asymptomatic, the occlusive nature of PVD can have profound influences on assessment findings. Most significant PVD affects the lower extremities. This can lead to diminished peripheral pulses in the lower extremities and may require a Doppler device to detect arterial flow when pulses are not palpable. Significant PVD in one or both upper extremities can lead to falsely low arterial or cuff blood pressures in the affected arm. Verification of unusual blood pressures with measurement in a different extremity can help avoid unnecessary treatment.

When edema is present, the location and the severity should be noted. Pedal edema is usually graded on a scale from trace to 3+ or 4+ pitting depending on the scale used. Pedal edema should be evaluated by pressing on the skin behind the medial malleolus, over the shin, and over the dorsum of each foot with the thumb and index finger for at least 5 seconds. Indentation can be noted by running the pads of the fingers over the area pressed. A slight indentation that disappears in a short time is termed trace edema. Grade 3+ or 4+ (depending on the scale) is deep pitting that does not disappear readily. The location of the edema and the usual position of the patient should be noted and is used to differentiate between dependent and nondependent edema. In ambulatory and seated patients, edema develops in their lower extremities, whereas patients confined to bed may have more edema in the sacral area.

Caution should always be utilized with subjective scales such as those used to grade pulses and edema. The reason for this is that discrepancy between caregivers can be limb threatening. It is important to perform bedside assessments with the nursing staff prior to leaving the bedside.

Interpretation of the ECG rhythm is essential. As mentioned earlier, if a 12-lead ECG has been recorded, a copy should accompany the transfer record. Questions to consider include the following: What is the underlying or baseline rhythm? What is the usual monitoring lead and morphology? What arrhythmias has the patient experienced? What effects did the arrhythmia have on the patient and was any treatment used? Has the patient ever required defibrillation or cardioversion? If the patient has a pacemaker and/or implanted cardiodefibrillator, a record of the current settings should accompany the transfer record.

Although it is comforting to a health care professional to have invasive monitoring equipment, many times, a skilled health care professional can obtain the same data by using assessment skills. For example, central venous pressure or pressure in the right atrium, which is an indicator of fluid status, can be obtained by using an invasive triple lumen catheter or just by observing for jugular venous distention **Figure 5-5**.

A useful assessment technique that uses inspection is testing the **hepatojugular reflex**. This technique is performed by applying midabdominal pressure while observing for jugular venous distention. If noted, the test result is positive. Pressure on the abdomen displaces fluid from an engorged liver, indicating volume overload.

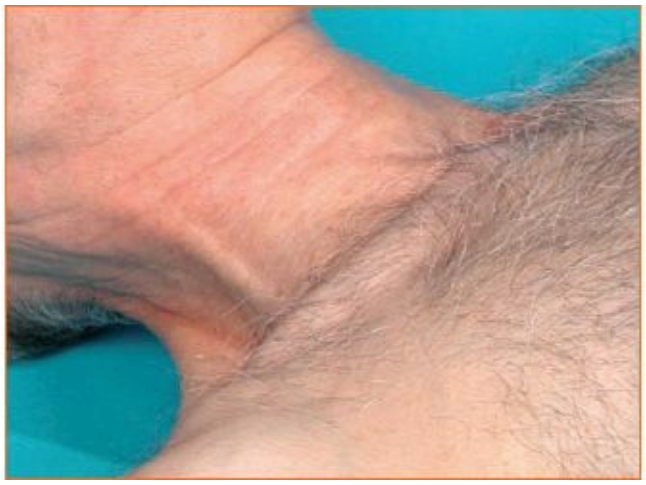

Figure 5-5 Jugular venous distention.

Assessing Pulse

Assessment of peripheral pulses provides valuable information. The carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsalis pedis should be assessed bilaterally for presence, strength, and pattern. Carotid pulses should be palpated one side at a time and without a massaging-type action. Failure to follow this guideline may result in a vagal response and loss of consciousness or embolization of carotid plaque deposits.

Often, trending of pulse assessment findings over time is more valuable than one-time assessments. For example, it is prudent to have two persons assess the strength of the pulses in a patient with a lower extremity crush injury before being transported to a trauma center from a tertiary center. Both should agree and record that, for example, the dorsalis pedis pulses are present bilaterally before transport, but in transit, reassessment shows the pulses still present but slightly weaker. This is a significant finding to be addressed immediately. This is a good example of when a CCTP and the nurse should assess circulatory status together at the bedside. Simultaneous assessment by the nurse and CCTP certainly is not necessary for the entire assessment of all patients, but when life or limb is compromised, it is prudent practice.

Patterns of pulsations are also of interest. In some ECG rhythms, not all electrical beats are perfused. For example, a patient may have ventricular bigeminy with a heart rate of 80 beats/min, but if only 40 of these beats are perfused, further assessment will be needed to determine hemodynamic stability. (A quick method of assessing how many beats are perfused is to compare the rate on the ECG monitor with the heart rate on a pulse oximetry display.) Similar scenarios can occur with sinus or atrial arrhythmias. Furthermore, a noted decrease in pulse rate with inspiration may occur with left ventricular failure.

Figure 5-6 Stethoscopes with a diaphragm and bell, single-lumen tubing, and short tubing are ideal.

Auscultation

Auscultation of heart sounds is an art that requires years of practice to become proficient. The heart should be auscultated at the aortic, pulmonic, tricuspid, and mitral valve locations with the diaphragm and bell of the stethoscope. Furthermore, a quality stethoscope should be used. Stethoscopes with a diaphragm and bell, single-lumen tubing, and short tubing are ideal **Figure 5-6**. Newer stethoscopes incorporate the features of the bell into the diaphragm. When the operator (or CCTP) applies pressure over the diaphragm, it produces the acoustics of a bell. Conventional bell and diaphragm stethoscopes are rapidly being replaced by these newer, easier to use models. Stethoscopes with microphones are not recommended because of the adventitious sounds that they can create.

A thorough understanding of anatomy and physiology is critical to understanding auscultation. Each heart sound is evaluated for pattern, intensity, quality, and pitch. This includes not only listening for the normal heart tones to be sure that they are in fact normal, but also listening for adventitious sounds that can be critical to your patient. Chapter 13 discusses heart sounds in greater depth.

Finding a new murmur may be significant. A systolic murmur appearing after an inferior myocardial infarction is much more significant than a diastolic murmur that a patient has had since turning 90 years old. Also, generally speaking, diastolic murmurs are more concerning than systolic murmurs.

Auscultation over the carotid, renal, and femoral arteries is another assessment parameter to consider in critically ill patients. Detection of bruits and/or loud, harsh sounds indicates blood flow through a narrowed artery and, particularly in the carotid arteries, can be quite significant even in the absence of symptoms.

Blood pressure is a common but often underemphasized clinical parameter. Normal blood pressure in critically ill patients is defined by the individual patient, not a textbook. Indeed, a systolic blood pressure of 90 mm Hg in a 20-year-old may be normal, but this pressure would be abnormal in a patient with a recent myocardial infarction and a history of hypertension. Before transport, trends in blood pressure over time should be noted, especially in response to cardiogenic medications and interventions. When applying the transport unit monitoring equipment, CCTPs should be certain to compare measurements obtained with trends reported and investigate any differences before packaging the patient for transport. Blood pressure should be reassessed at intervals based on patient condition or local protocol. Typically, blood pressure is reassessed every 5 minutes in acutely ill critical care patients and up to every 15 minutes in stable critical care patients. Obviously, more frequent measurements may be

warranted to assess the results of medications or other interventions or if it appears that the patient's condition has changed. When titrating pressors, 5-minute intervals would be the maximal safe interval for blood pressure measurement. Orthostatic blood pressure was previously used in the critical care environment to assess the need for fluid resuscitation. The practice had obvious limitations because it required sitting and standing measurements of blood pressure, which are often impractical. **Passive leg raising (PLR)** is presently used to assess fluid responsiveness in patients with suspected volume depletion. PLR is performed with the patient in a supine position by a provider raising both of the patient's legs to a 45° angle **Figure 5-7**. The blood pressure is then assessed again while the patient's legs are raised. Within 30 seconds, PLR results in a reversible autotransfusion of some 150 to 300 mL of blood into the central circulation. Improvement in blood pressure using PLR suggests fluid-responsive volume depletion. Lack of improvement suggests that no benefit would be derived from volume administration.

Figure 5-7 Passive leg raising is useful for assessing the need for fluid resuscitation. If blood pressure improves while the legs are raised, the patient will benefit from fluid resuscitation.

As the art and science of physical assessment is studied, the question arises, "In what order do I perform assessment parameters?" Again, CCTPs must understand that not all parameters are assessed on all patients, nor are all parameters checked on the same patient at each assessment. A generally accepted critical care standard is that a head-to-toe assessment should be completed no less frequently than every 4 hours and more often when required, based on patient acuity. It is also important that all health care professionals develop an assessment sequence with which they are comfortable. Following the same pattern all the time will prevent inadvertently leaving out an assessment parameter. Adhering to this strategy also improves the time management skills of CCTPs.

Respiratory Assessment

Inspection

Inspection involves the visual examination of the patient with emphasis on the chest. CCTPs should assess the patient and inspect the chest for the following:

- Mental status
- Skin color and temperature; dry or diaphoretic skin
- Presence of an artificial airway (endotracheal or tracheostomy tube)
- Breathing spontaneously vs need for mechanical ventilation
- Equal chest expansion with each breath

- Use of accessory muscles such as scalene, sternocleidomastoid, and/or intercostals
- Work of breathing; labored or unlabored Presence of chest tubes, central lines, and dressings Presence of signs of injury (such as bruising, laceration, and penetrating wounds)

The shape of the chest wall provides evidence of trauma, congenital anomalies, and chronic obstructive pulmonary disease (barrel chest or increased anterior-posterior diameter). Respiratory patterns may lend a clue to an underlying problem as outlined in Chapter 6.

Work of breathing is assessed by inspection of the use of accessory muscles, intercostal retractions or bulging, and nasal flaring. Increased work of breathing requires great metabolic reserve and can be tolerated only for a short period before respiratory decompensation occurs. *Children with signs and symptoms of increased work of breathing are in grave condition and require immediate aggressive interventions*.

Special Populations

Children with signs and symptoms of increased work of breathing are in grave condition and require immediate aggressive interventions.

Palpation

Palpation can also yield information about the skin and subcutaneous tissues. Is the skin warm and dry or cool and clammy? Is there crackling when the skin and tissues are palpated? Feeling a "snap, crackle, pop" during palpation indicates the presence of subcutaneous emphysema, indicating that air is escaping from the pleural space and is dissecting through the subcutaneous tissues. Although subcutaneous emphysema is itself benign, the underlying cause may be life threatening.

A few critical care respiratory assessment parameters worth mentioning include palpation of the trachea for alignment, palpation of the chest wall for bilateral chest excursion, and palpation for subcutaneous emphysema. Each of these parameters has unique considerations. A deviated trachea may indicate the presence of a solid tumor (trachea moves away from tumor) or pneumothorax (trachea moves toward affected lung in a simple pneumothorax but deviates away in a tension pneumothorax). One way of remembering this is that the trachea deviates to the area of least resistance.

Chest excursion should be equal and symmetrical bilaterally. In other words, the chest should rise and fall with inspiration and expiration. A good method of determining where the chest excursions are equal bilaterally is to look at the patient while standing at the patient's feet rather than at the side. By standing at the feet, even small changes in excursion patterns, right vs left, can be detected. Unequal or asymmetrical chest excursion may indicate disease such as a pneumothorax.

Finally, subcutaneous emphysema is a useful indicator of disease states such as a ruptured **bleb**. In a patient with a chest tube, subcutaneous emphysema may indicate an air leak. A small amount of subcutaneous emphysema at the insertion site of a chest tube is a normal variant. A critically ill patient who requires mechanical ventilation and in whom subcutaneous emphysema develops during transport may be receiving too much tidal volume or positive end-expiratory pressures from mechanical ventilation. Another possibility is that the chest tube could have dislodged during transfer from bed to stretcher. A good rule to follow is to assess not only endotracheal tube placement, but also all line positions before and after any transfer.

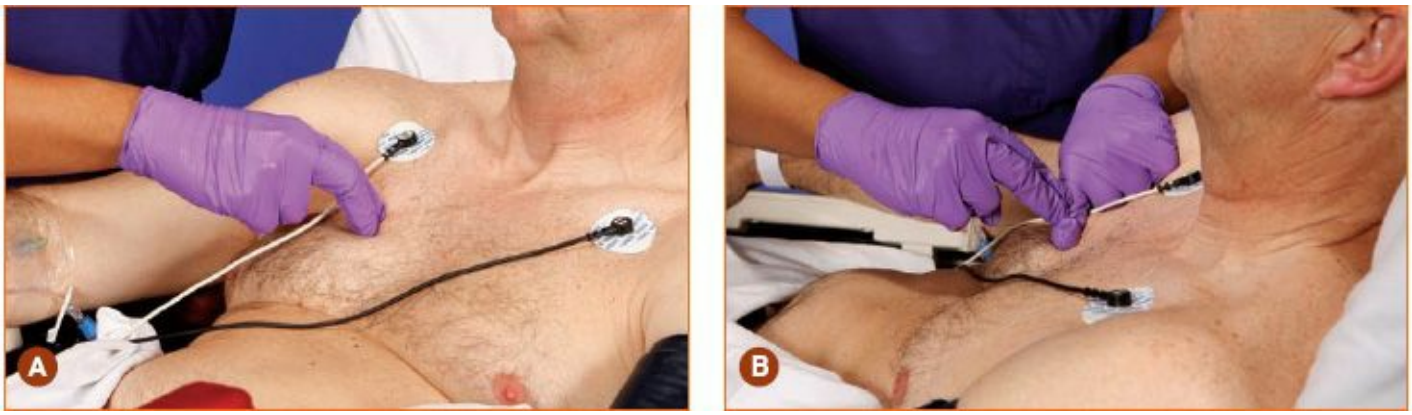

Figure 5-8 **A.** One-handed percussion. **B.** Two-handed percussion.

Percussion

This skill, although often underused, is valuable but requires CCTPs to have a sound knowledge of anatomy, physiology, and percussion technique. This technique is particularly useful when radiography is not available, although it requires a less noisy environment than often found in an intensive care or critical care transport environment. The technique of percussion is performed using one or two hands. The one-handed technique involves using the index and middle fingers to rapidly strike the skin over the lung fields **Figure 5-8A**. The two-handed technique involves striking the index finger of the free hand as it sits over the lung field to be examined **Figure 5-8B**. Attention is given to the sound made by percussion.

Normal lung fields produce **resonance** during percussion. If dullness or flatness is noted, fluid or solid tissue (tumor) may be present. **Hyperresonance** produced during percussion may indicate an air-filled emphysematous lung. Differentiating percussion sounds comes with practice and experience. These sounds are summarized in **Table 5-2**.

Auscultation

The importance of auscultation over all lung fields cannot be overemphasized. Lungs should be auscultated anteriorly, posterially, and medially at the midaxillary lines. All lung fields should be assessed for the presence of normal breath sounds, such as tracheal, bronchial, vesicular, and bronchovesicular sounds, and for adventitious sounds, such as crackles, rhonchi, stridor, and wheezing.

TABLE 5-2 Summary of Percussion Sounds

Sound	Intensity	Pitch	Example
Tympany	Loud	High	Air-filled stomach
Hyperresonance	Loud (louder than resonance)	Low	Emphysematous lung
Resonance	Loud	Low	Normal lung
Dullness	Medium	Medium	Liver, muscle, bone
Flatness	Soft	High	Thigh

The choice of auscultation sites affects the sound heard. One side of the chest wall should be compared directly with the opposite side. Bony landmarks should be used to ensure listening to the same site on each side of the chest, to compare bilaterally. Normally, sounds heard in a particular part of the chest on the right side should sound the same on the corresponding location on the left side. Each of the five lung lobes should be auscultated for a baseline assessment. This is accomplished by listening in as few as six places on the anterior chest wall; the specific locations are shown in Chapter 6 with an in-

depth discussion of abnormal breath sounds.

Normal breath sounds are only normal when heard over the area at which the sound is considered normal. For example, tracheal sounds heard past the midline would not be normal. Notation should be made to the anatomic location, the phase of respiration, and the presence of adventitious sounds. Crackles indicate air passing over fluid in small airways and accompany conditions such as atelectasis and fluid congestion. Rhonchi indicate air moving through large airways containing secretions. Wheezing indicates air moving through narrowed airways. Inspiratory wheezing occurs in upper airway obstructions, and expiratory wheezing occurs with asthma attacks.

When transporting a critically ill patient who is mechanically ventilated, it is important to note current ventilator settings and parameters. Baseline arterial blood gas measurements are essential as well. Maintaining the airway and adequate ventilation is of highest priority during transport. It is important to remember that more oxygen is not always better. CCTPs should always be prepared to invasively protect the airway. The patient's response to the transport ventilator, which may be different from response to a nonportable ventilator, should be assessed. CCTPs need to be prepared to take corrective measures if necessary. Adjustment of inspired oxygen levels to maintain saturations between 94% and 98% is probably appropriate for most patients. It is important to remember that oximetry reflects the percentage of hemoglobin saturated with oxygen. In the presence of very low levels of hemoglobin, even 100% saturated hemoglobin may not be sufficient to meet tissue oxygen needs.

Neurologic Assessment

Neurologic assessments are often the most challenging for CCTPs because of the complexity of the neurologic system. The focus of this discussion is a general neurologic assessment. The neurologic exam is somewhat different from the other system exams because it tends to be more focused to the individual needs of the patient.

Before critical care transports, a neurologic exam is necessary to establish the patient's baseline status for comparison with later findings to determine changes in the patient's condition. CCTPs must have a thorough knowledge of the range of normal responses to determine whether the patient's condition is improving or worsening.

The diagnosis and immediate clinical history of the patient guide CCTPs as to the detail needed for a proper neurologic examination. The LOC is the most important parameter in evaluating a patient with a central nervous system injury.

The GCS is the focal point of assessing a critical care patient. The scale assesses the LOC by evaluating eye opening, verbal, and motor responses to stimulus. This information is scored as shown in **Table 5-3**, and a total value in the range of 3 to 15 is assigned to the patient. The GCS was developed to standardize observations for the objective and accurate assessment of the LOC. A score of 3 indicates deep coma, and a score of 15 is normal. As the score falls, the morbidity and mortality of the patient increases. Medications such as anxiolytics, narcotics, paralytics, and the like all affect GCS. Therefore, where possible the GCS should be assessed both while the patient is sedated and not sedated. As with pulse and blood pressure, trending the GCS scores for a patient over time is especially helpful in the presence of neurologic insult.

In order to illicit a response from the patient, the least noxious stimulus required to illicit a response should be utilized. Deep nail bed pressure is a good starting point.

Decerebrate and decorticate posturing are ominous signs of upper brain stem or deep cerebral injury. Decerebrate posturing **Figure 5-9A** is characterized by hyperextension of the neck, stiff and extended extremities, and palmar flexion of the hands. This posturing results from a lesion in the brain stem. Decorticate posturing **Figure 5-9B** is characterized by arm flexion and adduction with fists clenched and

internal rotation of extended legs. This posturing is the result of a lesion at or above the upper brain stem.

Changes in the GCS score are critical to note because they may indicate increasing ICP. Often the first sign of increased ICP is a change in the LOC, perhaps restlessness or confusion. One must not confuse the effects of medications (such as for pain or sedation) with pathologic neurologic deterioration. For example, if a patient were medicated with lorazepam before transport, CCTPs should associate this with a decreased LOC. Late signs of increased ICP include elevated systolic blood pressure, profound bradycardia, and abnormal respirations (Cushing triad).

TABLE 5-3 Glasgow Coma Scale

Response	Reaction	Score
Eye opening response	Open spontaneously	4
	Open to speech	3
	Open to pain	2
	No response	1
Verbal response	Oriented to person, place, and time	5
	Confused	4
	Inappropriate	3
	Makes incomprehensible sounds	2
	No response	1
Motor response	Obeys verbal command	6
	Localizes pain	5
	Nonpurposeful movement	4
	Flexion: abnormal, decorticate posturing	3
	Extension: abnormal, decerebrate posturing	2
	No response	1

TABLE 5-4 Pupil Response

Pupil Finding	Possible Etiology
Unilaterally dilated, fixed, and nonreactive	Increased intracranial pressure May be normal in some patients Herniation of brain tissue Impending death
Bilaterally dilated, fixed, and nonreactive	Hypoxia Severe brain damage at the level of the midbrain
Bilaterally pinpoint and nonreactive	Narcotic use Severe brain damage at the level of the pons Ischemia

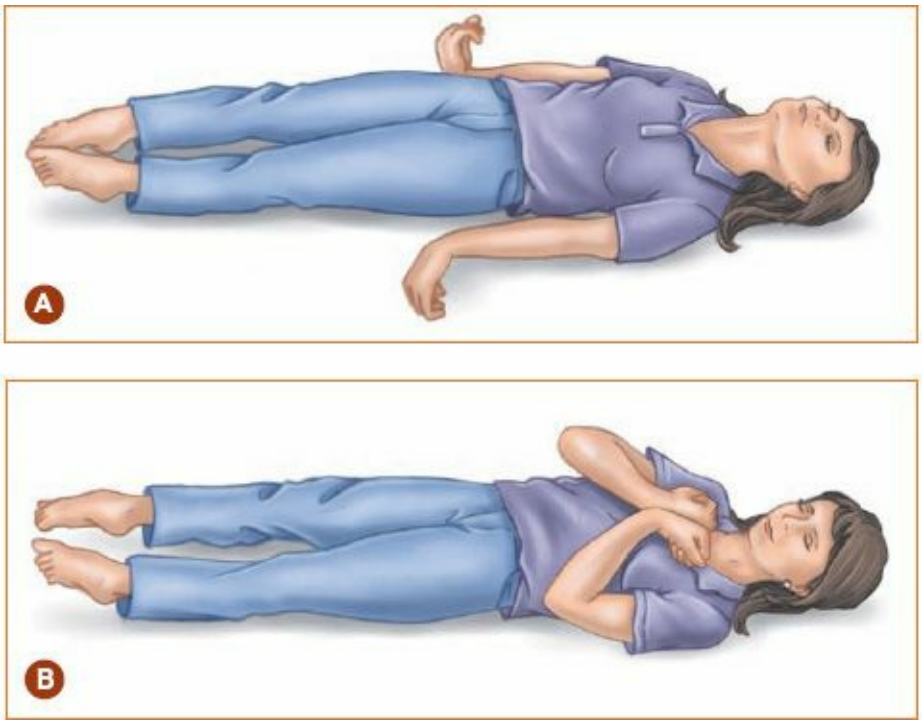

Figure 5-9 Posturing indicates significant ICP. **A.** Decerebrate posturing. **B.** Decorticate posturing.

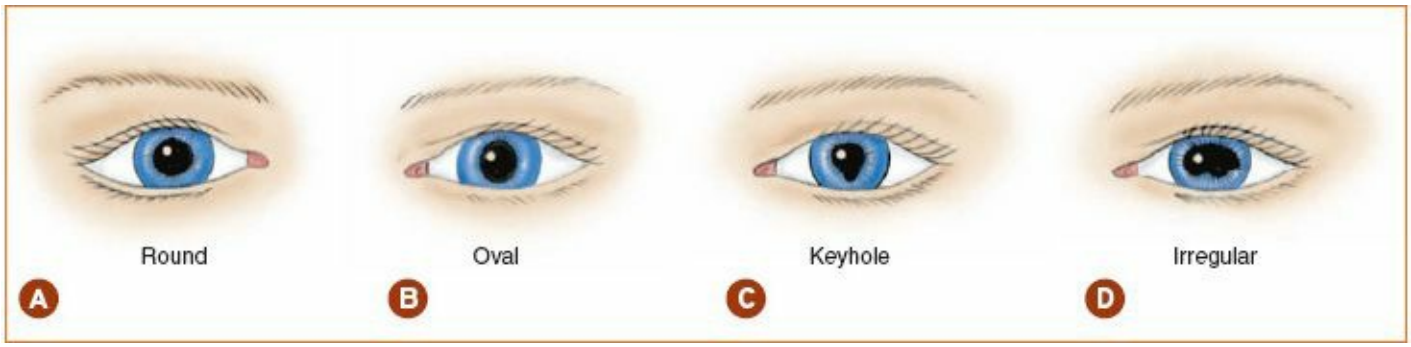

Figure 5-10 The four pupil shapes. **A.** Round. **B.** Oval. **C.** Keyhole. **D.** Irregular.

Another neurologic indicator of great concern is the pupil assessment. Pupils are assessed bilaterally for size (1 to 6 mm), reactivity to light (direct and consensual), and shape. **Table 5-4** lists common pupil findings related to size and reactivity and their possible causes.

Pupil reactivity to light is described as brisk, sluggish, or nonreactive. Occasionally, a CCTP will note a pattern of response in which there is rapid constriction of the pupil to light followed by dilation. This is called the **hippus phenomenon** and may be a variant of normal, but it is also seen with compression of cranial nerve III. **Anisocoria**, unequal pupil size bilaterally, is a normal variant and is seen in about 17% of the population.

There are four common shapes of pupils: round, oval, keyhole, and irregular **Figure 5-10**. Round is normal and the most common. An oval pupil is indicative of increased ICP and is often seen just before herniation of brain tissue. A keyhole pupil (resembling a keyhole in a door) is seen after iridectomies and usually reacts sluggishly. An irregular pupil is jagged looking and occurs most often after orbital trauma.

Unexplained changes in pupil assessment findings should be reported immediately. Consideration must be given to medications the patient is receiving (such as narcotics or cholinergics), anxiety, and other extraneous influences on pupils.

Finally, a cranial nerve assessment is valuable in a patient with a neurologic insult. Subtle changes may indicate impending herniation. Cranial nerve assessment is covered in detail in Chapter 11. Cranial

nerve III is especially helpful in assessing the patient with a neurologic insult. Changes in the extraocular movements and papillary response controlled by the nerve are often the first changes seen with an increase in intracranial pressure.

Controversies

The value of cranial nerve assessment is often downplayed. For many providers, assessment of cranial nerves is limited to preparation for certification or licensing examinations. In practice, cranial nerve assessment is an invaluable tool for localizing sources of sensory or motor dysfunction. Cranial nerve dysfunction can be an early warning sign for otherwise subtle but potentially significant neurologic deterioration but will be detected only if the CCTP is familiar with cranial nerve assessment.

Gastrointestinal Assessment

Inspection

A general overview of the oral mucosa and abdominal areas gives CCTPs general information about the gastrointestinal system. For example, the lips and mucous membranes should be moist and without lesions. Dry mucous membranes may indicate dehydration. A large abdomen may indicate ascites, especially if abdominal wall veins are noted. Hernias or masses may be visible. Bruising over the abdominal wall may indicate trauma or bleeding into the abdominal cavity. Abdominal girth is another assessment parameter used to document enlarging of organs or swelling from internal bleeding. The measurement should be taken at the same location each time. It is important to note that a chief complaint of "abdominal pain" is a major source of emergency department litigation claims.

Critical care patients often have gastrointestinal bleeding as a secondary stress response to their illness. Stools should be assessed for color, consistency, and a foul odor. Upper gastrointestinal bleeding is characterized by dark melena stools and lower gastrointestinal bleeding by stools mixed with bright red blood. Either of these findings should be reported promptly.

Auscultation

Important to note in gastrointestinal assessment is that auscultation of the abdomen occurs before palpation or percussion of the abdomen. The rationale is that one may get a false-positive assessment for bowel sounds if manual manipulation of the intestines occurs first. Bowel sounds should be present in all four quadrants of the abdomen. Bowel sounds may be hypoactive or hyperactive in various disease states. It is important to note, however, that there is great variation in bowel sounds with clinical conditions such as an illeus.

Percussion

Percussion is useful in establishing the size and location of the liver and sometimes the spleen. Percussion can be used to determine hepatomegaly. To percuss the liver, the CCTP should percuss upward on the midclavicular line from the level of the umbilicus. The tympany of the stomach will turn into dullness at the lower liver border. Percussion upward will then turn to resonance at the level of the lung. The distance between these two landmarks indicates liver span. If one performs percussion at the lowest left intercostal space and the sound is dull, the spleen is enlarged; this area is normally resonant.

Palpation

A CCTP typically uses palpation to document tenderness or rebound tenderness. Tenderness occurs with simple palpation; rebound tenderness is when the pain is reported as the pressure of palpation is

removed. Rebound tenderness suggests peritoneal inflammation. If a pelvic fracture is suspected, the pelvis should not be assessed for stability by every caregiver. The reason for this is that any hematoma that has formed to maintain hemostasis may be disrupted, causing internal hemorrhage to the patient.

Murphy's sign is noted when there is severe right upper quadrant pain on deep palpation, often exacerbated by deep inspiration and associated with cholecystitis. Deep palpation is performed by applying firm pressure to the abdominal wall. The liver may also be palpated by placing the left hand behind the patient under the liver and applying firm pressure upward. The fingers of the right hand are placed on the right upper quadrant of the patient's abdomen, and the patient is asked to take a deep breath. The edge of the liver can be felt as it comes down to meet the examiner's fingers. Next, the applied pressure is lightened and nodules or tenderness is noted as the liver slips under the fingers **Figure 5-11**. Nodules of the liver may be related to a malignancy. The spleen is generally not palpable. The right kidney may be palpated, but this examination is not of much clinical value. The kidney should never be palpated if there is a history of polycystic kidney disease.

Genitourinary Assessment

Assessment of the genitalia includes the mammary, testicular, and prostate glands. These assessments are limited to patients with specific needs, such as those with spinal cord injuries or trauma.

Proper kidney function is vital because the kidneys excrete the majority of toxins from the human body. The best indicator of kidney function is the serum creatinine level. The more nephrons (the functioning unit of the kidney) that have been destroyed, the higher the creatinine level.

Figure 5-11 Palpation of the liver.

The **blood urea nitrogen (BUN)** value is more an indicator of hydration than of renal function. The BUN-creatinine ratio is important because it helps determine whether a patient has any type of renal failure. A normal ratio is in the range of 10:1 to 20:1. A normal creatinine level is typically 0.6 to 1.2 mg/dL; and a normal BUN level, 8 to 23 mg/dL. Before signs and symptoms of renal failure occur, 75% of the nephrons of the kidney can be destroyed.

Most often in critical care, renal insufficiency or renal failure is a secondary diagnosis. Because the kidney cannot clear the by-products of metabolism, patients with renal insufficiency or renal failure are prone to metabolic acidosis, congestive heart failure, and electrolyte imbalances. They are also prone to anemia because a diseased kidney does not produce erythropoietin, a hormone that stimulates red blood cell production. Monitoring of lab values, levels of arterial blood gases, fluid intake, and urine output is crucial in a patient with renal impairment.

Some patients are especially prone to renal failure because of burn and crush injuries. The reason is

that the release of large protein molecules from damaged tissue destroys nephrons. The patients often require large amounts of fluid to flush the molecules through the kidney.

In end-stage renal disease, patients may require peritoneal dialysis (PD) or hemodialysis. PD involves a catheter being placed in the peritoneum, where the peritoneum serves as the filter to remove waste from the peritoneal cavity using a dialyzing solution. The patients are especially prone to peritonitis. Therefore, an aseptic technique is important when assessing or performing PD. Patients undergoing hemodialysis will have an arteriovenous (AV) shunt, usually placed in the arm, that is attached to a machine that acts as a mechanical kidney to remove wastes from the body. This AV site should be assessed for a thrill (palpable) and a bruit (audible), which indicate a patent and normally functioning shunt. An absence of one or both of these may indicate clotting of the shunt. AV sites should be used only for hemodialysis. In patients who have a central line and tunneled line access for dialysis, these lines should not be accessed except in dire emergency and only while maintaining as strict sterile technique as possible. Additionally, these lines are typically heparin locked at the completion of treatments. Lines that contain heparin should not be flushed prior to aspiration of a significant amount of waste (minimum of 10 mL per port).

Musculoskeletal Assessment

A CCTP's main concern regarding the musculoskeletal system is maintaining stability of the joints and assessing for neurovascular compromise of distal extremities. Many times, a musculoskeletal concern in a critical care patient is a secondary diagnosis, such as in the case of a multisystem trauma patient.

Maintaining stability of a joint is done with a variety of splints or soft and hard casts. The joint should be maintained at the anatomic degree of flexion or extension found at rest or as ordered by the physician. CCTPs should assess for neurologic changes and vascular compromise related to the immobilizing device. Assessments should be completed bilaterally routinely. A common misconception is that only the operative or injured extremity should be assessed. Complete neurovascular checks include assessment of the distal skin color, nail bed color, skin temperature, mobility of distal joints, pulses, pain, and sensation.

Psychosocial and Emotional Assessment

If a patient has been hospitalized for more than 24 hours, it is likely that a complete psychosocial, emotional, and cultural needs assessment was completed. Information from this assessment should be transferred with the patient because it may be helpful to staff at the receiving facility.

Pertinent aspects relative to CCTPs would be a previously diagnosed psychiatric disorder, significant coping needs related to the present illness, and the level of anxiety the patient is experiencing. Psychiatric disorders may manifest in unsafe behaviors requiring physical or chemical restraint during transport. Significant coping issues or high levels of anxiety may interfere with adequate analgesia and/or require administration of anxiolytics or benzodiazepines.

A CCTP should not discount the therapeutic value of compassionate and empathetic interactions with a patient, even in the face of critical illness. Patients thought to have been deeply unresponsive, heavily medicated, or otherwise uncommunicative will often later recall providers who handled them gently, took the time to explain the care being provided, held their hand, and offered reassurance during a time of utmost stress and anxiety.

Communication and Documentation

Documentation of assessment findings should occur when the patient is first encountered, routinely as

patient condition warrants, and on arrival at the destination. Prudent CCTPs should diligently document findings to provide for continuity of care and patient safety and to protect themselves in case legal issues arise.

Communication should be ongoing with the transferring hospital, which is responsible for care of the patient until arrival at the receiving hospital. Changes should be called in immediately, orders obtained and implemented, and the response of the patient assessed and documented. Staff at the receiving hospital should also be made aware of events occurring en route so they are prepared to receive the patient.

Summary

Assessment skills are vital to CCTPs. Patients are classified as critical because they require frequent if not continuous monitoring. CCTPs are integral members of the health care team, and the continuum of care should be consistent with that provided in the acute care setting.

Assessments are done thoroughly and as frequently as warranted by the patient condition. When examined independently of one another, signs or symptoms hold little meaning. CCTPs must learn how to integrate the pieces of the puzzle into a large holistic view. Subtle changes in a patient or subtle changes in a finding over time may be significant. These subtle changes, if detected, could improve the patient's outcome, including saving the patient's life.

Finally, all assessment findings should be documented accordingly in the medical record. From a legal viewpoint, assessment and care that was not documented was not done.

Case Study

YOU AND YOUR CRITICAL CARE TRANSPORT TEAM are responding to an interfacility transport of a 48-year-old man who presented to the emergency department with severe chest pain. The patient was diagnosed with acute myocardial infarction and an intra-aortic balloon pump was inserted. The patient was admitted to the intensive care unit (ICU) awaiting transport to the specialty heart hospital. En route to the hospital, your crew receives an update on the patient's condition. You and your crew are informed that the patient's vital signs are as follows: blood pressure, 120/75 mm Hg; pulse rate, 110 beats/min; respiratory rate, 30 breaths/min; and pulse oximetry reading, 93%. The patient is on 4 L of oxygen by nasal cannula. He continues to complain of chest pain, rating his pain an 8 on a scale of 1 to 10. He is also complaining of severe back pain.

On your crew's arrival, you find the patient in the ICU. You and your team receive a report from the ICU nurse. She reports that the patient presented to the emergency department this morning around 8:30 complaining of severe chest pain. He was given an aspirin, started on a nitroglycerin drip, and administered a total of 5 mg of morphine. Blood was drawn for lab analysis. The ICU nurse hands you the lab results. You review the results and report the findings to the rest of your crew. The lab results were as follows:

- Calcium: 9.5 mg/dL (normal range, 8.2 to 10.2 mg/dL)
- Chloride: 100 mEq/L (normal range, 96 to 106 mEq/L)
- Magnesium: 2.0 mEq/L (normal range, 1.3 to 2.1 mEq/L)
- Potassium: 4.0 mEq/L (normal range, 3.5 to 5.0 mEq/L)
- Sodium: 142 mEq/L (normal range, 136 to 142 mEq/L)
- Hemoglobin: 14.4 g/dL (normal range, 14.0 to 17.5 g/dL)
- Hematocrit: 45% (normal range, 41% to 50%)

- White blood cell count: 10,400/μL (normal range, 4,500 to 11,000/μL)
- Platelet count: 210 × 10^3/μL (normal range, 150 to 350 × 10^3/μL)
- Creatine kinase-MB: 3.5 ng/mL (normal range, 0 to 7 ng/mL)
- Creatine kinase: 100 U/L (normal range, 40 to 150 U/L)
- Cholesterol: total, 198 mg/dL (normal range, 200 to 239 mg/dL); high-density lipoprotein, 278 mg/dL (normal range, < 40 mg/dL); low-density lipoprotein, 32 mg/dL (normal range, > 160 mg/dL); triglycerides, 205 mg/dL (normal range, < 160 mg/dL)

The arterial blood gas measurement results were as follows:

- pH: 7.30 (normal range, 7.35 to 7.45)
- $Paco_2$: 55 mm Hg (normal range, 35 to 45 mm Hg)
- HCO_3^-: 25 mEq/L (normal range, 21 to 28 mEq/L)
- Po_2: 93 mm Hg (normal range, 80 to 100 mm Hg)

An electrocardiogram (ECG) revealed sinus tachycardia with right axis deviation. As you enter the patient's room, you find the patient lying supine with 4 L of oxygen being delivered via nasal cannula. The patient is attached to the bedside cardiac monitor and the intra-aortic balloon pump (IABP). The cardiac monitor reveals a pulse rate of 130 beats/min, a blood pressure of 145/96 mm Hg, and a pulse oximetry reading of 93%. He is awake, oriented, and follows all commands. His skin is pale. His respiratory rate is 30 breaths/min.

Patient assessment reveals the following:

- **Cardiopulmonary assessment:** The patient's airway is patent, with a slight decrease in chest rise on the right side. Breath sounds are present bilaterally, but slightly diminished on the right side. No wheezes, crackles, or rhonchi were noted. Respiratory effort is labored. No subcutaneous emphysema is noted on palpation. Skin is pale and diaphoretic. Capillary refill is 4 s. No murmur, rubs, friction, or gallops were noted on auscultation of the heart. Pulses are equal in pattern, intensity, and quality in all four extremities. The ECG reveals sinus tachycardia with a rate of 133 beats/min. No pitting edema is noted to extremities.
- **Neurologic assessment:** The patient has a Glasgow Coma Scale score of 15. He is able to move all four extremities without difficulty. His pupils are equal, round, and reactive to light. All cranial nerves are intact.
- **Gastrointestinal assessment:** No ascites or bruising is noted on inspection of the abdominal area. The abdomen is soft, with no tenderness or distention on palpation. No masses or hernias are noted. No rebound tenderness is present. Auscultation of the abdomen reveals hyperactive bowel sounds. The patient denies having vomited blood or blood with a coffee-ground appearance and also denies having had dark, tarry stools.
- **Musculoskeletal assessment:** The patient is able to move all four extremities without difficulty. All reflexes are intact. No swelling to extremities is present. Pulses are present in all extremities.

1. What complications could be occurring with this patient?
2. What do the lab values, arterial blood gas results, and ECG reveal?
3. What is your general impression of this patient?
4. What additional information should you request from the hospital? Would you request any other test(s) prior to transport of this patient?

Analysis

The patient presented with severe chest pain that started 2 hours prior to his arrival at the emergency department. The patient stated that the pain occurred suddenly and nothing he could do relieved it. He described the pain as sharp, and originally rated it a 10 on a scale of 1 to 10. The emergency department physician made a diagnosis of acute myocardial infarction based on borderline lab values. An IABP was inserted and arrangements were made to transport the patient to a specialty heart hospital. The transport crew received the update that the patient was having severe back and chest pain.

The crew's first thoughts while en route to the patient included dissection of the aorta, which is a common complication after an IABP insertion. Classic presentation of an aortic dissection is chest and back pain. The crew discovered that a chest radiograph had not been obtained and asked for an updated chest radiograph. A chest radiograph should be performed before and after IABP insertion.

The lab results and ECG in this case did not confirm the physicians' diagnosis of a myocardial infarction. More testing was needed to confirm an accurate diagnosis. The general impression of this patient is that he is in respiratory distress. Further investigation is warranted because of the possibility of heart failure, respiratory infection, or pneumothorax. Assessment reveals the possibility of a pneumothorax, which must be investigated further, for example with the chest radiograph already requested.

In addition to the chest radiograph, the CCTP should consider requesting a determination of the patient's troponin level. Troponin is a cardiac enzyme specific to injuries of the cardiac muscle. Physicians diagnose myocardial infarction based on several factors, including an ECG, lab values, and patient presentation.

In terms of assessment and treatment, the patient has diminished breath sounds in the right side of the chest. He has labored respirations, and arterial blood gas determinations revealed respiratory acidosis, which are all classic signs of a pneumothorax and possible tension pneumothorax. In situations in which you believe more testing should be done to determine the diagnosis, the critical care team should discuss their assessment findings and ask whether a radiograph or other relevant test can confirm their assessment. Professional and nonconfrontational communication patterns are expected. Respectful behavior on the part of the CCTP, regardless of the situation, helps to promote positive working relationships, while disrespect or negativity may result in a referring facility no longer calling that particular CCT service. If the physician disagrees with your team, a team member should contact the medical director and have him or her contact the transferring physician to help determine the best course of action.

In this case, on the crew's arrival to pick up the patient, the relieving attending physician stated that chest radiography revealed a pneumothorax. After chest tube insertion, the patient was transported to the specialty facility and was evaluated. No cardiac problems were found.

Prep Kit

Ready for Review

- The assessment process ensures proper discovery and management of a patient's critical care needs and improves outcomes.
- CCTPs should be familiar with the assessment process used to establish the initial care plan and have an understanding of pathophysiology and differential diagnoses to be able to make treatment decisions and assess the effects of treatments.

- The assessment process should combine the paramedic model of assessment, which treats major life-threatening problems during the assessment process, and the medical or nursing model of assessment, which targets treatment to underlying problems.
- The systems-based assessment approach must recognize that critical care patients are usually receiving treatment for problems involving multiple systems and interrelated complications.
- Patient assessment should include the use of subjective and objective data and performance indicators to measure physiologic status.
- Assessment ideally includes bedside clinical observations, listening to patients and families, and balancing personal and clinical observations with findings through the use of technology.
- The assessment process differs for scene and interfacility transports.
- At scene transports, CCTPs should ascertain as many details from the scene as possible, interact and communicate with other providers, and defer complex assessment and treatments until arrival at a care facility.
- CCTPs should note interventions provided before their arrival and clearly document patient response to these interventions.
- Multiple variables such as patient location, care in progress on arrival, temperature and weather conditions, and the type of transport vehicle inform the process of patient packaging.
- Local protocols and procedures dictate the sequence of packaging and moving a patient for transport and the methods used to secure lines, tubes, and equipment before and during an interfacility transport.
- For interfacility transports, assessment begins on entry to the sending facility with an overview of the surroundings and routes of travel to ensure safe and feasible transport of the patient, equipment, and personnel to the transport unit.
- CCTPs should review all available data and patient information before their arrival and use anticipated transport time as a consideration for differentiating necessary information from information that is helpful but nonessential.
- In interfacility transports, nurse-patient dynamics should be considered. A patient may experience separation anxiety and increased stress during the transfer.
- CCTPs should scan the scene at the transferring facility for obvious signs of the patient's condition, note medication infusions, and document settings of ventilators and monitoring equipment.
- Patient assessment should include evaluation of each therapy before and after transfer to the transport unit.
- At the transferring facility, CCTPs should inquire about treatments and previous responses to current treatments, determine patient status (for example, stable or unstable), and learn if there are any advance directives in place.
- Patients requiring interfacility transport have often undergone extensive prior interventions; it is important to keep treatment focused on the principal concern that necessitated transport.
- CCTPs must determine if it is necessary to divide tasks (for example, one provider obtaining a report from the transferring facility and the other conducting a patient assessment).
- To help maintain a balanced, holistic approach to the patient and the situation, CCTPs should request a general patient overview and medical record.
- Critical care assessment uses observational skills and clinical parameters of physiologic status to assess general appearance: cardiovascular, respiratory, neurologic, gastrointestinal, genitourinary, and

musculoskeletal systems; and psychosocial and emotional state.

- Assessment of each system and the data needed must be individualized to each patient and his or her specific condition.
- In addition to the exam, CCTPs should always assess and validate differential diagnoses and obtain subjective assessment data from the patient and family.
- Evaluation of general appearance includes an assessment of the patient's overall apparent health status, apparent age relative to chronological age, and level of consciousness.
- Cardiovascular physical assessment includes consideration of the patient's skin color (central and peripheral), making note of any pallor or cyanosis of the lower extremities, redness, cyanosis of the nail beds, clubbing, or edema.
- Cardiovascular assessment must include ECG rhythm interpretation and consideration of heart rate, rhythm, and a history of arrhythmia.
- Invasive monitoring equipment, while helpful, may not be necessary, because skilled providers can obtain substantial data by using assessment skills.
- Carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsalis pedis pulses should be assessed bilaterally for presence, strength, and pattern.
- CCTPs should consider trending of pulse assessment findings over time and patterns of pulsations.
- In the cardiovascular assessment, the heart should be auscultated at the aortic, pulmonic, tricuspid, and mitral valve locations with the diaphragm and bell of the stethoscope.
- Auscultation should be performed over the carotid, renal, and femoral arteries for bruits.
- Blood pressure can be a valuable clinical parameter, but it is important to remember that normal blood pressure is defined by the individual patient. Further, be cautious with the overuse of machines to take blood pressure. There is a margin of error with these machines, especially in hypovolemic states.
- Before transport, trends in blood pressure over time should be noted, especially in response to cardiogenic medications and interventions.
- Vital sign frequency is dictated by the condition of the patient and may range from continuous to every 15 minutes.
- Passive leg raising should be used to assess fluid responsiveness in patients with suspected volume depletion.
- Although not all parameters are assessed on all patients, it is an accepted critical care standard that a head-to-toe assessment be completed at least every 4 hours.
- A CCTP should develop a comfortable and familiar assessment sequence to reduce omissions of parameters and improve time management.
- Assessment of the respiratory system involves visual examination of the patient with emphasis on the chest and evaluation of work of breathing by consideration of use of accessory muscles, intercostal retractions or bulging, and nasal flaring.
- Palpation may yield important information about the skin and subcutaneous tissues.
- Additional respiratory assessment parameters include palpation of the trachea for alignment, palpation of the chest wall for bilateral chest excursion, and palpation for subcutaneous emphysema.
- When radiography is unavailable, percussion may be a valuable assessment tool, although it requires strong knowledge of anatomy, physiology, and technique.

- The ability to differentiate percussion sounds comes with practice and experience. Normal lung fields produce resonance; providers should note dullness or flatness (which may indicate fluid or tumors) or hyperresonance (which may indicate an air-filled, emphysematous lung).
- Lungs should be auscultated from the front and back, at the right and left mid-axillary lines, and over the trachea and bronchi.
- All lung fields should be assessed for the presence of normal breath sounds, such as tracheal, bronchial, vesicular, and bronchovesicular, and for adventitious sounds, such as crackles, rhonchi, stridor, and wheezing.
- When possible, one side of the chest wall should be compared directly with the opposite side.
- When transporting a patient who is mechanically ventilated, it is important to note current ventilator settings and parameters.
- Before critical care transport, a neurologic exam is necessary to establish the patient's baseline status for comparison with the findings of later examinations.
- Neurologic evaluations should be repeated frequently, noting the level of consciousness, Glasgow Coma Scale score, cranial nerve assessment, and pupil assessment, including size, reactivity to light, and shape.
- Neurologic assessment should also include evaluation of posturing and of sensory and motor function in each extremity, comparing both sides.
- Gastrointestinal assessment begins with a general overview of the oropharynx and abdominal areas, noting lesions, swelling, discoloration, and girth.
- Providers should assess stool for color, consistency, presence of blood, and odor.
- Unlike evaluation of other systems, in gastrointestinal assessment, auscultation of the abdomen precedes palpation and percussion.
- Percussion is useful in establishing the size and location of the liver and spleen.
- Palpation can determine tenderness and rebound tenderness.
- Genitourinary assessment includes assessments of the mammary, testicular, and prostate glands. These are generally limited except in the case of trauma.
- The focus of musculoskeletal system assessment is maintaining stability of the joints and considering neurovascular compromise of distal extremities.
- Psychosocial, emotional, and cultural assessment may have been completed before arrival of CCTPs and includes information such as previously diagnosed psychiatric disorders, significant coping needs related to the present illness, and levels of anxiety.
- Regardless of the patient's conditions, CCTPs should always strive for compassionate and empathetic interactions with patients and families, even in the face of critical illness.
- Assessment findings before transfer, en route, and after arrival (based on the acuity of the patient) should be documented.
- The medical record should include documentation of all assessment findings; even subtle changes in an individual patient or an individual finding may become significant.

Vital Vocabulary

anisocoria A condition in which the pupils are not of equal size.

bleb A blister or bladderlike structure that may be filled with fluid.

blood urea nitrogen (BUN) A test used to measure urea, which is a biomarker for adequate kidney function.

differential diagnosis A list of all possible diagnoses, aside from the projected diagnosis, that could be causing a patient's symptoms.

hepatojugular reflex A reflex tested in assessment in which midabdominal pressure is applied while observing for jugular venous distention; if noted, the test result is positive and indicates volume overload.

hippus phenomenon A pattern of pupil response to light in which there is rapid constriction of the pupil followed by dilation; can be normal or signify compression of cranial nerve III.

hyperresonance An abnormal respiratory sound that is exaggerated or increased beyond normal and low in pitch.

morbidity Number of nonfatally injured or disabled people; usually expressed as a rate, meaning the number of nonfatal injuries in a certain population in a given period divided by the size of the population.

mortality Deaths caused by injury and disease; usually expressed as a rate, meaning the number of deaths in a certain population in a given period divided by the size of the population.

Murphy's sign Pain when pressure is applied to the right upper quadrant of the abdomen in a specific manner; helps detect gallbladder problems.

passive leg raising (PLR) A technique used to assess fluid responsiveness in patients with suspected volume depletion, performed by raising both of the patient's legs to a 45° angle and then taking the blood pressure; improvement in blood pressure suggests that the patient will benefit from fluid administration.

projected diagnosis An assumed decision on the medical condition of a patient from preliminary investigation; assists in the provision of initial treatment and projection of further diagnostic testing requirements.

resonance Normal lung sound heard with percussion.

turgor The elasticity of the skin.

tympany A loud, high-pitched, abnormal lung sound.

Respiratory Emergencies and Airway Management

Authors

Thomas J. Butler, PhD, RRT, RPFT

Thomas T. Levins, BSN, RN, CCRN, CFRN

Objectives

1. Summarize the anatomy and physiology of the respiratory system (p 128–134).
2. Define the five requirements for normal ventilation and oxygenation (p 134).
3. Discuss basic airway management strategies (p 141–145).
4. Differentiate between obstructive and restrictive diseases (p 135).
5. Assess a respiratory cycle (p 139).
6. Identify and interpret normal and abnormal breath sounds (p 130).
7. Identify abnormal respiratory patterns (p 137–139).
8. Review the breath sound assessment technique used in critical care transport patients (p 137).
9. Define tidal volume, vital capacity, and peak flow (p 134).
10. Describe how pulse oximetry, capnometry, and capnography can be used to monitor respiratory function (p 140).
11. Identify the parameters measured in arterial blood gas monitoring and identify which parameter reflects the effectiveness of ventilation and oxygenation (p 140).
12. Describe particular clinical events that alter the functioning of the respiratory system in the critical care patient (p 135).
13. Describe how ventilation and perfusion abnormalities affect blood gas values (p 131–133).
14. Perform a basic respiratory assessment for adequacy of ventilation and oxygenation using inspection, auscultation, palpation, and noninvasive monitoring (p 137, 139).
15. Differentiate invasive and noninvasive ventilation (p 174).
16. Differentiate positive- and negative-pressure ventilators (p 173).
17. Differentiate pressure, volume ventilators, and flow- and time-cycled ventilators (p 173–174).
18. Define the parameters of tidal volume, fraction of inspired oxygen, respiratory rate, peak flow, ratio of the length of expiration to inspiration (I:E) ratio, mode, and positive end-expiratory pressure (PEEP) (p 134, 136).
19. Identify the components of a ventilator circuit (p 171).
20. Define the various modes of mechanical ventilation (p 175).
21. Explain the use of PEEP (p 174).
22. Troubleshoot low pressure (disconnect), high pressure, power failure, and other common alarms (p 174).

Introduction

There is no more important or controversial skill associated with prehospital care than airway management. No other skill has the potential for such an impact, positive or negative, on patient outcome. The ability to assess and manage the airway at the BLS level is the starting point in airway management. As ALS providers, it is a standard to fall back on. Assessment of airway and breathing is the critical first step in the ABCs of resuscitation. This assessment will guide you in developing a treatment plan that may be as simple as providing supplemental oxygen to a spontaneously breathing patient or as complex as placing an artificial airway device, or providing adequate ventilation with a bag-mask device or ventilator.

Ensuring the adequacy of ventilation and oxygenation in critically ill patients is one of the primary treatment goals of the CCTP. Patient history, visual inspection of the chest, vital signs, auscultation, and the blood gas measurements all provide key information about the functioning of the respiratory system. A thorough understanding of respiratory function and assessment is essential in order to meet this goal. Without these basic skills, you will be unable to provide the necessary intervention when a patient's respiratory status deteriorates during transport. When respiratory compromise occurs in your patient, time is critical, and the CCTP must be prepared to perform a rapid, accurate respiratory assessment followed by the appropriate intervention.

Anatomy and Physiology of the Respiratory System

An understanding of airway anatomy and physiology is essential to successful airway management.

Upper Airway Structures

Important airway structures of the upper airway include the nose, mouth, pharynx, and larynx, which contains the epiglottis.

Nose

The nose is a cartilaginous, bony structure in the midline of the face that warms and humidifies inspired air. The nose is lined with coarse hairs in the vestibular area, which act as a filter to trap small inspired particles. Olfaction (sense of smell) also originates here via the first cranial nerve (olfactory nerve). The nasal cavities connect to the four sinuses: frontal, ethmoidal, sphenoidal, and maxillary. These four sinuses are hollow chambers lined with membranes that secrete mucus into the nasal cavities. The nasal cavity subsequently opens into the nasopharynx.

The nose, which is extremely vascular (Kisselbach's plexus), can be a significant source of epistaxis, which may complicate airway patency and management.

Mouth

Primarily designed for phonation and mastication, the mouth begins at the lips and ends with the oropharynx. The size of the oral cavity (the larger the better) can affect airway management **Figure 6-1**. The mouth contains the tongue, which is attached to the mandible, and the teeth. Both of these structures may make airway management more difficult if edema of the lingual or sublingual spaces is present. Additionally, prominent central incisors (buck teeth) may also make airway management more difficult, as this may interfere with insertion of the laryngoscope blade. Salivary glands continuously secrete saliva, which may make topical anesthesia and visualization of airway structures difficult. Remember, the tongue is the most common cause of airway obstruction in the unconscious patient. A simple jaw thrust maneuver may temporarily alleviate airway obstruction and allow effective bag-mask ventilation.

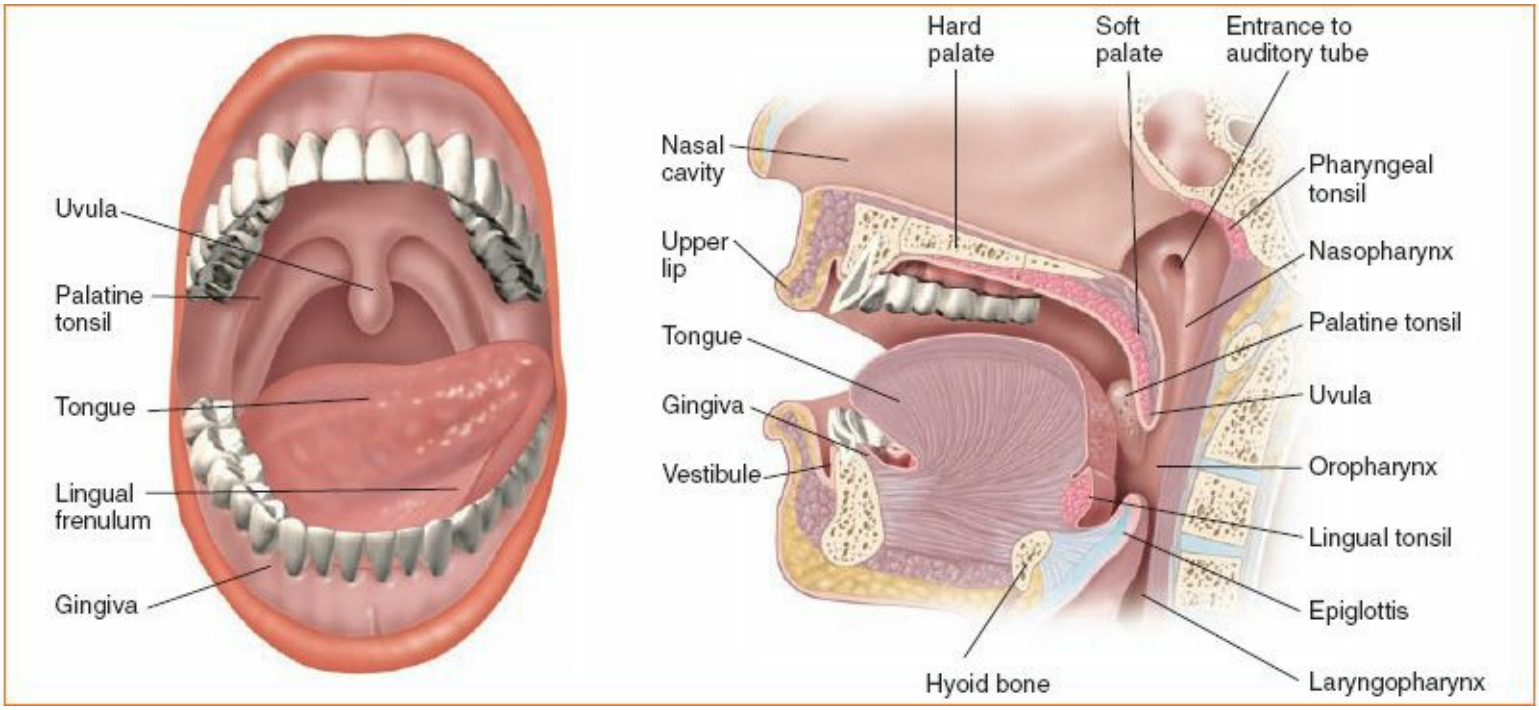

Figure 6-1 The oral cavity.

Pharynx

The pharynx is a U-shaped tube that begins at the base of the skull and extends to the lower border of the cricoid cartilage near the esophagus **Figure 6-2**. It is composed of three parts: the nasopharynx, the oropharynx, and the hypopharynx (or laryngopharynx):

- Nasopharynx: Extends from the posterior choane (the posterior portion of the nasal cavity) of the nose to the soft palate and contains the adenoid tissue and the eustachian tubes.
- Oropharynx: Extends from the soft palate to the vallecula. It is the portion that is visible when the mouth is opened.
- Hypopharynx: The portion of the pharynx inferior to the epiglottis.

The normal resting muscle tone of the oropharynx maintains upper airway patency. The ninth cranial nerve, the glossopharyngeal, provides sensory innervation to many of the structures in this area (posterior tongue, valleculae, and parts of the epiglottis). The inferior portion of the pharynx ends with the entrance to both the trachea and the esophagus.

Larynx

Structures contained within the larynx are the thyroid cartilage, aryepiglottic folds, epiglottis, vallecula, and arytenoid cartilages **Figure 6-3**. The larynx is the final structure before entering the trachea. The vagus nerve, a branch (superior laryngeal) of the 10th cranial nerve, provides strong sensory innervation to the larynx. Stimulation of the larynx may cause significant sympathetic stimulation and result in significant increases in heart rate and blood pressure. The cricothyroid membrane is also located here, extending from the lower surface of the cricoid cartilage to the upper border of the thyroid cartilage. In the adult patient, the cricothyroid membrane is approximately 6 to 8 mm from superior to inferior border.

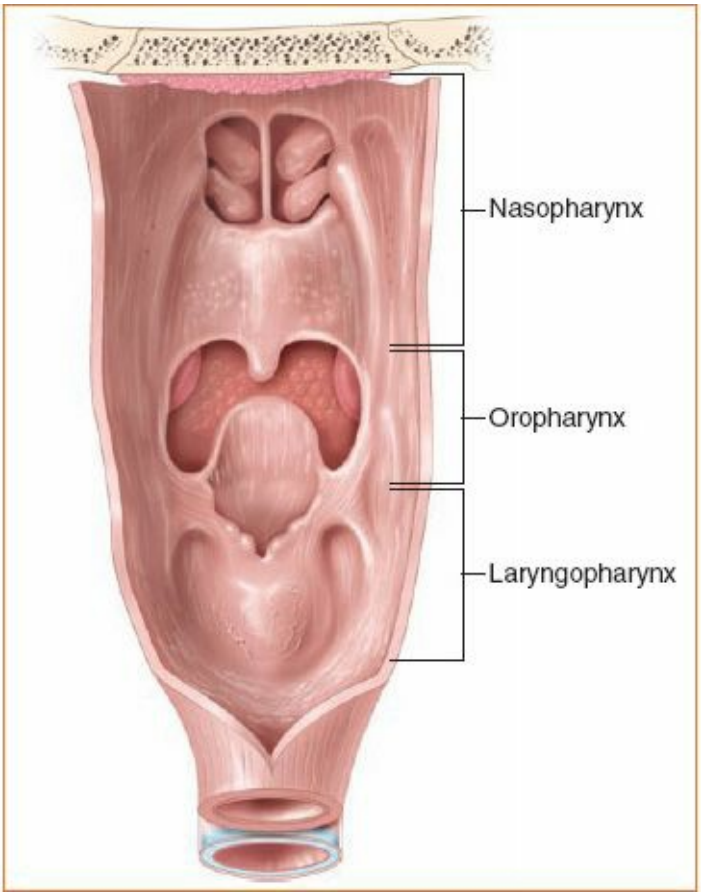

Figure 6-2 The pharynx.

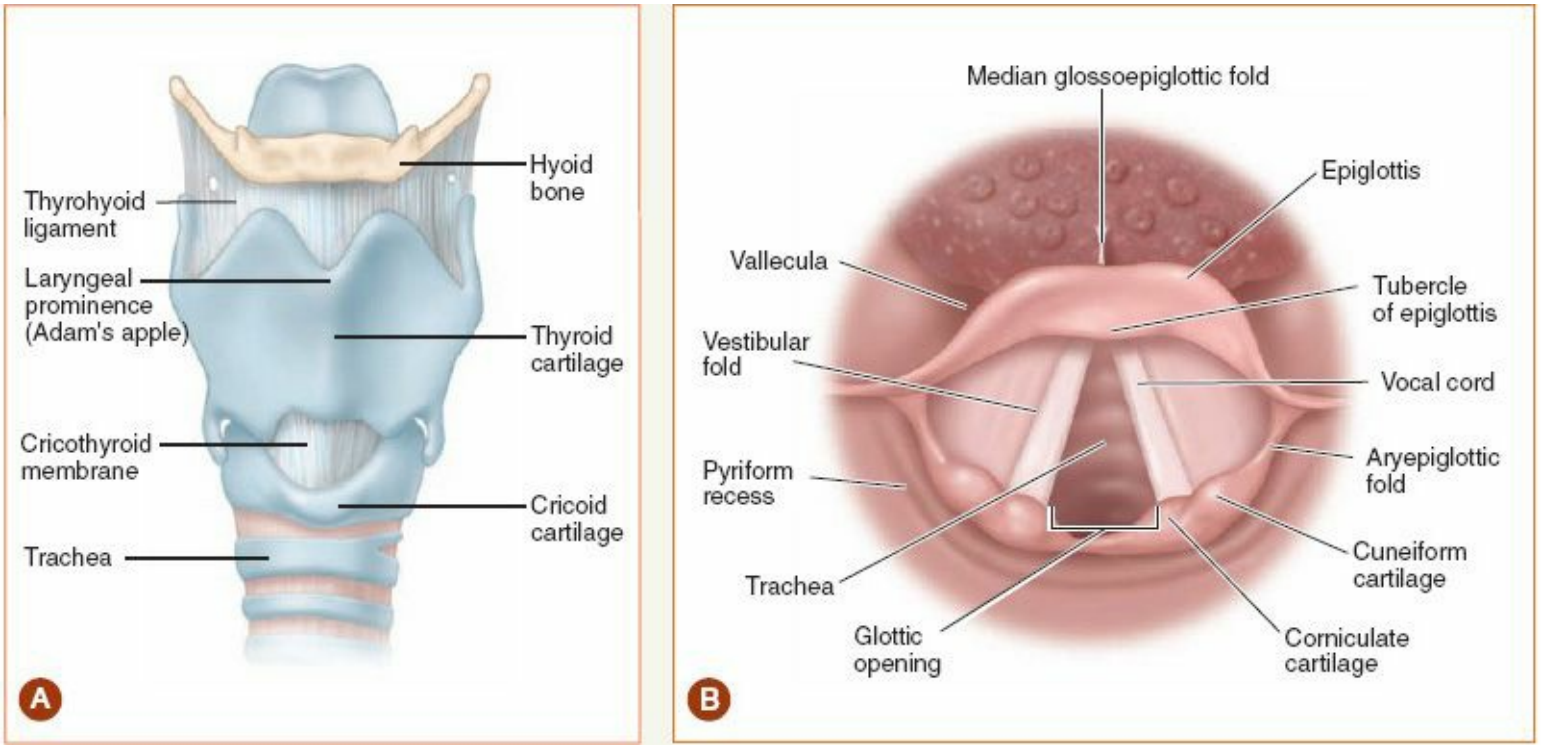

Figure 6-3 **A.** The larynx. **B.** The glottis and surrounding structures.

Lower Airway Structures

Important structures of the lower airway include the trachea, right and left main stem bronchi, bronchioles, alveolar ducts, and sacs.

Trachea

Beginning at the inferior border of the cricoid ring and ending at the carina, the trachea is approximately 9 to 15 mm in diameter and approximately 12 to 15 cm long. Not quite cylindrical, it is composed of 16 to 20 C-shaped cartilaginous rings on the anterior portion, with the posterior portion being fibrous tissue and muscular fibers. These rings help maintain luminal patency to allow unimpeded air flow. The trachea is larger in adult males than in adult females.

Lungs

The trachea divides into the right and left mainstem bronchi. These bronchi lead to the right and left lobes of the lungs **Figure 6-4**. The right lung is divided into three lobes; the left lung has two lobes. The bronchi continue to divide into smaller bronchi, which then divide into progressively smaller branches called bronchioles. After a total of 23 divisions into smaller and smaller branches, the bronchioles end at the alveolar ducts. These alveolar ducts lead to the alveoli, the area where gas exchange occurs. The adult lung contains about 300 million alveoli, each one in contact with a pulmonary capillary. This interface is referred to as the alveolar capillary (AC) membrane. An alveolus is made up of type I and type II squamous epithelial cells. Type I cells are involved in gas exchange, whereas type II cells manufacture surfactant. Surfactant is an important phospholipid that reduces the surface tension within the alveolus, preventing collapse and making it easier for the alveoli to expand during inhalation. Without surfactant, the work of breathing would be significantly more difficult. A lack of surfactant is commonly found in premature neonates and is a leading cause of respiratory issues in this patient population. Another type of cell, the alveolar macrophage, is also present; its function is to help defend the body by ingesting inhaled particles.

The blood supply in the lung arises from the right ventricle. The pulmonary trunk then splits into the right and left pulmonary arteries. The pulmonary arteries contain deoxygenated blood that is high in carbon dioxide (CO_2). The arteries subdivide into the pulmonary capillaries. This vasculature is a low-pressure system. The pressure in the normal pulmonary artery is approximately 25/10 mm Hg as compared with a normal systemic pressure of approximately 120/80 mm Hg. In order for gas exchange to occur, there must be blood flow in contact with the alveoli. This is defined as the $\dot{V}/\dot{Q}$ **ratio**. The normal ratio is 0.8 for the entire lung. This means that for every 4 L of air ($\dot{V}$), there must be a blood flow ($\dot{Q}$) of 5 L. Gravitational effects cause perfusion to be better in areas that are positioned lower (dependent areas) and ventilation to be better in other (nondependent) areas. Changes in the $\dot{V}/\dot{Q}$ ratio are one of the most common causes of hypoxemia. Disruptions can include changes in gravity, pulmonary artery pressure, alveolar pressure, airway obstruction, and lung compliance. Many diseases can cause these changes, such as chronic obstructive pulmonary disease (COPD), pulmonary embolism, heart failure (HF), and pneumonia, to name a few.

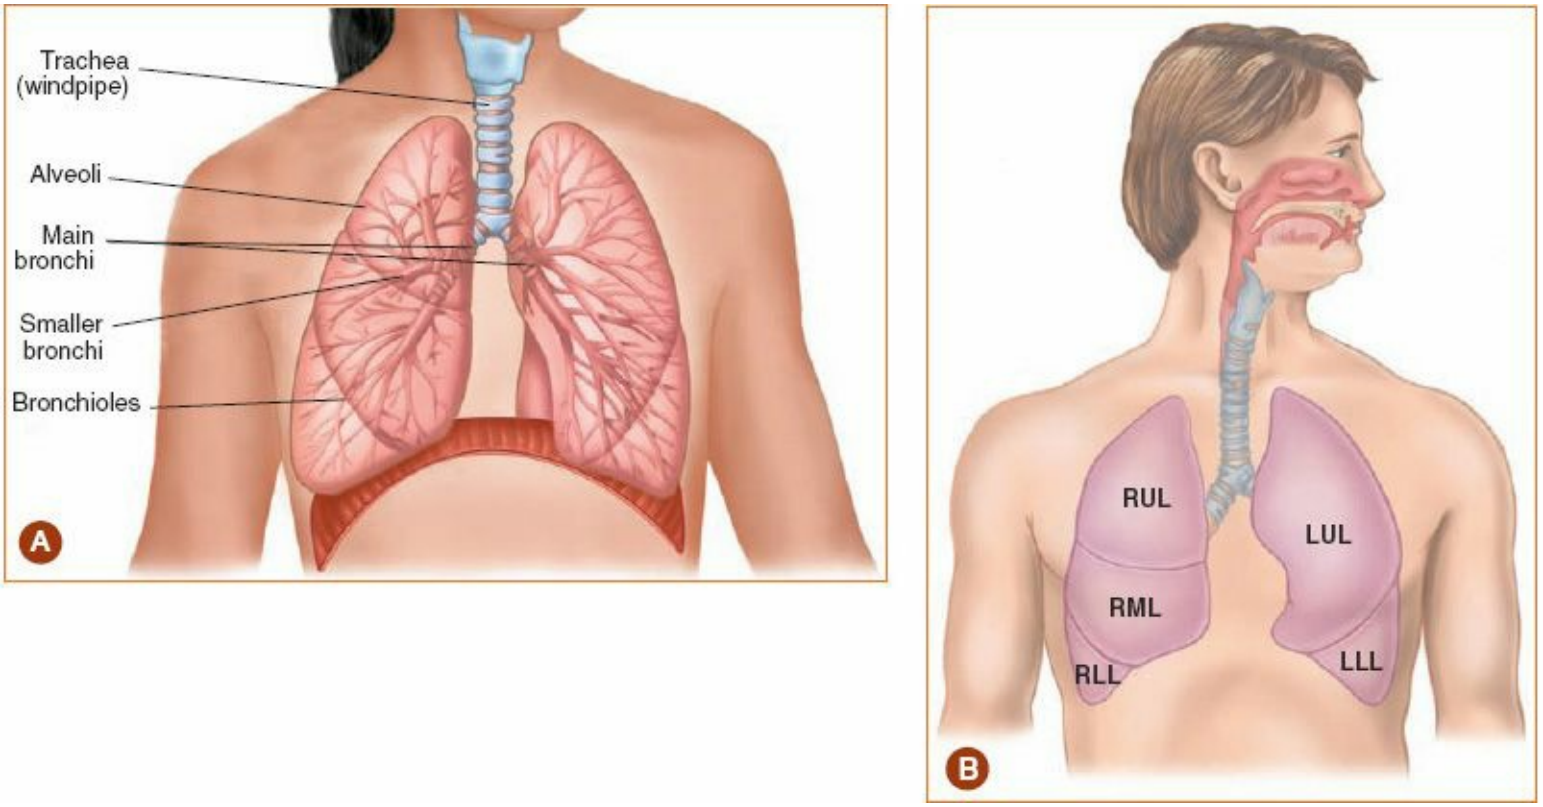

Figure 6-4 **A.** The respiratory system. **B.** The lobes of the lungs: RUL, right upper lobe; RML, right middle lobe; RLL, right lower lobe; LUL, left upper lobe; LLL, left lower lobe.

Pediatric Considerations

There are several variations in airway anatomy specific to the pediatric patient. Newborns and infants have a proportionally larger head with a prominent occiput. This may cause flexion of the airway and difficulty in visualizing laryngeal structures unless proper positioning is maintained (the use of a towel under the infant's shoulders to raise the rest of the body and straighten the airway usually improves airflow). Infants are obligate nose breathers, and congestion may result in respiratory distress. The tongue occupies a much larger proportion of the mouth in pediatric patients compared with adults. This difference in tongue size may result in airway obstruction in the unresponsive pediatric patient and make visualization of the glottis more difficult when performing laryngoscopy. The glottic opening is more cephalad and anterior in the pediatric patient. A child's epiglottis is at a 45° angle to the anterior pharyngeal wall, whereas an adult's lies parallel to the base of the tongue. The epiglottis is proportionally larger, floppier, and U-shaped compared with an adult **Figure 6-5** and may necessitate use of a straight blade to lift the epiglottis to improve visualization during laryngoscopy. Larger adenoidal tissue, particularly in infants, may result in significant hemorrhaging when traumatized. The cricothyroid membrane is small in children younger than 4 years, which may make needle cricothyrotomy difficult and surgical cricothyrotomy impossible (and contraindicated). There is one additional difference in the pediatric population—children have significantly higher oxygen consumption rates when compared with adults. Oxygen consumption in the pediatric patient is approximately double that of an adult. This increased consumption, coupled with a decreased functional residual capacity, can result in significant hypoxemia despite adequate preoxygenation. With pediatric patients, make sure that you are not overzealous in using the bag-mask device. Excessive volumes exacerbate gastric distention, causing vomiting, and increase the risk of pneumothorax.

Special Populations

Needle and surgical cricothyrotomy may be difficult or impossible in children younger than 4 years due to the small size of the cricothyroid membrane.

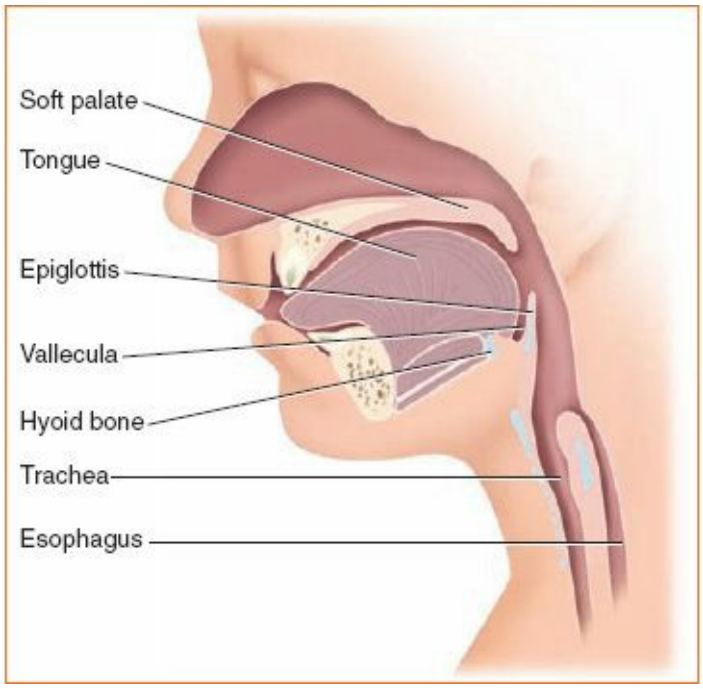

Figure 6-5 The child's epiglottis and surrounding structures.

Special Populations

Children have significantly higher oxygen consumption rates when compared to adults.

Physiology of the Respiratory System

Gas exchange occurs as a result of pressure gradient changes across the AC membrane **Figure 6-6**. In the capillary, the partial pressure of oxygen (PO2) is 40 mm Hg, whereas the partial pressure of carbon dioxide (PCO2) is 45 mm Hg. In the alveolus, the P_{CO_2} is 40 mm Hg and the P_{O_2} is 100 mm Hg. As the gases diffuse they move from an area of higher concentration to an area of lower concentration, seeking equilibrium. The end result is that the blood returning to the left side of the heart via the pulmonary vein contains 100 mm Hg of oxygen and 40 mm Hg of CO_2. (These are normal **arterial blood gas (ABG)** values.) Keep in mind that CO_2 diffuses 20 times faster than oxygen.

Factors that can affect the diffusion of gases across the membrane are known as **ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch**. $\dot{V}/\dot{Q}$ mismatch can be due to inadequate ventilation, perfusion, or both. There are three types of $\dot{V}/\dot{Q}$ mismatch: low, high, and silent.

- Low $\dot{V}/\dot{Q}$ ratio: characterized by perfusion exceeding ventilation. The low ratio results in blood being shunted past the alveoli without adequate gas exchange. A 20% shunting results in severe hypoxia. Causes include pneumonia, atelectasis, tumor, and mucous plug.
- High $\dot{V}/\dot{Q}$ ratio: characterized by ventilation exceeding perfusion, resulting in dead space. The alveoli are inadequately perfused, thus preventing adequate gas exchange from occurring. Causes of high $\dot{V}/\dot{Q}$ ratio include pulmonary embolus, pulmonary infarction, and cardiogenic shock.
- Silent unit: characterized by the result of decreased ventilation and perfusion as seen in patients with

a pneumothorax and severe acute respiratory distress syndrome (ARDS).

Although it is common to assess oxygenation in terms of the partial pressure of oxygen (arterial) (Pa_{O_2}), hemoglobin is the iron-containing protein found in erythrocytes that functions as the transporter of oxygen to tissues. The Pa_{O_2} drives oxygen to be bound to hemoglobin. The relationship is expressed in the oxyhemoglobin dissociation curve **Figure 6-7**. A patient can be experiencing tissue hypoxia if anemia or dysfunctional hemoglobin is present even though the Pa_{O_2} and oxygen saturation are normal. Many substances can bind to hemoglobin and cause it to be dysfunctional. Carbon monoxide, for example, has 240 times the affinity for hemoglobin than oxygen. Carbon monoxide binding to hemoglobin results in the formation of carboxyhemoglobin. The formation of carboxyhemoglobin prevents oxygen from being transported and released to the tissues. Nitrite poisoning can result in the formation of abnormal hemoglobin. Nitrite binds to hemoglobin, resulting in methemoglobinemia. This also alters the oxygen-carrying capacity of the hemoglobin molecule and can result in hypoxia.

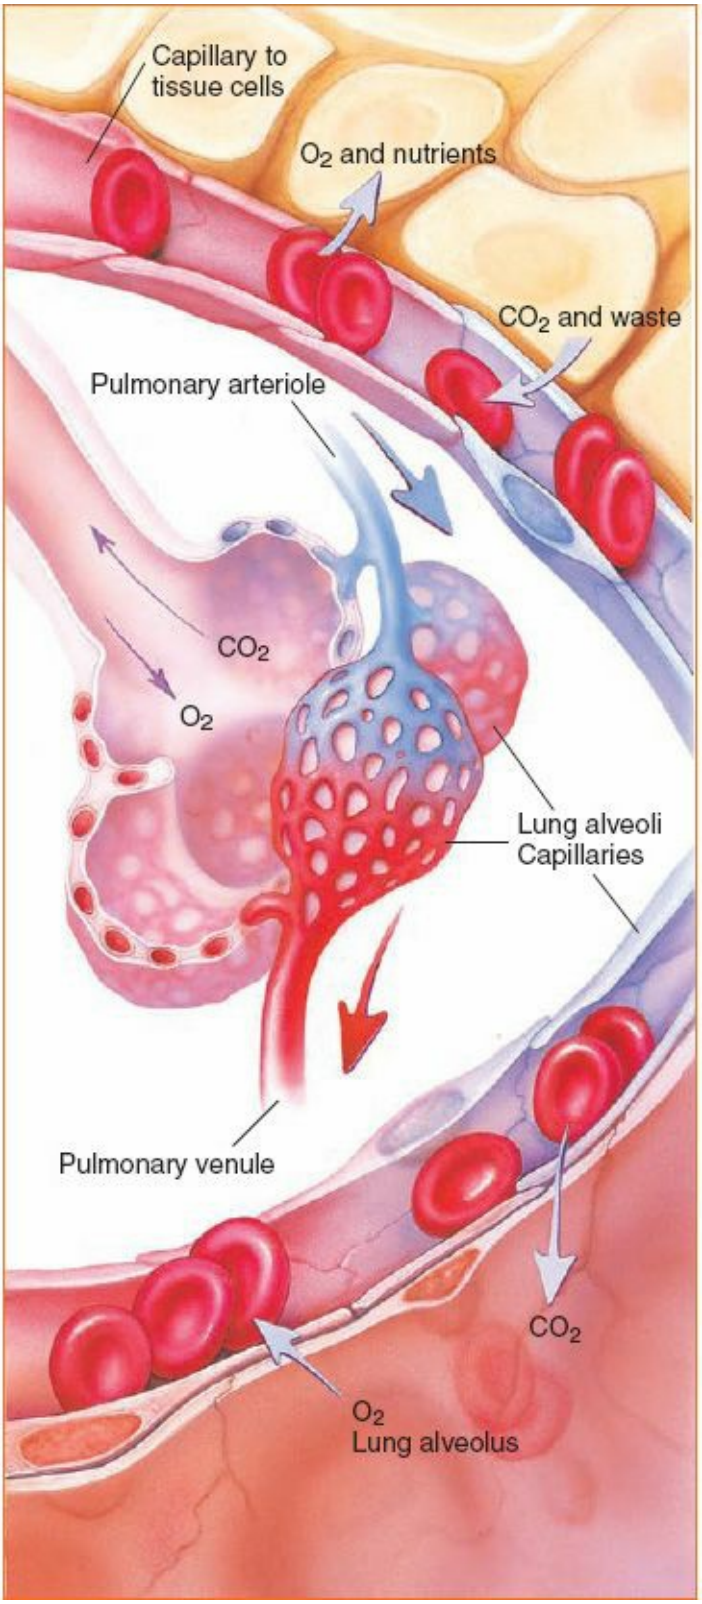

Figure 6-6 With diffusion, molecules of oxygen (O_2) move from the alveoli into the blood because there are fewer O_2 molecules in the blood. Similarly, molecules of carbon dioxide (CO_2) diffuse from the blood into the alveoli because there are fewer CO_2 molecules in the alveoli.

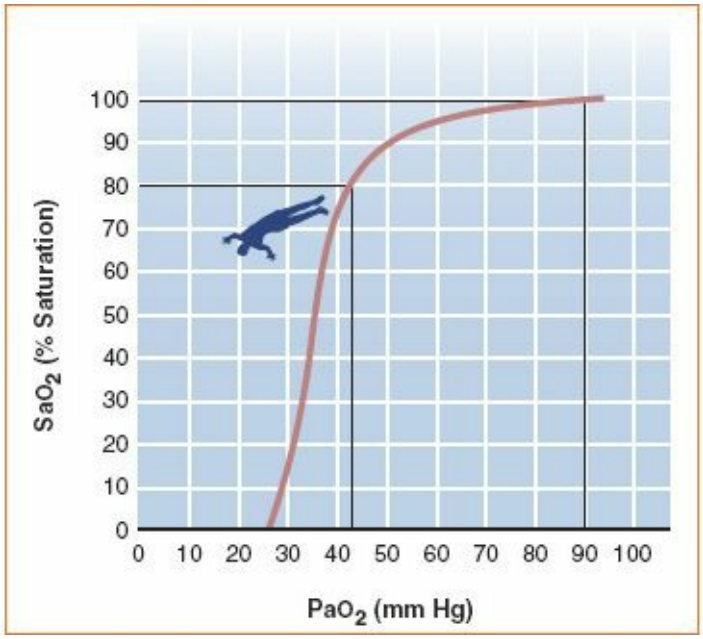

Figure 6-7 Oxyhemoglobin dissociation curve.

The mechanics and dynamics of breathing involve the concepts of elastance, compliance, resistance, and pressure gradients. Lung tissue, in an independent state, would tend to collapse, a condition known as elastance. The construction of the bony thorax and ribs creates an opposing force that prevents the lung tissue from collapsing completely. The ease with which the thorax and lungs expand is referred to as compliance. If compliance is reduced, it is harder for the lungs to expand; therefore, any process that affects the integrity of this relationship results in increased work to expand the lungs. For example, if the chest wall becomes rigid due to pain, injury, or disease, it becomes more difficult to expand and breathing becomes more difficult. If the lung parenchyma becomes diseased and becomes stiffer, more work is needed as well.

We can define compliance as a change in volume per unit of pressure: $\Delta V/\Delta P$. Resistance refers to the amount of force needed to move a gas or fluid through a single capillary tube. Poiseuille's law shows that viscosity, length of the tube, driving pressure, and radius of the tube contribute to the work required to move a liquid or gas through a tube. Of these conditions, the radius of the tube is the most important factor affecting flow. If the radius of the tube is decreased by half, the work required increases 16 times. It is for this reason that you should generally use the largest appropriate size tube possible when intubating. It is also the reason that in broncho-spasm, this decreased radius results in more resistance to flow of gas and that even small amounts of swelling in the pediatric airway can cause significant distress. The decreased flow of gas results in increased work of breathing and respiratory distress. Increased mucus production, basal membrane edema, and artificial airways all reduce airway diameter, increase resistance, and may result in increased work of breathing.

Pressure gradients allow for the bulk movement of gas in and out of the lung. During inspiration, contraction of the muscles of inspiration increases the size of the thorax. The increased size of the thorax results in an increase in the volume contained within the thorax. This increase in volume results in a decrease in the pressure within the thorax relative to the atmosphere, which causes air to move into the lungs. At the end of inspiration, the muscles relax, allowing the thorax to return to its original size. The volume decreases, the pressure increases, and exhalation occurs. Inspiration is an active process that requires work, whereas exhalation is usually a passive event. This concept is applicable during flight; because pressure is required to facilitate the passing of oxygen from blood to the cells, a decrease in pressure can lead to hypoxia.

The thoracic expansion that begins the inspiratory cycle is provided by muscle contraction. The

primary muscles used during inspiration are the diaphragm and external intercostal muscles. In times of increased stress, the accessory muscles such as the pectorals, sternocleidomastoid, and scalenes are utilized. Use of these accessory muscles increases oxygen use. Continued use of these muscles can quickly lead to muscle fatigue, hypercapnia/hypoxemia, and respiratory failure. Some muscles can augment exhalation in times of increased work of breathing, although it is mostly a passive process. When needed, the intercostal and abdominal muscles can assist exhalation **Figure 6-8**.

The stimulus and innervation of breathing is a complex process involving the pulmonary, cardiac, and neurologic systems. Normally, the drive to breathe comes from the need to eliminate CO_2. In the blood, CO_2 combines with water (H_2O) to form carbonic acid, which dissociates into H^+ and HCO_3^-. The end result is that as CO_2 increases, so does the level of H^+. Recall that pH is a function of H^+ concentration. As H^+ increases, pH decreases. This change is transmitted across the blood-brain barrier and stimulates the respiratory centers in the brain stem. As a back-up mechanism, chemoreceptors are located in the aortic arch and carotid arteries. These are sensitive to changes in oxygen levels. When the PaO_2 level drops below 60 mm Hg, these receptors reach maximal stimulation and provide the stimulus to increase breathing.

The respiratory centers are located in the brain stem, which comprises the medulla and pons **Figure 6-9**. In the medulla, the dorsal respiratory group regulates impulses to the diaphragm. The ventral respiratory group controls expiratory impulses, the upper airway muscles, and the intrinsic pattern of breathing. The pontine respiratory group and the pneumotaxic center fine-tune the respiratory pattern. The innervation of the diaphragm is from the phrenic nerve, which branches from the spinal cord at the level of C3 to C5. Spinal cord injury near this level dramatically affects the ability to breathe adequately.

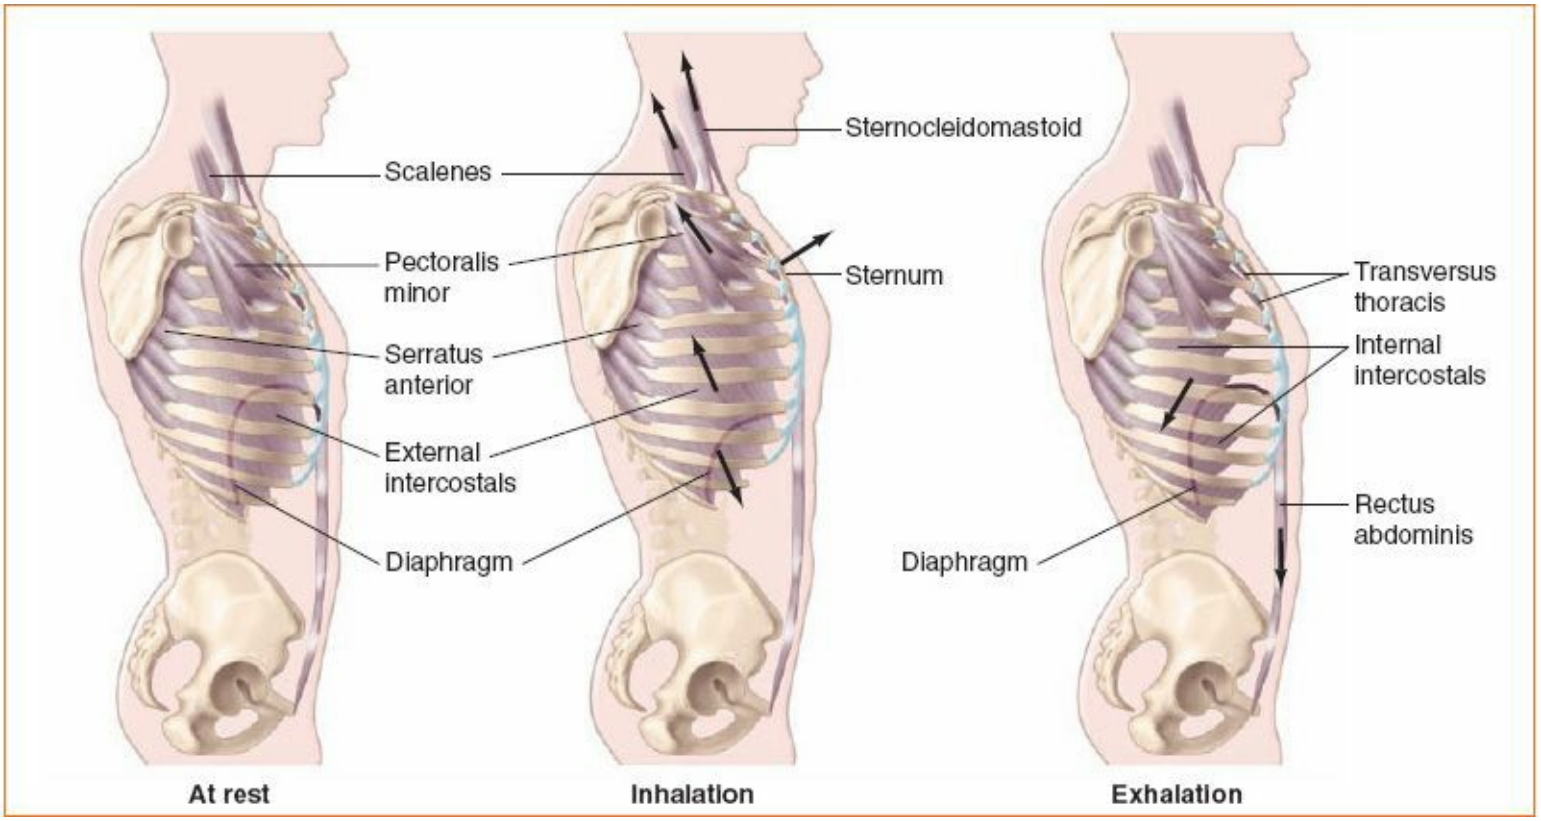

Figure 6-8 The mechanics of breathing.

The proper functioning of the respiratory system can be explained by the following five factors:

1. **Ventilation**: There must be an adequate bulk flow of gas in and out of the lung.

2. **Distribution**: The gas must be delivered into the areas of the lung that are able to engage in gas exchange. Changes in compliance or resistance will send the gas to areas of the lung with an unsuitable $\dot{V}/\dot{Q}$ ratio.
3. **Diffusion**: The AC membrane must be able to engage in gas exchange. Widening of the space (as in pulmonary edema) or disease (such as fibrosis) results in a decreased diffusion capacity.

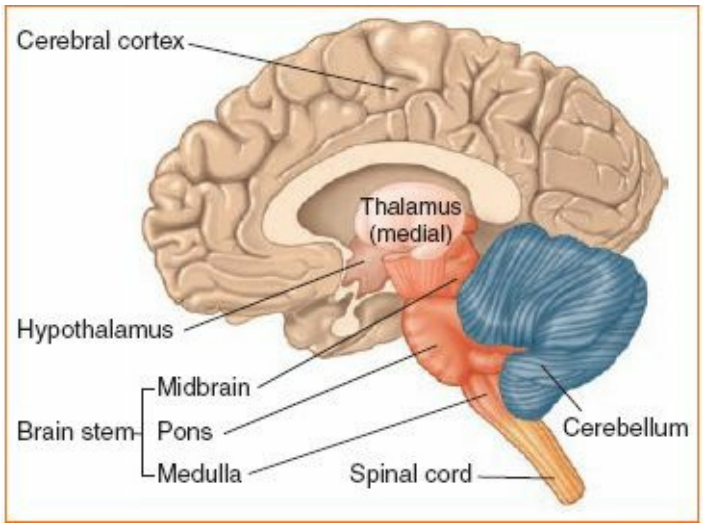

Figure 6-9 The pons and medulla are involved in neurocontrol of respiration.

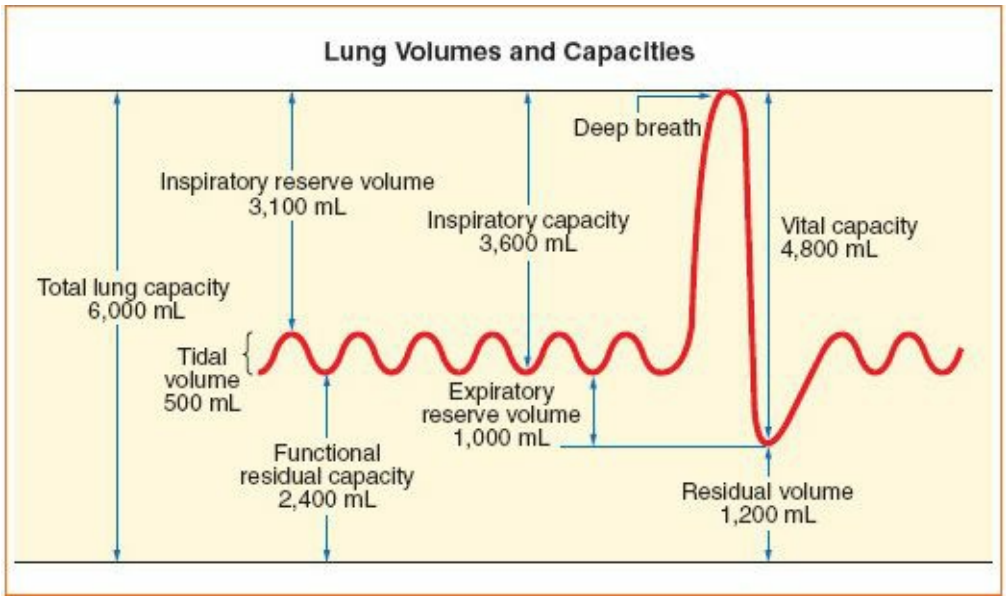

Figure 6-10 Respiratory cycle, capacities, and volume. The numbers are approximations.

4. **Perfusion**: As already discussed, blood flow through the pulmonary vasculature and contact with the alveolus is essential.
5. **Circulation**: The heart must be able to pump blood not only to the lung, but also distribute blood through the systemic circulation. There must also be adequate levels of hemoglobin for delivery of oxygen to the cells.

Respiratory Volumes and Capacities

The lungs of a healthy male adult can hold between 5 and 6 L of gas. This is called the **total lung capacity (TLC)**, which can be divided into different lung volumes and capacities. Several different lung

volumes make up total lung capacity **Figure 6-10**. A spirometer **Figure 6-11** measures respiratory capacities and the volumes of air in liters.

Tidal volume (V_T) is the amount of air inhaled and exhaled during each normal breath. **Minute volume** is the amount of air breathed in 1 minute and is calculated by multiplying the respiratory rate per minute by the average tidal volume. The adequacy and stability of minute ventilation maintain normal oxygen and CO_2 levels. Normal minute ventilation is 5 to 10 L/min. The amount of air that can be inhaled after a V_T is inhaled is the **inspiratory reserve volume (IRV)**, whereas the air that can be expelled from the lungs after a normal exhalation is the **expiratory reserve volume (ERV)**. The **inspiratory capacity (IC)** is the sum of IRV and V_T. **Vital capacity (V_C)** represents the total amount of air that can be exhaled following a maximal inspiration and is referred to as the pulmonary reserve. Normal V_C is 60 to 70 mL/kg of ideal body weight. V_C is dependent on gender, age, and height; decreases with age (approximately 20 mL/kg per year for those > 20 years); and increases with height. Women have a smaller V_C than men. A decrease in vital capacity to less than 10 to 15 mL/kg indicates poor pulmonary reserve and the inability to cough effectively. These persons almost always require some form of mechanical ventilation.

At the end of a maximal forced exhalation, a volume of air remains; this is referred to as the **residual volume (RV)**. RV added to ERV is the **functional residual capacity (FRC)**. The FRC allows for gas exchange between breaths. This is also where the application of **positive end-expiratory pressure (PEEP)** works. Applied PEEP increases the FRC and increases oxygenation. One other volume to be aware of is the **anatomic dead space (V_D)**. This space is found in the upper airway, the areas that do not participate in gas exchange. The volume in this space is normally approximately 2 mL/kg.

Figure 6-11 A spirometer.

Pathophysiology: Obstructive and Restrictive Disease States

Disease states can be categorized in several ways. Disease states resulting in difficulty with moving air out of the lungs can be classified as **obstructive diseases**, which include asthma, COPD, cystic fibrosis, and bronchioectasis, and involve an increase in airway resistance. Diseases that result in difficulty moving air in to the lungs are defined as **restrictive diseases**. These conditions result in the loss of chest or lung compliance, either individually or together. Restrictive diseases typically include occupational lung diseases (asbestosis, mesotheolioma), idiopathic pulmonary fibrosis, pneumonia, atelectasis, chest wall deformities and injuries, and all the neuromuscular diseases that affect breathing (for example, Guillian-Barré syndrome).

Diseases and temporary conditions can alter the $\dot{V}/\dot{Q}$ ratio. Ventilation in excess of blood flow

creates a dead space effect, and gas exchange is impaired (such as in tachypnea, pulmonary embolism). When blood flow is in excess of ventilation, gas exchange is also impaired, but this creates a **shunt** effect. A good example is pneumonia, in which a lobe of the lung is perfused but not ventilated because of infection in the air spaces. Be aware that there are also anatomic shunts that prevent blood from participating in gas exchange. Some anatomic shunts are congenital heart defects; others such as the bronchial and thebesian veins are normal and occur in the lung. The extent of shunt effect is indicated by the abbreviation Qt. The normal Qt range is 3% to 5%; a value greater than 20% indicates that the patient's condition is critical. Because oxygen is vital to the life and metabolism of every cell in the body, the evaluation of the presence of hypoxia and its treatment is crucial. It is important to understand these mechanisms as well as the causes of hypoxemia:

- Hypoxic hypoxia: defined as insufficient oxygen in the blood; tissues are therefore affected. Several causes exist, including hypovolemia, airway obstruction, decreased cardiac output, and coronary artery disease.
  - Low oxygen tension in the alveolus itself, and therefore not enough oxygen can diffuse across the alveolar-capillary membrane; can be caused by hypoventilation, high altitude (low barometric pressure), and suffocation.
  - Diffusion defects such as fibrosis or edema.
  - Shunting can be intrapulmonary, as caused by atelectasis, bronchospasm, and pneumonia, or can be extra-pulmonary, as with a congenital heart defect.
- Anemic hypoxia (also called hypemic hypoxia): caused by reduced or dysfunctional hemoglobin. Hypemic hypoxia interferes with the transportation phase of respiration, causing a reduction in oxygen-carrying capacity. Specific causes of hypemic hypoxia include anemias, hemorrhage, hemoglobin abnormalities, use of certain medications (sulfa drugs), and intake of chemicals. Carbon monoxide is present in exhaust fumes—from ambulances and both conventional and jet-engine aircraft. It is also present in cigarette smoke.
- Stagnant hypoxia: reduced cardiac output resulting in tissue hypoxia due to lack of circulation. Specific causes include heart failure, shock, continuous positive-pressure breathing, acceleration (*g* forces), and pulmonary embolism. A reduction in regional or local blood flow may be caused by extremes of environmental temperatures, postural changes, tourniquets, hyperventilation, embolism by clots or gas bubbles, and cerebral vascular accidents.
- Histotoxic hypoxia: occurs when cells are unable to use oxygen due to inactivation or destruction of key enzymes, such as in cyanide and strychnine poisoning as well as in later stages of carbon monoxide poisoning.

Determining the mechanisms can dramatically affect the course of treatment. Simply providing supplemental oxygen may not be sufficient in alleviating the hypoxia.

Patient Assessment

Chapter 5 covers the techniques of inspection, auscultation, and palpation. This section covers respiratory-specific considerations during the assessment process.

Breath Sound Assessment Techniques

After an adequate airway is in place and secured, assessment of breath sounds is vital. Breath sounds are created as air moves through the tracheobronchial tree and the alveoli, and can be auscultated. The size of the airway determines the type of sound that will be produced. (Recall that there are significant

differences between adult, child, and pediatric airways.) The trachea and bronchi have large diameters, so the sound produced is higher in pitch and is heard during inspiration and expiration. **Tracheal breath sounds**, also called bronchial breath sounds, are heard by placing the stethoscope diaphragm over the trachea or over the sternum. Assess breath sounds for duration, pitch, and intensity. **Vesicular breath sounds** are softer, muffled sounds and have often been described as wind blowing through the trees. The expiratory phase is barely audible. Breath sounds are heard over the majority of the chest, representing airflow in the alveoli. **Bronchovesicular sounds** are a combination of the two and are heard in places where airways and alveoli are found, the upper part of the sternum and between the scapulae. **Figure 6-12** describes the normal breath sounds. Locations for these sounds are shown in **Figure 6-13**. Bronchovesicular sounds should be assessed for duration, pitch, and intensity. Duration refers to the length of time for the inspiratory or expiratory phase of the breath. Normally, expiration is at least twice as long as inspiration. This relationship is expressed by the **I:E ratio**; a normal I:E ratio is 1:2. When a patient's airway is obstructed and the patient has difficulty getting air out, the expiratory component is prolonged and may be four to five times as long as inspiration; in this case the I:E ratio would be 1:5. In patients who are tachypneic, the expiratory cycle is short and approaches that of inspiration, and the I:E ratio may be 1:1. In mechanical ventilation, manipulation of the I:E ratio (expiration being longer than inspiration or inverse I:E) may be used to improve ventilation and hypoxemia in patients with severe lung injury.

Pitch is described as either higher or lower than normal, as in patients with stridor or wheezing. The intensity of sound depends on airflow rate, constancy of flow throughout inspiration, patient position, and the site selected for auscultation. Thickness of the chest wall may affect the intensity. Sounds that are less intense are said to be diminished. A common error in assessing the intensity of breath sounds occurs when auscultation is done over the patient's clothing. Sounds that might be classified as normal, but present in an unexpected area, can indicate an abnormal condition. For example, tracheal sounds in areas that should produce vesicular sounds may indicate consolidation or pneumonia.

The terminology regarding abnormal or **adventitious breath sounds** varies from text to text. The sounds are usually classified as continuous or discontinuous sounds. **Wheezes** and **rhonchi** are continuous sound as air flows through a constricted airway. Wheezes are usually high-pitched, whereas rhonchi are low-pitched, indicating that the airway is not as obstructed and is associated with mucus in the airways. **Crackles** (formerly known as *rales*) occur when airflow causes mucus or fluid in the airways to move. These tend to clear with coughing. Crackles may also be heard when collapsed airways or alveoli pop open. Crackles are classified as discontinuous sounds and may occur early or late in the inspiratory cycle. Early inspiratory crackles usually occur when larger, proximal bronchi open. These sounds are common in patients with COPD and tend not to clear with coughing. Late inspiratory crackles occur when peripheral alveoli and airways pop open and are more common in the dependent lung regions. These sounds are common in patients with reduced lung volumes. **Stridor** results from foreign body aspiration, infection, swelling, disease, or trauma within or immediately above the glottic opening. Stridor produces a loud, high-pitched sound ("seal bark"), particularly in pediatric patients.

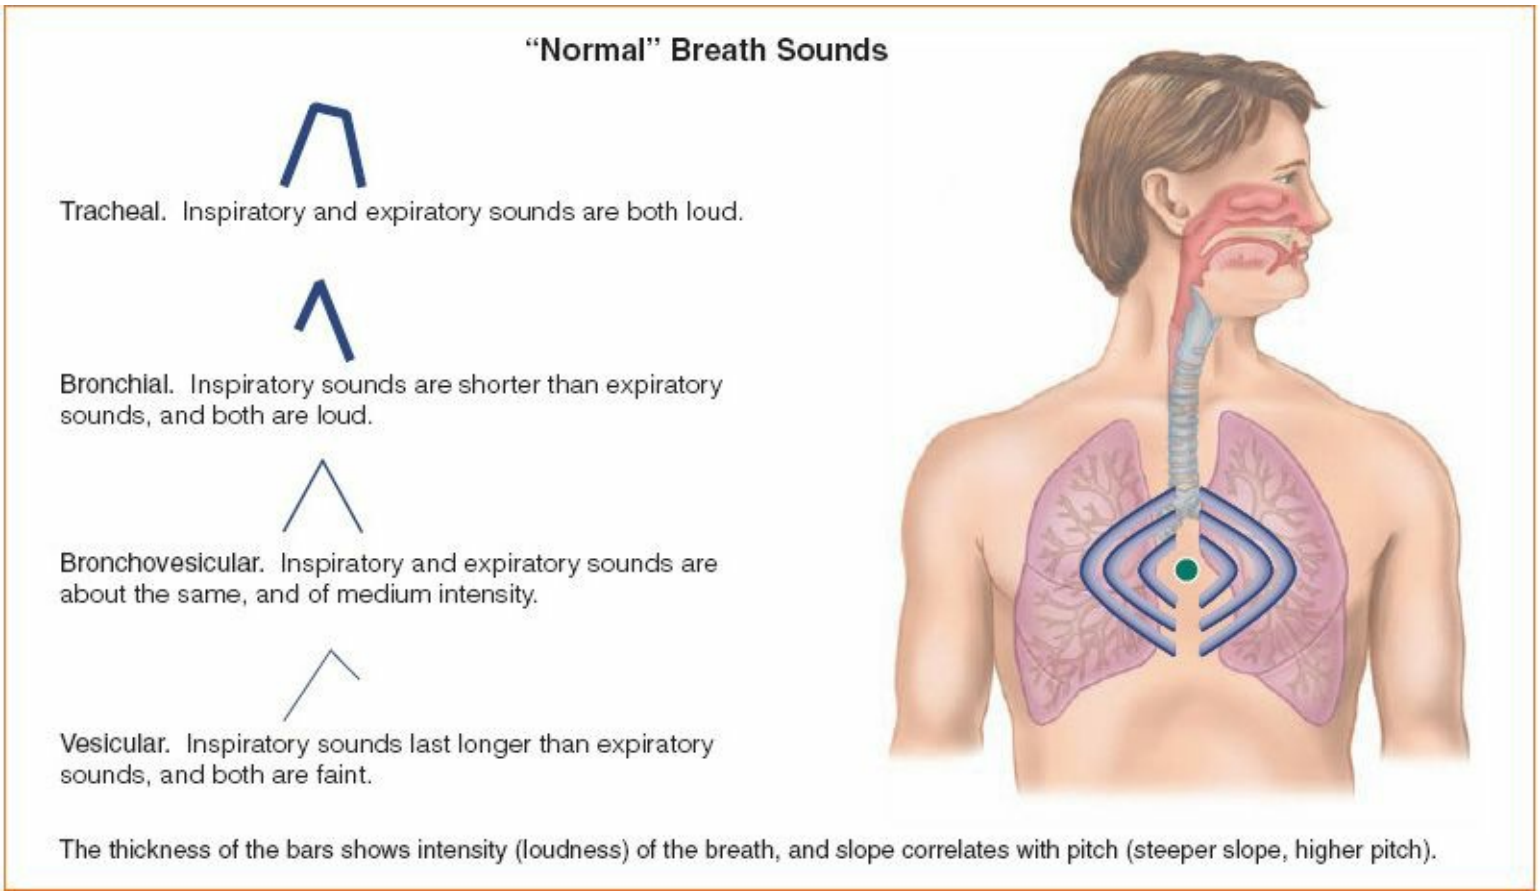

Figure 6-12 Normal breath sounds are heard over different parts of the chest. As you move away from the largest airways, breath sounds become softer. The character of inspiration vs exhalation also changes.

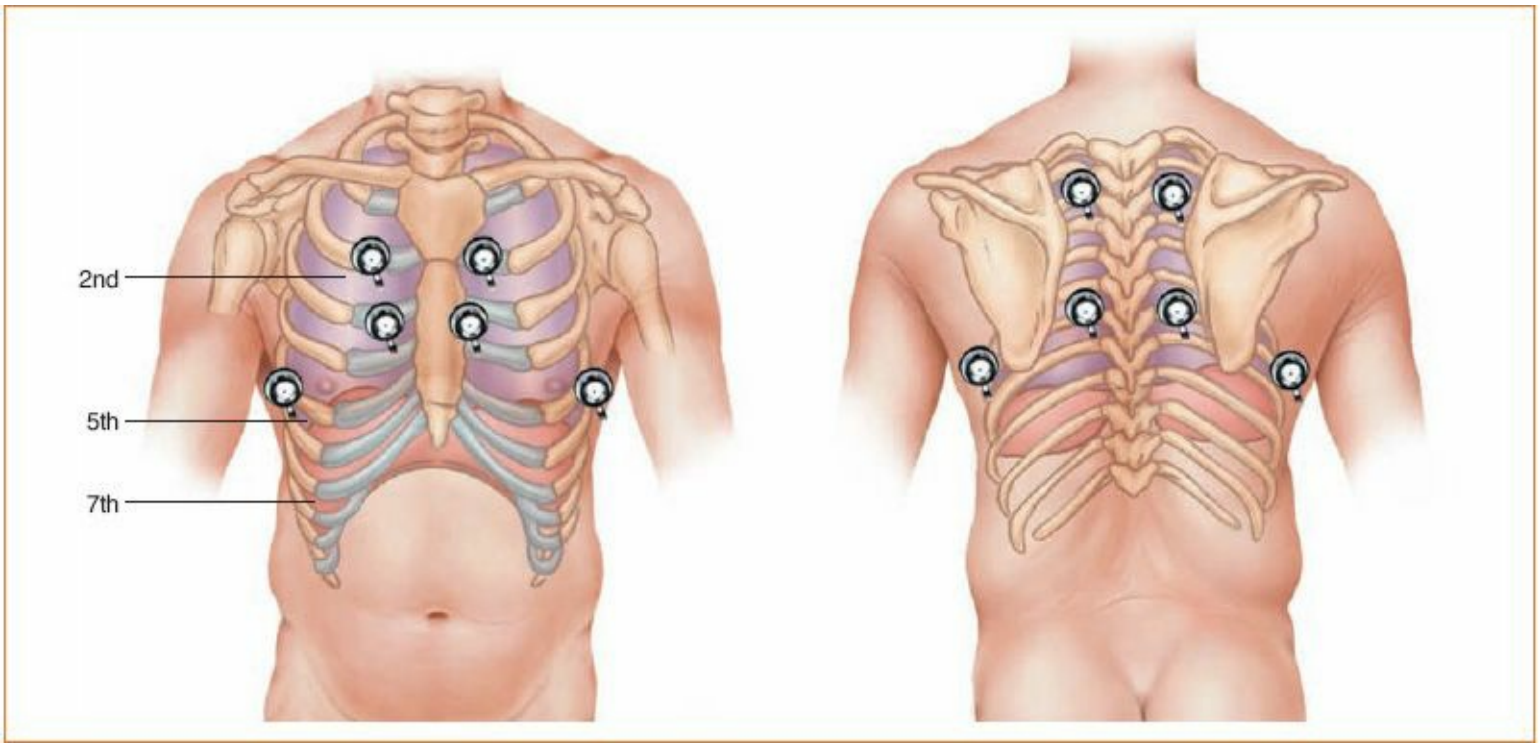

Figure 6-13 Common auscultation sites.

A **pleural friction rub** results from inflammation that causes the pleura to thicken. The pleural space can decrease as a result, allowing the surfaces of the pleura to rub together. This decrease often creates stabbing pain with breathing or any movement of the thorax.

Auscultation

Baseline breath sound assessment is discussed in Chapter 5. For the patient with an invasive airway device such as an endotracheal (ET) tube, Combitube, or laryngeal mask, listen over the epigastrium and sternal notch **Figure 6-14**, as well as the six recommended sites on the anterior chest wall. Assess this area for proper device placement and airflow. The baseline respiratory assessment establishes the standard by which subsequent assessments will be compared.

Breath sounds are best evaluated while the patient is taking slow, deep breaths through an open mouth and seated in a semi-Fowler's or high Fowler's position. Because of clinical circumstances, this often cannot be done. If the patient cannot be elevated, auscultate as many of the six recommended sites as possible. The diaphragm of the stethoscope should be placed firmly on bare skin. Remember, to avoid misinterpretation of lung sounds, auscultation should not be performed through clothing. Be aware of your patient's comfort while assessing breath sounds. Rushing the patient through the process may cause hyperventilation or exacerbate existing dyspnea. Document the sites chosen for auscultation in your patient care report and the status (patency, appearance, integrity) of any artificial airway. In addition to periodic monitoring of breath sounds during transport (which may be difficult to hear), evaluate breath sounds at the following times: immediately upon arrival at the patient's bedside, after any gross patient movement, and immediately before transferring the patient's care to other providers.

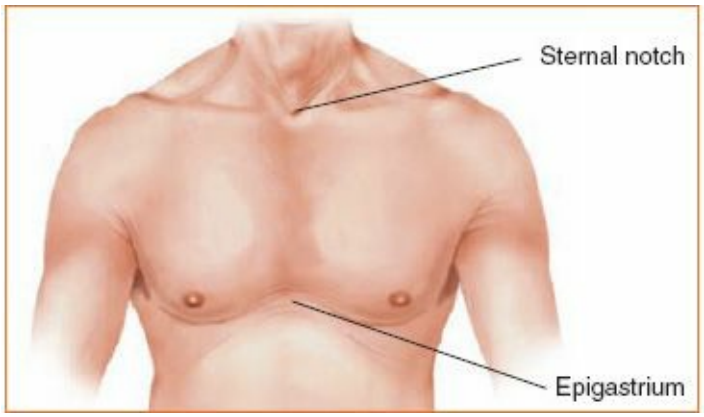

Figure 6-14 In patients with an invasive airway, listen for breath sounds over the epigastrium and sternal notch.

Normal and Abnormal Respiratory Patterns

When you are assessing respiratory patterns, consider the following three characteristics: rate, depth, and rhythm.

Rate

Eupnea is normal breathing at a rate of approximately 12 to 20 breaths/min in the adult patient. Pediatric norms range from 30 to 50 breaths/min in the newborn to 12 to 20 breaths/min in the adolescent. A number of factors can cause **tachypnea**, an abnormally fast respiratory rate—fever, pneumonia, metabolic acidosis, hypoxemia, some poisonings and drugs (aspirin overdose, stimulant use), and lesions of the respiratory center in the brain. Stress, anxiety, and pain can also result in tachypnea. Although tachypnea is a compensatory mechanism, it also has negative effects. Because rapid respiratory rates usually result in shallower breaths, the amount of **alveolar ventilation (V_A)** (the volume of air that comes into contact with the alveolar capillary membrane surfaces and participates in the exchange of gases between the lung and the blood) decreases in the tachypneic patient. More muscle work is used to generate "wasted" ventilation. This increased "work" also results in increased oxygen consumption.

Numerous factors can also lead to **bradypnea**, a slower than normal respiratory rate: narcotic or

sedative drugs, alcohol, metabolic disorders, respiratory system decompensation or fatigue (particularly in pediatric patients), and traumatic and nontraumatic central nervous system (CNS) lesions. Mild bradypnea is normal in certain stages of sleep. **Apnea**, the absence of respiration, may be episodic or periodic. Periods of apnea longer than 15 seconds require immediate intervention. The patient may need ventilatory support or other resuscitative efforts.

Depth

In addition to respiratory rate, always assess the depth of respiration. Assessment of depth can be achieved by direct observation or by palpation. **Hyperpnea** describes a deeper than normal breath, whereas **hypopnea** refers to a shallow breath. Hyperpnea can lead to low levels of CO_2 (thus increasing pH, resulting in respiratory alkalosis), whereas hypopnea can result in increased CO_2 levels (thus decreasing pH, resulting in respiratory acidosis) and decreased oxygen values.

Pattern

Several abnormal respiratory patterns present with characteristic alterations of the respiratory rate, depth, or regularity **Figure 6-15**.

Cheyne-Stokes respiration features a cyclic pattern of increased respiratory rate and depth with periods of apnea. Following the apnea, the patient begins breathing with slow, shallow breaths that increase in rate and depth until apnea returns. The condition can be caused by increased intracranial pressure, renal failure, meningitis, drug overdose, or hypoxia secondary to congestive heart failure. Otherwise, healthy individuals may breathe in a Cheyne-Stokes pattern following exposure to altitude changes or with hyperventilation syndrome. Acidosis, particularly when caused by CO_2 levels, can also trigger Cheyne-Stokes respirations.

Cluster breathing is another abnormal respiratory pattern, in which a cluster of irregular respirations that vary in depth are followed by a period of apnea at irregular intervals.

Biot's (ataxic) breathing is similar to Cheyne-Stokes respirations, but the pattern is irregular. While Cheyne-Stokes has repeating patterns of gradual increases concluding with apnea, three patterns occur in Biot's breathing: (1) slow and deep; (2) rapid and shallow; and (3) apnea without any predictability of which pattern will follow. Causes of Biot's breathing include meningitis, increased intracranial pressure, and central nervous system dysfunction. The condition often indicates lesions higher in the respiratory center in the brain stem than those that produce Cheyne-Stokes respirations.

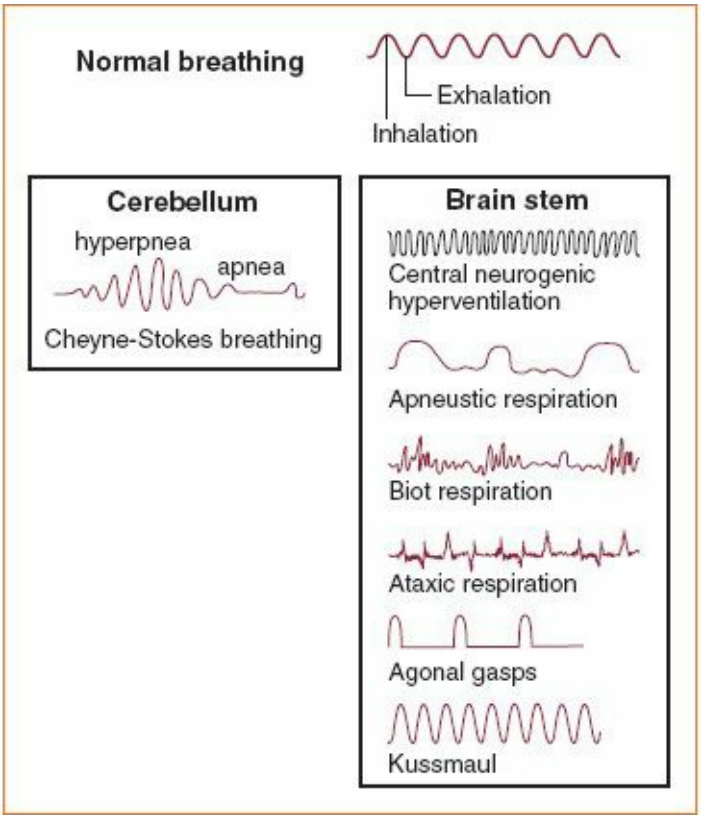

Figure 6-15 Abnormal breathing patterns.

Kussmaul's respiration is fast and deep without periods of apnea. The rate and depth are greater than the normal rate expected for the patient's age group. Breathing is labored, with periods of deep breaths punctuated by sighs. Kussmaul's pattern may indicate metabolic acidosis, including diabetic ketoacidosis, or renal failure. It generally appears in conditions that cause severe acidemia.

Apneustic breathing indicates lesions in the respiratory center of the brain stem. The patient exhibits a prolonged, gasping inspiration followed by an extremely short, ineffective expiration at a rate between 1 and 2 breaths/min. Over a period of several minutes of ineffective exhalation, the patient's lungs may hyperinflate. This pattern results in severe hypoxemia and, if uncorrected, rapid death.

Central neurogenic hyperventilation is a pattern of deep, rapid respirations at rates of 40 to 60 breaths/min. A midbrain lesion or dysfunction is the cause. Patients exhibiting central neurogenic hyperventilation are generally comatose with Glasgow Coma Scale scores of less than 8. These patients require intubation and ventilatory assistance in order to stabilize arterial blood gas parameters. Hyperventilation syndrome presents with increases in rate and depth of respiration. Hyperventilation can result from exertion, fear, anxiety, fever, hepatic coma, acid-base imbalance, or midbrain lesions. A respiratory rate between 20 and 30 breaths/min in the adult is classified as moderate hyperventilation. A prolonged respiratory rate greater than 30 breaths/min is severe, and ventilatory support is often necessary to prevent respiratory muscle fatigue. Use caution when assessing the underlying cause of hyperventilation before initiating any corrective treatment. Never withhold oxygen from a patient showing signs or symptoms of hypoxia.

A state of hyperventilation may develop in a patient who is intubated or being ventilated. Closely monitor vital signs, pulse oximetry, capnometry readings, end-tidal CO_2 ($ETCO_2$) levels, mental status, and skin color in any patient receiving ventilatory support.

Agonal respirations, also abnormal, are a pattern of deep, slow, shallow, irregular, "all-or-none" breaths or occasional gasping breaths, accompanied by a slow respiratory rate.

Another abnormal respiratory pattern is seen in patients with obstructive diseases such as COPD and

asthma. The pathology of these diseases leads to airway collapse and hyperinflation of the lungs. These individuals have difficulty exhaling completely, which leads to air trapping in the lungs and shallow compensatory respirations.

In order to assist with exhalation, these individuals exhale for longer periods of time and with the lips pursed. Pursed lip breathing applies a back pressure to the airways to try to prevent airway collapse. This pursed lip breathing is an attempt to maintain PEEP (the amount of pressure above ambient pressure present in the airway at the end of the respiratory cycle). The I:E ratio in patients with obstructive disease is usually abnormal.

For patients who are on ventilatory support, the ventilator can provide supplemental PEEP and **continuous positive airway pressure (CPAP)**. CPAP is similar to PEEP in that they both can maintain pressure in the airway and alveoli at the end of the exhalation phase.

The appropriate level of intervention in these breathing abnormalities is directly related to the work of breathing and the ability of the patient to maintain that work. Remember that all muscle activity uses oxygen to metabolize glucose and manufacture adenosine triphosphate. CO_2 is produced as a waste product. This increases the need for further ventilation that in turn may exacerbate muscle fatigue. Remember also that the diaphragm is the most efficient of the respiratory muscles. The accessory muscles, the scalene, sternocleidomastoid, and external intercostals, use more oxygen. The ability of the patient to maintain this increased workload depends on age, physical conditioning, degree of cardiopulmonary reserve, and other combined medical conditions. Failure to adequately manage the work of breathing can lead to cardiopulmonary arrest. Do not confuse the work of breathing with shortness of breath. Shortness of breath is a subjective complaint, whereas assessment of the work of breathing is a clinical evaluation.

Palpation

Chapter 5 reviews palpation—placement of the hands directly on the chest wall to evaluate the status of the lungs, skin, and subcutaneous tissues and chest expansion. A "snap, crackle, pop" sensation indicates the presence of subcutaneous emphysema, in which air is escaping from the pleural space and dissecting through the subcutaneous tissues. Although subcutaneous emphysema is benign, the underlying cause may be life threatening. If subcutaneous emphysema is detected, it is important to inquire about recent trauma or invasive procedures (ie, intubation, central line placement) and whether these are new findings.

When a person is speaking, the vibrations of the vocal cords are transmitted to the chest wall. This is called vocal fremitus. Vocal fremitus is assessed when you are performing tactile fremitus, which is done by placing the hands bilaterally on the upper thorax and asking the patient to say "99." This procedure is repeated in a methodical way down the chest. An increase in the fremitus, or vibration, indicates that the underlying lung tissue is more solid (consolidated) and contains less air than normal, which may indicate pneumonia or atelectasis. In addition, if secretions are present in the airways, the vibrations will increase. This finding may indicate that the patient needs to cough or be suctioned. The procedures of vocal fremitus and tactile fremitus are useful in patient assessment, but are usually not practical in the transport setting.

Assessment in Preparation for Transport

Prior to transport, review the patient care report, noting any medications, disease processes, or trauma that might compromise ventilation. Review the patient care record noting lab studies, and review the patient's vital signs. Take special note of when the last arterial blood gas (ABG) measurement was performed and whether the data are valid. If an artificial airway is in place, note the size and type, and confirm proper placement before transport. If the patient requires mechanical ventilation, note the ventilator settings and patient response. If there is any doubt about the placement of tracheal tubes,

nasogastric (NG) tubes, or central lines, communicate your concerns to hospital personnel. If the transport is to be by air, remember that altitude-induced pressure changes can occur during travel by helicopter or fixed-wing aircraft. Boyle's law (at a fixed temperature, the volume of a gas varies inversely with the pressure surrounding it) may cause air or gases within the body to expand as altitude increases (and barometric pressure decreases). These pressure changes are particularly important for air within the pleural space (pneumothorax). Equipment with air-filled spaces, such as the balloon of an ET tube, may need to be replaced with fluid to prevent problems with expansion during ascent during transport. During these transports, monitor the patient closely for evidence of dyspnea or the development of an air embolus.

When assessing the respiratory system, begin with the basics.

1. Assess the ABCs.
2. Determine the stability of the airway.
3. Observe the rate, rhythm, depth, and character of respiration.
4. Inspect the chest looking for symmetric rise and fall with each respiratory cycle. Note any accessory muscle use. Note the presence of any central lines or Hickman catheters, nitroglycerin or other medication patches, or in-dwelling devices such as pacemakers, implanted defibrillators, chest tubes, or medication delivery devices.
5. Note any wounds, abrasion, or bruising. Note the presence and location of bony crepitus or subcutaneous emphysema.
6. Examine any dressings on the chest (wounds, central venous access, chest tubes) and determine if they are dry and intact.
7. Observe any drainage being collected and note its color and consistency.
8. Auscultate the chest noting the presence or absence, quality, and type of breath sounds heard. Compare breath sounds from one side of the chest to the other.
9. If the patient requires oxygen, assess that the oxygen delivery device and the delivered **fraction of inspired oxygen (FIO_2)** meets the patient's needs and adequately maintains the desired oxygen saturation as measured by pulse oximetry (**SpO_2**).

Because cardiac and respiratory functions are intimately linked, assess the patient's circulation to obtain a complete clinical picture. Check the patient's blood pressure, pulse rate, capillary refill time, skin color, and temperature. Mental status is also an important consideration, because hypoxia directly affects mental status and level of consciousness.

ABG Monitoring

The gold standard for assessing the functioning of the respiratory system is measuring the ABG level. In this procedure, blood is obtained from a superficial artery, such as a radial or brachial artery, with a heparinized syringe. The blood is then analyzed for pH, $PaCO_2$, PaO_2, HCO_3^- (concentration of bicarbonate ion), base excess (BE, indicating whether the patient is acidotic or alkalotic), and SpO_2. Normal blood gas values are summarized in **Table 6-1**. The technique for obtaining an ABG value is covered in Chapter 8.

The values for pH, FIO_2, and HCO_3^- are used to evaluate the acid/base status of the patient. The $PaCO_2$ is an indicator of the effectiveness of ventilation. The values for PaO_2 and SpO_2 are indicators of oxygenation. A more complete discussion of blood gas interpretation and abnormalities is in Chapter 8. In

order to maintain normal blood gas values, a relationship between alveolar ventilation and perfusion of the alveolar capillaries must be maintained. This is expressed as the $\dot{V}/\dot{Q}$ ratio. Recall that $\dot{V}/\dot{Q}$ imbalances are the most common cause of hypoxemia.

Although advanced technology has made portable blood gas analysis possible, most CCTPs will rely on noninvasive methods of assessing ventilation and oxygenation. Pulse oximetry provides information about arterial oxygen saturation and the pulse **Figure 6-16**. All pulse oximetry models work on a similar principle. The machine's diode directs two wavelengths of light, red and infrared, through body tissues toward a photoreceptor. Bound hemoglobin alters light absorption; the degree of change in light transmission indicates the level of arterial oxygen saturation. Most detectors also supply the monitor with a pulsatile waveform that shows beat-to-beat changes in pulse amplitude and regularity. The finger, pinnae of the ear, toe, and sometimes the bridge of the nose are used as monitoring sites.

The significance of this reading is based on the relationship between oxygen and hemoglobin. A number of factors can alter this relationship. Abnormal hemoglobin levels, such as those seen in conditions that produce carboxyhemoglobin, methemoglobin, and sulfhemoglobin, significantly reduce the reliability of pulse oximetry. Conventional pulse oximetry is unable to differentiate between normal oxyhemoglobin and the dyshemoglobinemias. Because the dysfunctional hemoglobin is still bound, the pulse oximetry reading will be normal. Newer, pulse carbon monoxide-oximetry uses additional wavelengths of both infrared and visible spectrum light to measure and differentiate oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, methemoglobin, and hemoglobin itself. A pulse carbon monoxide-oximeter can be useful in situations where dyshemoglobins might be present. Decreased tissue perfusion (hypotension, cardiogenic shock) to the periphery may result in impaired light absorption and inaccurate pulse oximetry readings. Hypothermia may also alter pulse oximetry readings because of peripheral vasoconstriction. Peripheral vascular disease (PVD) may also alter blood flow to the periphery and pulse oximetry readings. Normal pulse oximetry readings should be 95% to 100% but can vary with underlying diseases such as COPD.

Capnography (graphic representation of exhaled CO_2) and **capnometry** (numeric value) are both important adjuncts to determining airway patency and appropriateness of ventilation **Figure 6-17**. These devices monitor the exhaled CO_2 concentration by analyzing air samples obtained directly from the airway (endotracheal or tracheostomy), through nasal prongs in the spontaneously breathing patient with a natural airway, or by insertion of a sampling port into the ventilator circuit. Because CO_2 readily diffuses across the alveolar capillary membrane and quickly equilibrates in the alveolar gases, exhaled gases, particularly those present near the end of exhalation, closely approximate arterial CO_2 levels (35 to 45 mm Hg).

TABLE 6-1 Normal ABG Values

Parameter	Normal Value	Range
pH	7.40	7.35–7.45
$PaCO_2$	40 mm Hg	35–45 mm Hg
PaO_2	100 mm Hg	80–100 mm Hg
HCO_3^-	24 mEq/L	22–26 mEq/L
Base excess	± 2 mEq/L	–2–3 mEq/L
SpO_2	97%	> 95%

Abbreviations: $PaCO_2$, partial pressure of carbon dioxide (arterial); PaO_2, partial pressure of oxygen (arterial); Hco_3–, concentration of bicarbonate ion; SpO_2, oxygen saturation as measured by pulse oximetry.

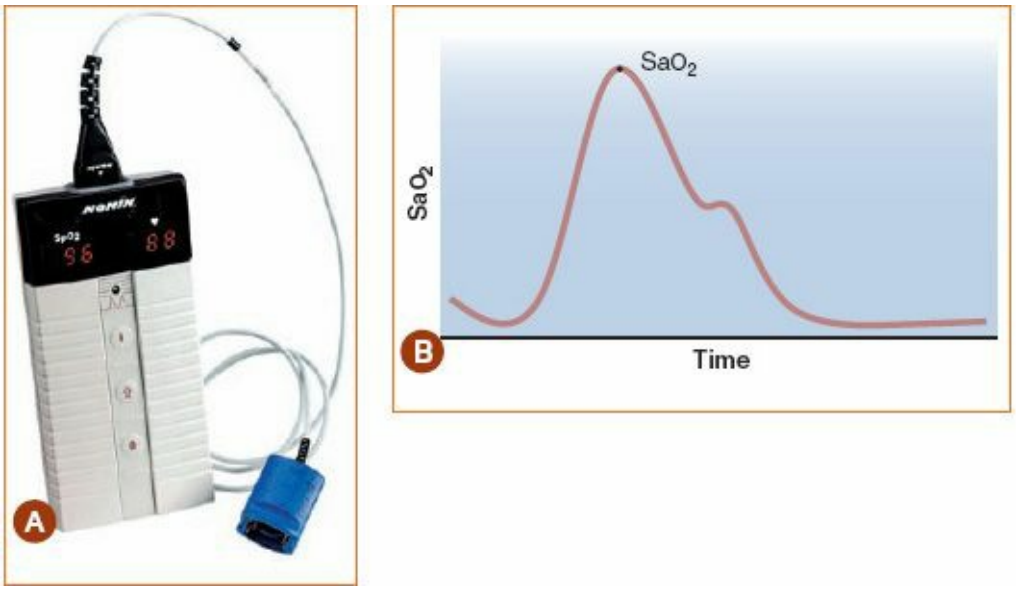

Figure 6-16 **A.** A pulse oximeter. **B.** The characteristic shape of the waveform when the pulse oximeter is properly sensing. Sao_2 indicates percentage of available hemoglobin that is saturated with oxygen.

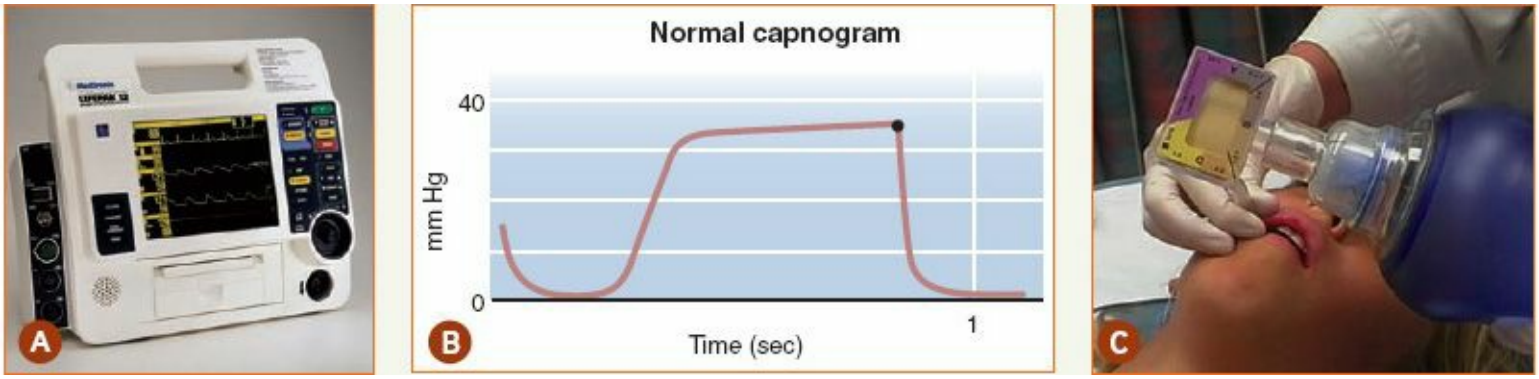

Figure 6-17 Carbon dioxide monitoring equipment. **A.** Capnometer. **B.** A normal capnogram waveform. **C.** An end-tidal carbon dioxide detector.

Capnography and capnometry provide data on the patency of the airway and the adequacy of ventilation. Use of $ETCO_2$ monitoring is limited in the face of cardiac arrest. In a patient who had just arrested, $ETCO_2$ may be detected despite a lack of perfusion. Patients in prolonged cardiac arrest will have no $ETCO_2$, and the return of measurable $ETCO_2$ is an indicator of effective CPR and the possible return of spontaneous circulation.

Controversies

Research suggesting that patients are ventilated too fast when in cardiac arrest has resulted in a push for compression-only CPR. Studies have shown that with patients in cardiac arrest, chest compressions

without ventilations have the same effect as CPR with ventilations. Providers may choose between standard CPR and compression-only CPR. Neither method has been proven as superior to the other; currently, data are inadequate.

Many prehospital systems are now suggesting a ventilation rate of 6 to 8 breaths/min during cardiac arrest and are using metronomic devices to time ventilation rates.

Respiratory and Ventilation Abnormalities

Respiratory insufficiency is the inability of the respiratory system to keep up with the metabolic demands of the body. Careful respiratory assessment helps the CCTP to determine whether the insufficiency is from ventilation or oxygenation. Treatment depends on the cause of the insufficiency. For example, thoracic, head, or spinal cord injury, central nervous system depression, drugs, and conditions in which fatigue challenges the patient's ability to breathe normally may cause **respiratory depression**. Symptoms of respiratory depression consist of a low respiratory rate (<12 breaths/min in adults) for a prolonged period of time or hypoventilation. In this case, increasing ventilation will resolve the insufficiency. Oxygen therapy is indicated in patients who cannot maintain normal oxygen saturation.

Respiratory failure occurs when the respiratory system fails to meet the body's metabolic needs. Respiratory failure can present with decreasing respiratory effort and depth. The patient may be anxious, confused, or obtunded. If not reversed, respiratory failure leads to respiratory or cardiopulmonary arrest. There are two basic types of respiratory failure: oxygenation failure and ventilatory failure. Tachypnea is the hallmark of oxygenation failure. The ability to sustain a high respiratory rate is related to the amount of accessory muscle use that the patient can endure before muscle fatigue occurs. The astute CCTP must intervene before the patient suffers an arrest. Ventilatory failure develops with increased arterial tension of CO_2.

Basic Airway Management

Although intubation is considered the gold standard for airway management, basic airway skills are the starting point in the initial patient assessment and treatment and what we fall back on in times of difficulty. These basic skills may be as simple as positioning the nontrauma victim in the recovery position or using the head tilt–chin lift or jaw-thrust maneuver to maintain airway patency. Other basic skills may use other adjuncts such as the oropharyngeal airway (OPA) or nasopharyngeal airway (NPA).

Positioning

Patients are usually able to assume a position that makes breathing easiest. This position is usually sitting upright in the "sniffing" position. Under most circumstances, you should allow the patient to do this or be prepared to assist the patient if he or she is immobile **Figure 6-18**. Patients with spinal precautions or those with a diminished level of consciousness are unable to assume this position or adequately protect their airway. As the level of consciousness decreases, control of the muscles located within the oropharynx is lost, causing the tongue to contact the posterior pharyngeal wall or soft palate, which results in airway obstruction. Muscular control of the epiglottis may also be lost, causing partial or total airway obstruction.

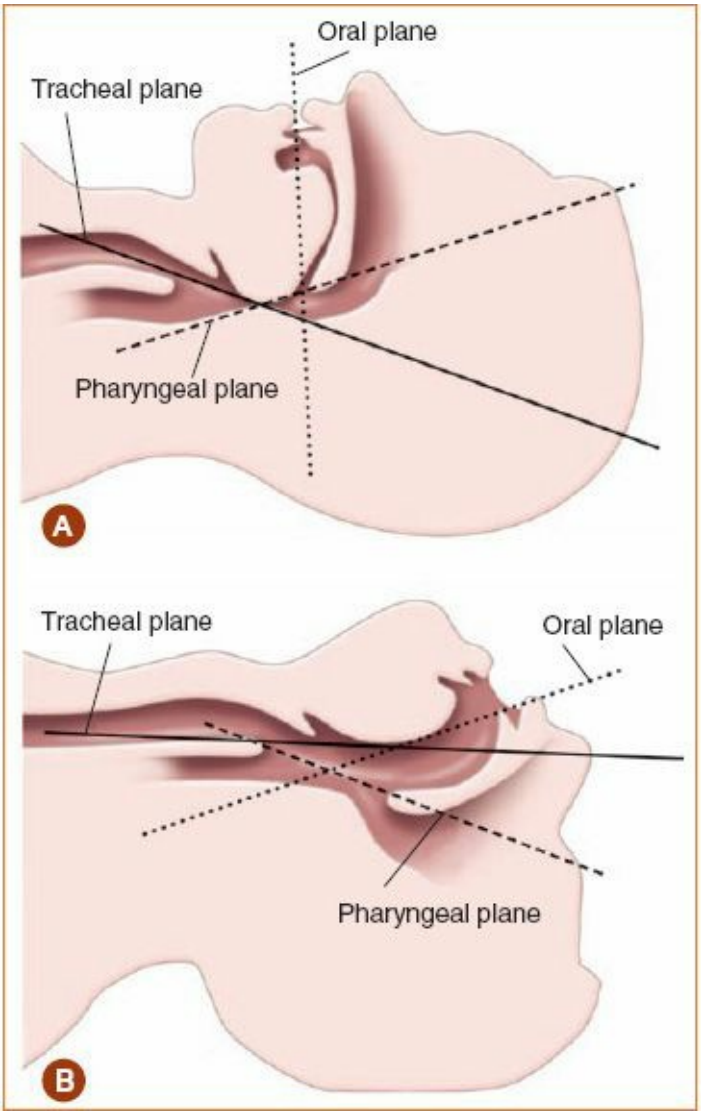

Figure 6-18 Sniffing position. **A.** The three axes of the airway (oral, pharyngeal, and tracheal) in the neutral position. **B.** The three axes in the sniffing position.

As a patient's level of consciousness diminishes, the ability to control secretions also becomes diminished. This diminished control may result in significant aspiration, especially when patients are found unconscious and supine. Patients are also resuscitated in the supine position. Placing unconscious patients (nontrauma) who are breathing in the recovery position helps to minimize airway obstruction and aspiration.

In patients undergoing resuscitation that requires supine positioning, manual airway maneuvers may be used to open the airway:

- Head tilt–chin lift: This is the most commonly known and used manual method of opening the airway of the unconscious, nontrauma victim **Figure 6-19**.
- Tongue-jaw lift: This lift is most commonly used to open and assess a patient's airway for foreign body obstruction. The patient cannot be ventilated using this maneuver **Figure 6-20**.

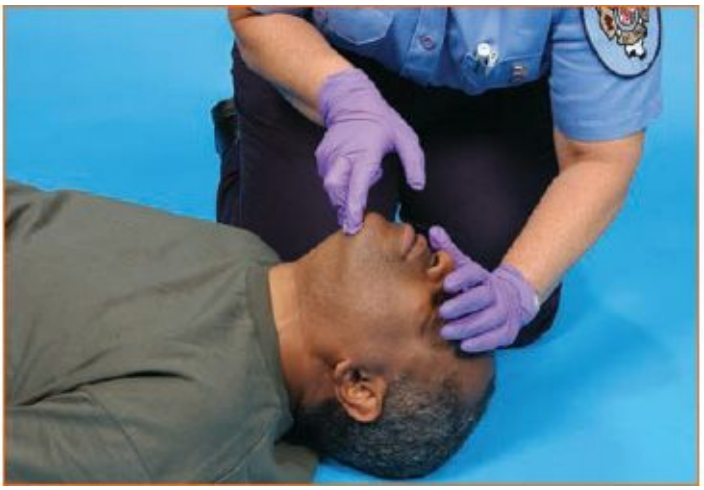

Figure 6-19 Head tilt-chin lift.

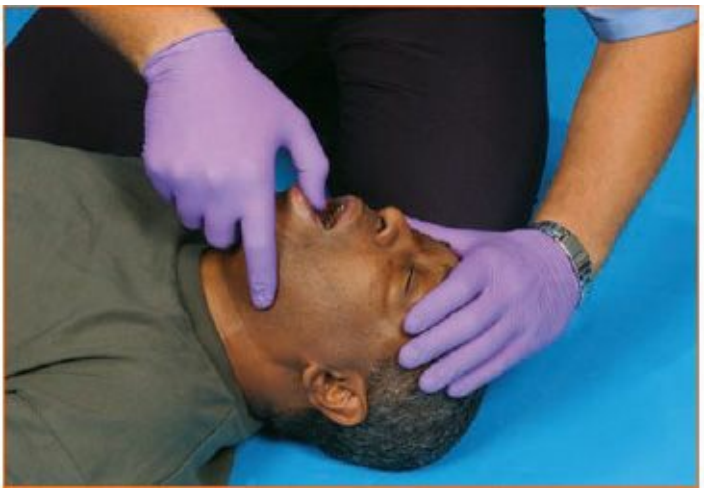

Figure 6-20 Tongue-jaw lift.

Figure 6-21 Jaw thrust maneuver.

- Jaw thrust: This thrust is frequently used to provide a patent airway and cervical spine protection in the unconscious trauma patient. In the nontrauma patient, this thrust may be combined with a slight head tilt to provide better airway opening **Figure 6-21**.

Airway Adjuncts

Both the OPA and the NPA are used along with manual airway maneuvers to provide a patent airway. In

the unconscious patient, neither can be used independently, as both adjuncts require maintaining manual airway maneuvers.

The OPA is a rigid device made of plastic or similar material that is placed in an unconscious patient's mouth **Figure 6-22**. The patient's gag reflex must not be present or the airway must be removed immediately. The size of the airway can be appropriately determined by measuring from the central incisors to the angle of the jaw. An airway that is too small or too large will not provide a patent airway and may worsen an already compromised airway. Placement of the device does not replace the need for manual methods but supplements them.

The NPA is a flexible rubber or silicone device that is placed in the nares and extends to the oropharynx. It is better tolerated than the OPA in semi-conscious patients. Its length can be appropriately sized from the tip of the nose to the tragus of the ear. Its diameter should be the largest possible, but not large enough to cause blanching of the naris. Placement should not be forced as the mucosa of the nose lacerates easily and may bleed significantly. Head trauma with evidence of basilar skull fracture or facial fracture is a contraindication for insertion. As with the OPA, the NPA does not take the place of manual methods but supplements them **Figure 6-23**.

Suction

One of the first rules in airway management is that your patient has a full stomach and is waiting to vomit on you. The ability of the prehospital provider to clear debris (vomit, blood) from a patient's airway, while a basic skill, may be lifesaving. It can restore airway patency and minimize the potential for aspiration. In the context of upper airway suctioning, a large-bore suction apparatus, of which there are various types, both fixed and portable, can be used. These suctioning devices use rigidtype suction catheters (Yankauer, tonsil tip) to remove debris. In the patient with large volumes of debris or vomit, turning the patient to his or her side while using a large-bore suction device works best **Figure 6-24**.

Flexible or soft-type suction catheters are used for suctioning the nasopharynx, the oropharynx, and the lower airways in patients with an artificial airway in place. These suction catheters are not designed to remove large volumes or large particulate matter and come in a variety of sizes referred to as French. Remember that suctioning of the nasopharynx, the oropharynx, and the lower airway may cause hypoxemia and hemodynamic instability. Patients should be preoxygenated, and suction attempts should be limited to 10 seconds or less while withdrawing the catheter. Patients should be oxygenated and ventilated if necessary between suction attempts.

In the critical care transport setting, you will use suctioning while an ET tube is in place. Indications for suctioning in this scenario include:

- Dyspnea
- Obstruction
- Excessive secretions

Complications are as follows:

- Hypoxemia
- Cardiac arrhythmias
- Mechanical trauma
- Infection
- Increased intracranial pressure
- Inability to remove material due to a mucous plug or dried crusting

Skill Drill 6-1 shows the steps for suctioning a patient with an ET tube in place, which are also described here:

1. Choose an appropriate suction adjunct: Yankauer for larger objects, French ("whistle tip") catheter for fluid or ET obstructions.
2. Check, prepare, and assemble your equipment **Step 1**.
3. Maintain universal precautions.
4. Use a sterile technique.
5. Lubricate the suction catheter **Step 2**.

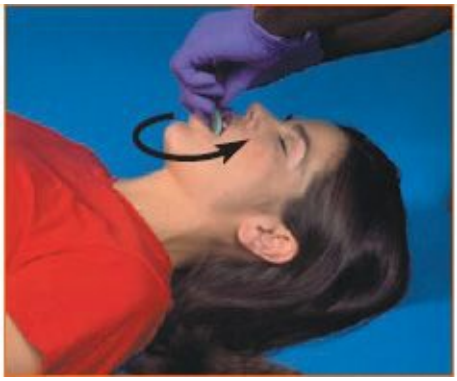

Figure 6-22 Use of an oropharyngeal airway.

Figure 6-23 Use of a nasopharyngeal airway.

Figure 6-24 Suctioning.

6. Preoxygenate the patient for 1 to 2 minutes with 100% oxygen **Step 3**.
7. Measure the suction catheter tip from the corner of the mouth to the angle of the jaw or insert through

ET tube until patient coughs **Step 4**.

8. Suction for no longer than 5 to 10 seconds as you remove the suction catheter with a twisting motion **Step 5**.
9. Continuously observe patient response to suctioning (vital signs).
10. Rinse the catheter with sterile water.
11. Assess the airway, ET, and lungs for effectiveness. Reattach the bag-mask device and resume ventilation and oxygenation **Step 6**.

Oxygen Administration

Oxygen is the most commonly administered drug in the hospital and prehospital environments. Oxygen administration has few side effects and potentially significant benefit when administered appropriately. As a general rule, all ALS patients should receive some form of supplemental oxygen based on provider assessment, regardless of documented Spo_2. Supplemental oxygen should not be withheld from a patient based upon a normal Spo_2 reading. Administering supplemental oxygen to a patient with a normal Spo_2 will do no harm and will potentially improve regional or global tissue hypoxia. Remember, it is possible for a patient to have an Spo_2 of greater than 95% and still be hypoxic at the cellular level.

Low-flow oxygen devices such as a nasal cannula can safely and comfortably deliver an FIO_2 up to approximately 40% **Table 6-2**. At flows greater than 5 L/min, a nasal cannula-type device can become ineffective and uncomfortable for the patient. Patients in significant respiratory distress or with significant hemodynamic instability require higher flow oxygen, usually through a nonrebreathing mask, which can deliver an FIO_2 closer to 1.0% (100%). Remember, with a critical patient, too much oxygen is better than too little.

The appropriate oxygen delivery device should be chosen based on the physical assessment of the patient. Patients in significant respiratory distress require high-flow oxygen via a nonrebreathing mask or bag-mask type device. Patients with agonal respirations or those who are apneic require bag-mask ventilations with supplemental high-flow oxygen. The device chosen must fit the patient's overall assessment.

Skill Drill 6-1

Suctioning a Patient With an Endotracheal Tube in Place

1 Check, prepare, and assemble your equipment.

2 Lubricate the suction catheter.

3 Preoxygenate the patient.

4 Gently insert the catheter into the ET tube until the patient coughs.

5 Suction in a rotating motion while withdrawing the catheter. Monitor the patient's cardiac rhythm and oxygen saturation during this procedure.

6 Reattach the bag-mask device and resume ventilation and oxygenation.

TABLE 6-2 Oxygen vs Approximate FIO_2

Oxygen, L/min	Approximate FIO_2, %
Nasal cannula 1	24
2	27
3	30
4	33
5	36
6	39
Simple face mask, 10	40–60
Nonrebreathing mask, 12–15	100

Supplemental Oxygen Delivery

Gas flow is usually from an area of greater concentration to an area of lesser concentration. Normal inspiration creates negative pressure by contraction of the intercostal muscles and the diaphragm. This expansion creates negative pressure with the thorax causing air to rush in, attempting to equalize intrathoracic pressure. During normal respiration, the amount of air that enters the thorax is approximately 5 to 7 mL/kg.

When gas flow is inadequate, positive-pressure ventilation is required. Delivery of positive-pressure ventilation when spontaneous respiration is inadequate may be lifesaving. Oxygen delivery may take many forms.

- Mouth-to-mouth ventilation: This is one of the oldest forms of artificial ventilation. Its main advantage is that it requires no equipment to deliver. Studies have shown that delivered tidal volumes can exceed those of other types of ventilation. The main drawback is mouth-to-mouth contact and the risk of communicable disease transmission. In actual practice, prehospital providers do not use mouth-to-mouth ventilation while working; alternative ventilation adjuncts should be readily available.
- Barrier device/resuscitation mask: These devices use the same principles of mouth-to-mouth ventilation. The addition of the barrier device reduces the psychological reluctance and minimizes

the transmission of disease **Figure 6-25**.

- Bag-mask ventilation: This is the most commonly used device to deliver supplemental oxygen and can be used with a mask or other invasive airway device **Figure 6-26**.

Advanced Airway Management

Although basic airway maneuvers are a starting point in our assessment and patient care, they are just that—basic skills. They are where you begin. However, these skills are not definitive airway management. Definitive airway management is considered to be the placement of an ET tube or tracheostomy tube within the trachea. This placement facilitates adequate oxygenation and ventilation of the patient. Patients primarily require intubation for two reasons:

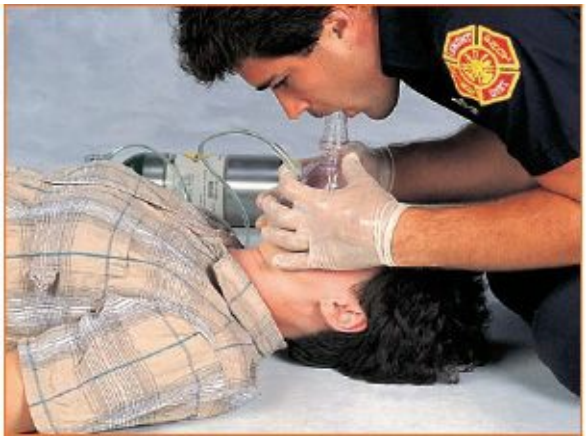

Figure 6-25 Use of a barrier device/resuscitation mask.

Figure 6-26 Use of a bag-mask device.

1. Failure to maintain a patent airway
2. Failure to adequately oxygenate or ventilate

By placing an ET tube within the trachea, the upper airway structures such as the tongue and epiglottis do not have an impact on airway patency. With a cuffed ET tube, aspiration of upper airway secretions and vomitus are minimized. A properly placed and maintained ET tube virtually ensures airway patency. An ET tube also facilitates delivery of oxygen and adequate ventilation. Some indications for ET intubation are as follows:

- Diminished level of consciousness with loss of airway control
  - Absent or diminished gag reflex
  - Glasgow Coma Scale score of 8 or less

- Potential for aspiration (secretions, blood, vomitus)

- Respiratory failure (hypoxemia, hypercarbia)
- Cardiac arrest, after adequate CPR or bag-mask ventilations have been provided

Predicting the Difficult Airway

In the prehospital environment, it is estimated that 20% of all emergency intubations are classified as "difficult." The prehospital provider has to decide how to accomplish airway management. Can I manage this airway at the BLS level? Can I intubate this patient's trachea? There are several factors to consider when treating a difficult airway.

History is one factor. Anatomic findings suggestive of a difficult airway may include congenital abnormalities, recent surgery, trauma, infection, or neoplastic disease (cancer).

A commonly used mnemonic to guide assessment of the difficult airway is LEMON, which stands for:

L	Look externally
E	Evaluate 3-3-2
M	Mallampati
O	Obstruction
N	Neck mobility

As indicated by the "L" in the mnemonic, simply looking at the patient may indicate the relative difficulty that may be encountered in airway management. Patients with short, thick necks may be difficult to intubate. Morbid obesity significantly complicates intubation. Dental conditions such as overbite or "buck" teeth may make intubation difficult.

The "E" in LEMON stands for Evaluate 3-3-2. Three different anatomic measurements are assessed using the **3-3-2 rule** **Figure 6-27**. The first "3" refers to mouth opening. Ideally, a patient's mouth opens at least three fingerwidths (approximately 5 cm). A width of less than three fingers indicates a possibly difficult airway. The second "3" refers to the length of the mandible. At least 3 fingerwidths is optimal. This length is measured from the tip of the chin to the hyoid bone. Smaller mandibles have less room for displacement of the tongue and epiglottis and can make airway management more difficult. The "2" part of this rule refers to the distance (two fingers wide) from the hyoid bone to the thyroid notch.

The "M" is for Mallampati. An anesthesiologist, Mallampati, developed the **Mallampati classification** to predict the relative difficulty of intubation **Table 6-3**. This classification notes the oropharyngeal structures visible in the upright, seated patient who is fully able to open his or her mouth for you. Although this is an accurate predictor of difficult intubation, it is of limited utility in unconscious patients or in patients who cannot follow commands. If a patient is cooperative and able to comply with this evaluation, emergent prehospital intubation is probably not necessary, but the evaluation is important in that it can provide useful information should intubation be needed.

TABLE 6-3 Mallampati Classification

Mallampati Class	Description
I	Entire posterior pharynx fully exposed **Figure 6-28A**

II	Posterior pharynx partially exposed **Figure 6-28B**
III	Posterior pharynx cannot be seen, base of uvula exposed **Figure 6-28C**
IV	No posterior structures can be seen **Figure 6-28D**

The "O" represents obstruction. Anything that might interfere with visualization or tracheal tube placement should be noted. Foreign body, obesity, hematoma, and masses are all examples of situations that can create a difficult airway.

The "N" stands for neck mobility. The ideal position for visualization and intubation is the "sniffing position" with the adult head slightly elevated and extended. The two most common patients with neck mobility problems are trauma patients (due to C-collars or injury) and the elderly (due to osteoporosis or arthritis). The inability to place the patient in the sniffing position can significantly impact the ability to visualize the airway.

Intubation

Once the decision to intubate a patient has been made, the CCTP needs to determine how to most effectively accomplish the procedure. Should the patient be intubated orally or nasally? What size blade should be used? What size ET tube should be used? What should be done if the intubation is unsuccessful? These are all important questions that must be answered.

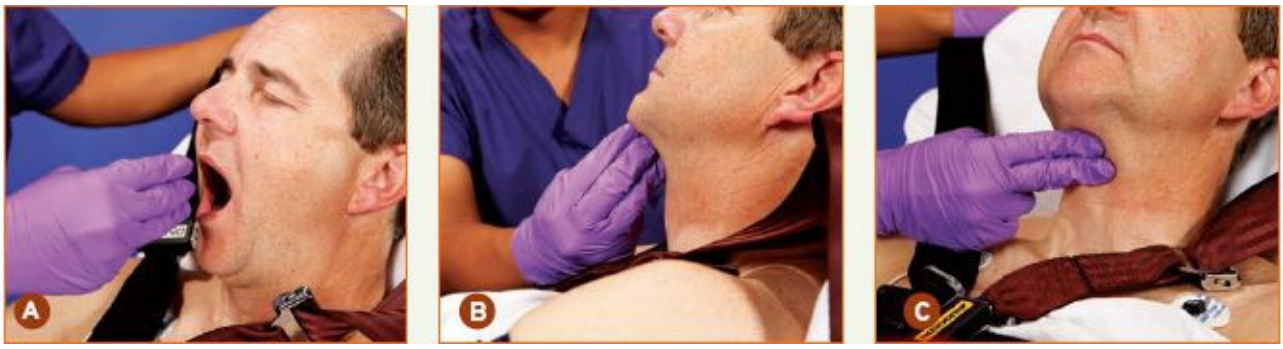

Figure 6-27 The 3-3-2 rule. **A.** The mouth should be at least three fingers wide when open. **B.** The space from the chin to the hyoid bone should be at least three fingers wide. **C.** The distance from the hyoid bone to the thyroid notch should be at least two fingers wide.

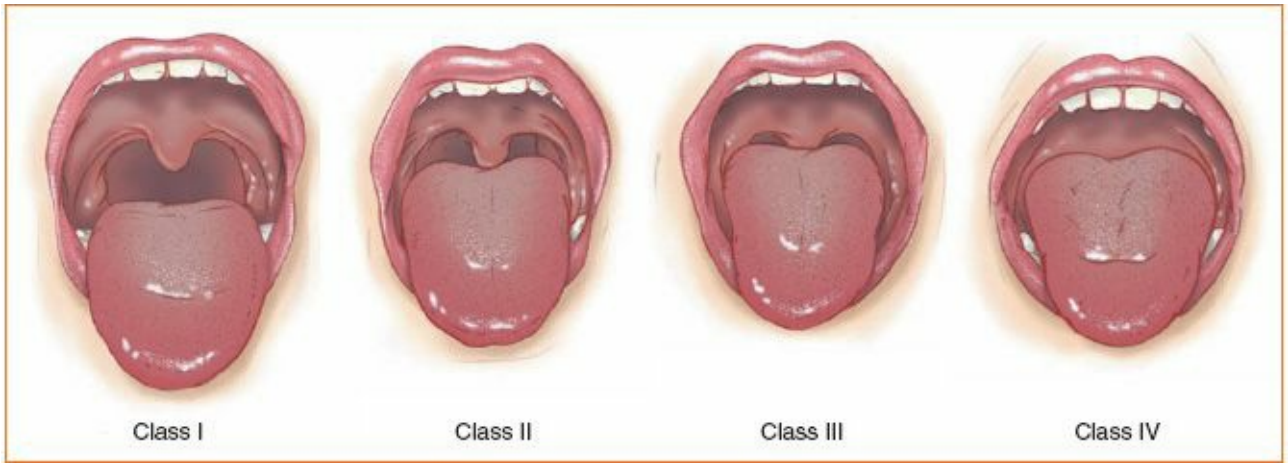

Figure 6-28 Mallampati classification.

The following pages discuss multiple techniques, devices, and procedures for airway management. It is important to abide by the protocols of your state and your service when using airway devices.

Equipment

The following equipment is needed to provide noninvasive advanced airway management.

- Gloves, mask, and goggles
- ET tubes of various sizes
  - Usual size range of 2.0 to 9.0
  - Most adults accept a size 7.0 to 8.0
- Appropriately sized stylet (adult or pediatric)
- Appropriately sized laryngoscope handle and blades (Miller or Macintosh)
- Suctioning equipment
- 10-mL syringe
- Water-soluble lubricant
- Commercial tube holding device
- Age- and size-appropriate bag-mask device with reservoir
- Supplemental oxygen
- Stethoscope
- $ETCO_2$ detector **esophageal detection device (EDD)**, or similar device for confirmation
- Magill forceps
- Topical anesthetic spray (for nasal intubation)
- Rescue airway device (Combitube, King LT, laryngeal mask airway [LMA])
- 20-mL syringe
- 40-mL syringe

Special Populations

In infants, children, and young adults, there are many methods to estimate the appropriate size ET tube to be used.

- For children older than 1 year, calculate the appropriate size by adding 16 plus the child's age in years, then dividing this number by 4.
- Look at the size of the child's small finger nail to estimate the diameter of the tube.
- Use a weight-based chart.

The laryngoscope handles and blades must also be appropriately sized.

- Straight blades: sizes 00-0-1-2-3-4
  - Miller
  - Wisconsin
- Curved blades: sizes 1-2-3-4
  - Macintosh

Many believe the type of blade used can have a significant impact on the success of intubation. For many

older children and adults, the choice of the blade is not as important as the comfort and experience of the CCTP with a particular blade type and the technique used in the intubation attempt. For smaller children, because of age-related anatomic differences, the choice of a straight blade to actually "pick up" the epiglottis may facilitate successful intubation. Remember, the curved blade is placed in the vallecula, which is located at the base of the tongue and displaces the epiglottis indirectly via pressure on the underlying hyoepiglottic ligament. After choosing the appropriately sized handle, blade, and ET tube, the CCTP must visualize the glottic opening and pass the tube. The following considerations need to be made during laryngoscopy.

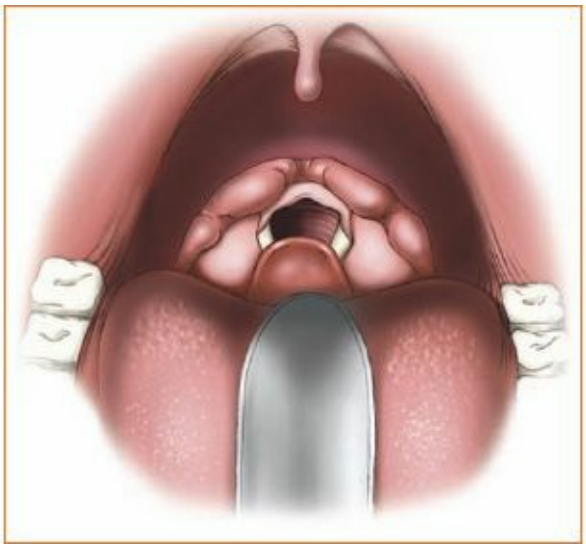

Figure 6-29 Laryngoscopic view of the vocal cords (white fibrous bands).

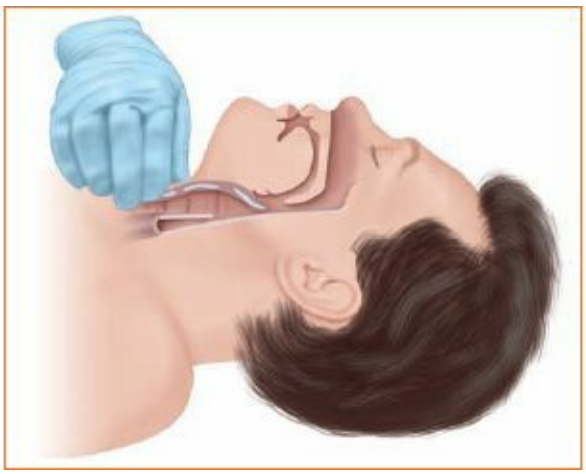

Figure 6-30 Cricoid pressure (Sellick maneuver).

The view obtained at laryngoscopy can be graded. The Cormack-Lehane grading system grades the view of the glottic opening. There are four grades as follows:

- Grade 1: The entire glottic opening is visible.
- Grade 2: The arytenoid cartilages or the posterior portion of the glottic opening is visible.
- Grade 3: Epiglottis only is visible.
- Grade 4: Tongue and/or soft palate only is visible.

Grades 3 and 4 views on laryngoscopy can result in significant difficulty intubating the trachea due to inability to visualize any part of the glottic opening **Figure 6-29**.

Figure 6-31 BURP maneuver.

Attempts at laryngoscopy should be limited to approximately 30 seconds or less. Lengthy attempts at intubation can result in significant hypoxemia, hypercarbia, and hemodynamic instability.

Cricoid pressure (Sellick maneuver) should be used to minimize passive regurgitation, although this has not been proven, and possibly improve laryngeal view, although this point is debated **Figure 6-30**.

If you are attempting intubation and not visualizing what you need, stop, ventilate, and try something different.

1. Reposition the head, if possible, to elevate the ear to the level of the sternal notch. In some patients, achieving this position may require that multiple blankets be placed under the head and shoulders and/or elevation of the head of the stretcher.
2. If spinal precautions are present, remove the front of the collar while maintaining manual spinal precautions to allow for increased mandibular displacement.
3. Consider performing the BURP maneuver: backward/upward/rightward pressure applied by an assistant to improve laryngeal view **Figure 6-31**. This is also called external laryngeal manipulation. In this technique, the prehospital care provider uses the right hand to manipulate the larynx to improve laryngeal view and then has an assistant maintain this view while passing the ET tube under direct visualization **Figure 6-32**.
4. Consider using a gum elastic bougie or intubating stylet. The gum elastic bougie is a 60-cm long, 15F intubating stylet with a 1-cm/30° bend at the distal tip. Reusable or disposable versions are available in adult and pediatric sizes. The stylet is utilized in epiglottis-only views to facilitate intubation **Figure 6-33**. Rather than attempting to use a standard stylet to "hockey stick" the ET tube and pass it beneath the epiglottis and into the trachea, the bougie is placed blindly, with its shape maximizing the chance of correct placement within the glottis. You may feel a "click" as the tip passes over the tracheal rings, usually stopping at the level of the carina. The ET tube is subsequently passed over this stylet and into the trachea.

Figure 6-32 External laryngeal manipulation.

Figure 6-33 The gum elastic bougie.

Special Populations

Pregnant patients have a four times higher *failed* intubation rate when compared with nonpregnant patients. Keep the following facts in mind when you are treating a pregnant patient:

1. The airway in pregnant patients is usually more anterior.
2. The airway tissues of a pregnant patient are often friable, and will bleed easily when manipulated.
3. Pregnant patients are at a high risk of aspiration secondary to the hormone relaxin.
4. Pregnant patients have more oral secretions and require more suctioning, even after being intubated.

The following sections discuss the indications, contraindications, and steps for the various types of intubation and other advanced airway maneuvers.

Orotracheal Intubation

Indications for orotracheal intubation include the following:

- Airway control as a result of coma, respiratory arrest, and/or cardiac arrest
- Ventilatory support prior to impending respiratory failure
- Prolonged artificial ventilatory support is required
- Patients without a gag reflex
- Medication administration (lidocaine, atropine, epinephrine, naloxone)
- Impending airway compromise (burns, trauma)

Relative contraindications for orotracheal intubation include:

- Inability to open the mouth because of trauma, dislocation, or pathologic condition
- Epiglottitis

- Inability to see the glottic opening
- Copious secretions, vomit, or blood in the airway

Skill Drill 6-2 shows the steps for orotracheal intubation, which are described as follows:

1. Use BSI precautions.
2. Preoxygenate the spontaneously breathing patient for as long as possible with high-flow oxygen. Attempt to avoid bag-mask ventilations if possible. Avoiding bag-mask ventilation minimizes air insufflation of the stomach and reduces the potential for regurgitation and aspiration **Step 1**.
3. Check, prepare, and assemble your equipment **Step 2**.
4. Choose an appropriately sized tube, with the tube still in the package to maintain sterility. Insert the stylet, lubricate the tube, and bend to the desired position **Step 3**. It is also a good idea to have a tube of a slightly smaller diameter prepared if needed.
5. Auscultate breath sounds prior to intubation.
6. Have Magill forceps and a commercial tube securing device ready.
7. Have a large-bore suction unit at the patient's side and turned on.
8. Place the patient in sniffing position if no trauma is involved **Step 4**. If the patient is a trauma patient, maintain cervical spine immobilization while intubating **Step 5**.
9. Apply cricoid pressure (Sellick maneuver) **Step 6**.
10. Insert the laryngoscope blade into the right side of mouth, sweep the tongue to the left, and visualize the cords **Step 7**.
11. If you are unable to visualize the glottic opening, change cricoid pressure to the BURP maneuver or external laryngeal manipulation.
12. Insert the ET tube to the appropriate depth until the cuff is just below the vocal cords.
13. Inflate the cuff with 10 mL of air and remove the syringe **Step 8**. Check placement with an EDD.
14. Attach the bag-mask device and ETCO2 detector and begin to ventilate **Step 9**.
15. Verify tube placement by auscultating the epigastrium and bilateral chest **Step 10**.
16. Observe for bilateral chest expansion, compliance of the bag-mask device, condensation in the tube, and the proper colorimetric change on the $ETCO_2$ detector.
17. Secure the ET tube with a commercial device or tape **Step 11**.
18. Frequently verify placement of the ET tube, ideally with waveform capnography. If continuous waveform capnography is not available, the tube position should be re-verified, at a minimum, each time the patient is moved.

Skill Drill 6-2

Performing Orotracheal Intubation

1 Use BSI precautions. Preoxygenate the patient.

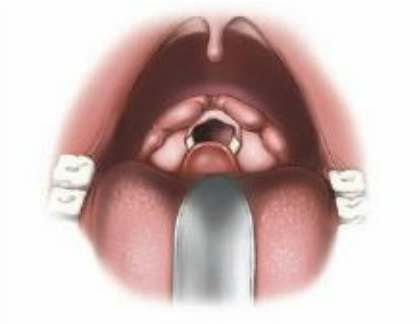
2 Check, prepare, and assemble your equipment.

3 Insert the stylet, lubricate the tube, and bend to the desired position. Auscultate breath sounds.

4 Place the patient in a sniffing position if no trauma is involved.

5 If the patient is a trauma patient, maintain cervical spine immobilization while intubating.

6 Apply cricoid pressure (Sellick maneuver).



7 Insert the laryngoscope blade into the right side of the mouth, sweep the tongue to the left, and visualize the cords. Insert the ET tube to the appropriate depth until the cuff is just below the vocal cords.

8 Inflate the cuff with 10 mL of air and remove the syringe. Check placement with an EDD.

9 Attach the bag-mask device and ETCO2 detector and begin to ventilate.

10 Auscultate the epigastrium and bilateral chest.

11 Secure the ET tube with a commercial device or tape.

Flight Considerations

When you are performing orotracheal intubation in a pressurized air medical environment, also consider filling the cuff with water to occupy the equivalent volume of 10 mL of air. This decreases the risk of tracheal injury due to overexpansion of the balloon with increased altitudes.

Nasotracheal Intubation

Nasotracheal (nasal) intubation was once the preferred airway management technique in patients suspected of having a spinal cord injury. With the advent of rapid sequence intubation (RSI), nasal intubation is, at best, used infrequently. Most patients who undergo nasotracheal intubation are in the prehospital environment where RSI may not be permitted or are spontaneously breathing but the potential for a difficult airway has been identified, making RSI inadvisable. Nasotracheal intubation also requires a spontaneously breathing patient. Success with nasotracheal intubation may be enhanced by using endotracheal tubes specifically designed for nasotracheal placement (Endotrol tube).

Nasotracheal intubation, however, carries a fairly high failure rate and also takes longer to perform than direct laryngoscopy. Also, prolonged attempts may result in significant hypoxemia and glottic edema

secondary to trauma. The procedure may also cause significant bleeding and vomiting. The risks of hypoxemia and hypercarbia in a patient with inadequate respirations must be weighed against the risks of performing nasal intubation. Combativeness, facial trauma with suspected basilar skull fracture, coagulopathy, and upper airway infection are a few of the relative contraindications to nasotracheal intubation. It also frequently requires placement of an ET tube of a smaller diameter compared with those placed during direct laryngoscopy. Indications for nasotracheal intubation include:

- Patients who are awake and breathing but are in danger of respiratory failure
- Patients with a gag reflex
- Patients who are breathing but cannot open their mouth

Contraindications to nasotracheal intubation include:

- Apneic or near-apneic patients
- Inability to pass the tube through the nostril
- Blood clotting or anticoagulation therapy
- Severe nasal, facial, or basilar skull fractures

Skill Drill 6-3 shows the steps for nasotracheal intubation, which are described as follows:

1. Use body substance isolation (BSI) precautions (gloves and face shield).
2. Preoxygenate the patient whenever possible with 100% oxygen by appropriate delivery device **Step 1**.
3. Check, prepare, and assemble your equipment **Step 2**.
4. Place the patient's head in a neutral position **Step 3**.
5. Select the proper size ET tube and form it into a circle **Step 4**.
6. Apply topical anesthetic spray to nostrils and pharynx **Step 5**.
7. Lubricate the tip of the tube with a water-soluble gel **Step 6**.
8. Release the circle from the ET tube and gently insert into either nostril with the bevel of the tube toward the septum **Step 7**.
9. Advance the tube until the tip passes through the nasopharynx **Step 8**. Listen for breath sounds and look for condensation in the tube.
10. As the tube approaches the larynx, breath sounds will be amplified. Gently and evenly push the tube into the larynx during inspiration.
11. The 15-mm adapter should rest close to the nostril. Passing the tube through the trachea may stimulate the gag reflex. This could result in the patient coughing and bucking. Watch and monitor for vomiting.
12. Inflate the distal cuff with 5 to 10 mL of air and detach the syringe **Step 9**. Check placement with an EDD.
13. Attach an $ETCO_2$ detector to the ET tube **Step 10**.
14. Attach the bag-mask device and ventilate. Verify tube placement by auscultating the chest bilaterally and over the epigastrium **Step 11**.
15. Secure the ET tube.

Skill Drill 6-3

Performing Nasotracheal Intubation

1 Use BSI precautions (gloves and face shield). Preoxygenate the patient.

2 Check, prepare, and assemble your equipment.

3 Place the patient's head in a neutral position.

4 Select the proper size ET tube and form it into a circle.

5 Apply topical anesthetic spray to nostrils and pharynx.

6 Lubricate the tip of the tube with a water-soluble gel.

7 Release the circle from the ET tube and gently insert into either nostril with the bevel of the tube toward the septum.

8 Advance the tube until the tip passes through the nasopharynx. Listen for breath sounds and look for condensation in the tube.

9 Inflate the distal cuff with 5 to 10 mL of air and detach the syringe. Check placement with an EDD.

10 Attach an $ETCO_2$ detector to the ET tube.

11 Attach the bag-mask device and ventilate. Auscultate the chest bilaterally and over the epigastrium. Secure the ET tube.

Digital Intubation

Digital intubation was one of the first techniques developed to facilitate the placement of an ET tube. With this technique, the epiglottis is manually elevated using the middle finger and the ET tube is guided into place by feel. Advantages are that other than an ET tube, no additional equipment is needed. Also, in confined space incidents when laryngoscopy may not be possible or a laryngoscope may not be available, such as during a building collapse or entrapment, digital intubation may be life saving. The major limitation of digital intubation is safety of the provider. Any patient who undergoes digital intubation must be profoundly unconscious without airway reflexes, or some type of bite block must be used to prevent injury.

Indications for digital intubation include:

- Deeply unconscious patients who are apneic and without a gag reflex When other techniques have failed, the patient is obese, or the patient has a short neck
- A laryngoscope is not available or the patient is in a confined space

- Oral secretions are obscuring the view, and the head cannot be moved due to trauma, or immobilization equipment is complicating other techniques
- Massive trauma has made identification of intubation landmarks impossible

Contraindications to digital intubation include:

- Patients with a gag reflex
- Inability to open mouth due to trauma, dislocation, fracture, or pathologic condition

---

Skill Drill 6-4 shows the steps for digital intubation, which are described as follows. Only attempt this maneuver if the patient is deeply comatose and oral and nasal intubation have failed or are not possible.

1. Use BSI precautions (gloves and face shield) **Step 1**.
2. Kneel next to the patient. Preoxygenate the patient for as long as possible with 100% oxygen via appropriate delivery device **Step 2**.
3. Check, prepare, and assemble your equipment **Step 3**.
4. Bend the ET tube by placing a slight curve at its distal end (like a hockey stick) **Step 4**.
5. Place the patient's head in a neutral position **Step 5**.
6. Place a bite block in between the patient's molars to prevent the patient from biting your fingers **Step 6**.
7. Insert your left index and middle fingers into the patient's mouth and shift the patient's tongue forward as you advance your fingers toward the larynx **Step 7**.
8. Palpate and lift the epiglottis with your left middle finger **Step 8**.
9. Advance the tube between your fingers with your right hand and into the trachea **Step 9**. Guide it in between the vocal cords with your left index finger.
10. Remove the stylet from the ET tube **Step 10**.
11. Inflate the distal cuff of the ET tube with 5 to 10 mL of air and detach the syringe **Step 11**.
12. Attach the $ETCO_2$ detector to the ET tube **Step 12**.
13. Attach the bag-mask device and ventilate. Verify tube placement by auscultating the chest bilaterally and over the epigastrium **Step 13**.
14. Secure the ET tube **Step 14**.

Retrograde Intubation

When intubation is unsuccessful by standard means, the technique of **retrograde intubation** may be utilized. In retrograde intubation, a needle is placed percutaneously within the trachea via the cricoid membrane. A wire is placed cephalad through the needle upward through the trachea and into the mouth. The wire is then visualized and secured, and the ET tube is placed over the wire and guided into the trachea. The wire is subsequently removed and the ET tube is advanced and secured.

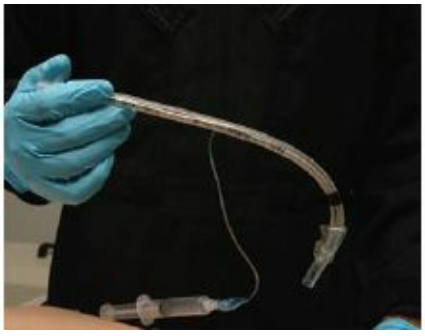
Skill Drill 6-4

Performing Digital Intubation

1 Use BSI precautions (gloves and face shield).

2 Kneel next to the patient and preoxygenate.

3 Check, prepare, and assemble your equipment.



4 Bend the ET tube by placing a slight curve at its distal end (like a hockey stick).

5 Place the patient's head in a neutral position.

6 Place a bite block in between the patient's molars to prevent the patient from biting your fingers.

7 Insert your left index and middle fingers into the patient's mouth and shift the patient's tongue forward as you advance your fingers toward the larynx.

8 Palpate and lift the epiglottis with your left middle finger.

9 Advance the tube between your fingers with your right hand and into the trachea.

10 Remove the stylet from the ET tube.

11 Inflate the distal cuff of the ET tube with 5 to 10 mL of air and detach the syringe.

12 Attach the $ETCO_2$ detector to the ET tube.

13 Attach the bag-mask device and ventilate. Auscultate the chest bilaterally and over the epigastrium.

14 Secure the ET tube.

Indications for retrograde intubation include:

- Dyspnea
- Obstruction
- Secretions
- Failure to intubate the trachea by other less invasive methods Contraindications to retrograde intubation include:
- Lack of familiarity with procedure
- Laryngeal trauma
- Unrecognizable or distorted landmarks
- Coagulopathy (relative)
- Severe hypoxia (due to inability to ventilate during procedure and time to perform procedure)

Complications of retrograde intubation include:

- Hypoxemia
- Cardiac arrhythmias
- Mechanical trauma
- Infection
- Increased intracranial pressure

Because retrograde intubation is essentially a different technique for placing the ET tube, assessment findings and transport complications with retrograde intubation are the same as with standard ET intubation.

Skill Drill 6-5 shows the steps for retrograde intubation, which are described as follows:

1. Place the patient supine.
2. Ventilate the patient with high-flow oxygen via the appropriate device while preparing the equipment and the patient.
3. Cleanse the anterior part of the neck from the laryngeal prominence to just below the cricoid ring and position a fenestrated drape **Step 1**.

4. If the patient is conscious, consider numbing the area over the cricothyroid membrane using a local anesthetic **Step 2**.
5. Puncture the cricothyroid membrane using a large needle aligned with the airway and pointed approximately 30° cephalad from the perpendicular at the level of the cricothyroid membrane **Step 3**.
6. Identify the tracheal lumen by aspiration of air into the syringe attached to the needle **Step 4**.
7. Pass the 70-cm guide wire through the catheter until it appears in the oropharynx, mouth, or one of the nares **Step 5**.
8. If guide wire is in the oropharynx, grasp it with a clamp or Magill forceps and pull the wire partially out of the mouth, ensuring that the distal end is still emerging from the neck and the wire is pulled taut **Step 6**.
9. Insert the guide wire emerging from the mouth, through Murphy's Eye of the ET tube, and pass through the lumen of the ET tube **Step 7**.
10. Advance the ET tube into the trachea **Step 8**.
11. Verify tube placement by auscultating the chest bilaterally and over the epigastrium **Step 9**.
12. Secure the ET tube in place and ventilate **Step 10**.
13. Once tube placement is confirmed, remove the guide wire by pulling on the distal end emerging from the neck, then advance the tube 2 to 3 cm futher **Step 11**.
14. If tube placement is incorrect, remove and attempt to ventilate. If ventilating adequately, continue to ventilate with high-flow oxygen and reassess. Determine if additional attempts at retrograde intubation are warranted or if another means of securing the airway is necessary (cricothyrotomy) **Step 12**.

Skill Drill 6-5

Performing Retrograde Intubation

1 Place the patient supine. Ventilate the patient while preparing the equipment and the patient. Cleanse the anterior part of the neck from the laryngeal prominence to just below the cricoid ring and position a fenestrated drape.

2 Numb the area over the cricothyroid membrane using a local anesthetic.

3 Puncture the cricothyroid membrane using a large needle aligned with the airway and pointed approximately 30° cephalad from the perpendicular at the level of the cricothyroid membrane.

4 Identify the tracheal lumen by aspirating the syringe attached to the needle.

5 Pass the 70-cm guide wire through the catheter until it appears in the oropharynx, mouth, or one of the nares.

6 If guide wire is in the oropharynx, grasp it with a clamp and pull the wire partially out of the mouth, ensuring that the distal end is still emerging from the neck and the wire is pulled taut.

7 Insert the guide wire emerging from the mouth, through Murphy's Eye, and pass through the lumen of the ET tube.

8 Advance the ET tube into the trachea.

9 Auscultate the chest bilaterally and over the epigastrium.

10 Secure the ET tube in place and ventilate.

11 Once tube placement is confirmed, remove the guide wire by pulling on the distal end emerging from the neck.

12 If tube placement is incorrect, remove the tube and start over or switch to a different technique.

Face-to-Face Intubation

Intubation may be performed with the provider's face at the same level as the patient's face when other positions are not possible—for example in a motor vehicle collision where the patient is in a seated position or in a tight space where the space above the head cannot be accessed. This is called **face-to-face intubation**, or the "Tomahawk" method. The procedure is the same as orotracheal intubation except for the following:

- The patient's head cannot be placed in the sniffing position. It is manually stabilized by a second provider during the entire procedure.
- Hold the laryngoscope (with a Macintosh blade) in your right hand with the blade facing downwards like a hatchet, while holding the ET tube in your left hand. Insert the laryngoscope blade into the right side of patient's mouth, sweep the tongue to the patient's left, and visualize the cords.
- Once the laryngoscope blade has been placed, the provider who is intubating may slightly adjust the patient's head for better visualization by pulling the mandible forward while pressing down.

Transillumination

With **transillumination**, a light source placed within the trachea is able to be visualized through the thin tissue that covers the trachea **Figure 6-34**. Direct visualization of the glottis is not required with this procedure. However, a specific piece of equipment is required, and it may be difficult to perform this procedure in morbidly obese patients and in patients with short necks because of increased amounts of soft tissue overlying the trachea, or in brightly lit conditions where the transillumination is difficult to see.

Figure 6-34 In transillumination intubation, a lighted stylet is inserted into the ET tube.

Complications of Intubation

Misplaced ET Tube

In the event of a misplaced ET tube, do the following:

- If breath sounds are not heard bilaterally but are heard over the epigastrium, deflate the cuff and extubate. Suction the airway and repeat the steps for oral intubation.
- If breath sounds are heard on the right side only, deflate the cuff and retract the ET tube until you can auscultate breath sounds bilaterally. Reinflate the cuff, resecure the tube, and auscultate breath sounds again.

Failed Intubation

It is estimated that, overall, less than 2.5% of attempted intubations result in failure, although several dedicated EMS studies seem to indicate that the failure rate in the prehospital environment is higher. It is further estimated that less than 1% of attempted intubations result in the critical "can't intubate/can't ventilate" scenario. A failed airway attempt is defined as the failure to maintain acceptable oxygen saturations during or after one or more failed intubation attempts or a total of three failed intubation attempts by an experienced intubator, even when the oxygen saturations can be maintained. Ways to minimize complications of airway management have been discussed. However, as stated earlier, you frequently do not have a choice in the prehospital environment to manage the airway. So, what do you do? There are many rescue airway techniques available.

- Perform simple BLS airway maneuvers with an OPA and/or an NPA and a bag-mask device. With good technique, adequate oxygenation and ventilation can be provided.
- Consider using a laryngeal mask airway (LMA), discussed next, or another blind insertion airway device.

The LMA

The LMA was designed by a British anesthesiologist, Archie Brain, for use as an alternative to mask ventilation and intubation in the operating room. The LMA has been advocated for use as a rescue airway

in the setting of failed intubation in both the emergency and EMS environments. LMAs have various designs, some of which allow an ET tube to be passed through it or a tube to decompress the stomach. The basic design is similar to an ET tube at the proximal end in that a standard adapter is present to allow ventilation. The distal end is equipped with an elliptical cuff, which, when inflated, covers the supraglottic area and allows ventilation.

An advantage of the LMA is ease of insertion because placement of the device does not require laryngoscopy. It also provides superior oxygenation and ventilation compared with bag-mask ventilation. Some disadvantages associated with LMA use are the risk of aspiration and difficulty with obtaining an adequate seal, allowing a loss of tidal volume and gastric insufflation.

Indications for LMA use include:

- Deep coma, cardiac arrest, and/or respiratory arrest
- When ET intubation is not possible or available Contraindications to LMA use include:
- Patients with a gag reflex
- Facial and/or esophageal trauma
- Suspected foreign body airway obstruction

Skill Drill 6-6 shows the steps for LMA placement, which is described as follows:

1. Check the cuff of the LMA by inflating it with 50% more air than is required for that size airway. Then deflate the cuff completely **Step 1**.
2. Apply a water-soluble lubricant to the base of the device **Step 2**.
3. Preoxygenate the patient with a bag-mask device and 100% oxygen. Ventilation should not be interrupted for more than 30 seconds to accomplish LMA placement **Step 3**.
4. Assemble and check equipment.
5. Place the head in the sniffing position. Insert your finger between the cuff and the tube. Place the index finger of your dominant hand in the notch between the tube and the cuff. Open the patient's mouth **Step 4**.
6. Insert the LMA along the roof of the mouth with the aperture of the mask facing the tongue and the back of the mask against the roof of the mouth **Step 5**. Use your finger to push the airway against the hard palate.
7. Blindly push until resistance is felt.
8. The black line on the tube shaft should be opposite the upper lip.
9. Inflate the cuff rim of the mask with the amount of air indicated for that size airway. Remove the syringe **Step 6**.
10. Attach the bag-mask device and begin to ventilate the patient. Check for chest rise and lung or epigastrium sounds **Step 7**. Continuously monitor the patient.

Skill Drill 6-6

LMA Insertion

1 Check the cuff of the LMA by inflating it with 50% more air than is required for that size airway. Then deflate the cuff completely.

2 Apply a water-soluble lubricant to the base of the device.

3 Preoxygenate the patient. Ventilation should not be interrupted for more than 30 seconds to accomplish LMA placement.

4 Place the head in the sniffing position. Insert your finger between the cuff and the tube. Place the index finger of your dominant hand in the notch between the tube and the cuff. Open the patient's mouth.

5 Insert the LMA along the roof of the mouth with the aperture of the mask facing the tongue and the back of the mask against the roof of the mouth.

6 Inflate the cuff with the amount of air indicated for that size airway.

7 Attach the bag-mask device and begin to ventilate the patient. Check for chest rise and lung or epigastrium sounds.

Esophageal Tracheal Combitube

Several supraglottic airways are available that can be used as rescue airways. The Combitube is a dual-lumen, dual-cuffed supraglottic airway that may be placed blindly. Placement occurs mostly within the esophagus. However, its dual-lumen design results in successful ventilation regardless of whether the placement is esophageal or, less likely, tracheal.

Indications for Combitube use are:

- When ET intubation is not possible, not available, or not successful
- As a rescue airway in failed intubation, especially in the setting of failed RSI. If the Combitube is used as a rescue airway after RSI, remember, the patient must be kept sedated and paralyzed once proper placement has been verified.
- Deep coma, cardiac arrest, and/or respiratory arrest
- To reduce the risk of gastric distention

Contraindications for the use of the Combitube are:

- Patients with a gag reflex
- Upper airway obstruction or suspected foreign body airway obstruction
- Facial and/or esophageal trauma
- Known esophageal disease
- Possibly caustic ingestions
- Children younger than 16 years
- Anyone shorter than 4′ (use the small adult [SA] Combitube for adults between 4′ and 6′ tall, and use the regular Combitube for adults taller than 6′)

Skill Drill 6-7 shows the steps for Combitube placement, which are described as follows:

1. Use BSI precautions (gloves and face shield) **Step 1**.
2. Preoxygenate the patient with a bag-mask device and 100% oxygen **Step 2**.

Skill Drill 6-7

Insertion of the Combitube

1 Use BSI precautions (gloves and face shield).

2 Preoxygenate the patient.

3 Assemble and check equipment.

4 Apply water-soluble lubricant to the tube. Place the patient's head in the sniffing position.

5 Open the patient's mouth with the tongue-jaw lift maneuver and insert the Combitube in the midline of the patient's mouth. Gently insert the tube until the incisors lie between the two reference marks.

6 Inflate line 1 (blue pilot balloon) leading to the pharyngeal cuff with 100 mL of air and remove syringe.

7 Inflate line 2 (white pilot balloon) leading to the distal cuff with approximately 15 mL of air and remove syringe.

8 Ventilate the patient through the pharyngeal (blue) tube first. Look for chest rise, which indicates esophageal placement of the distal tip, and listen for breath sounds and epigastric sounds.

9 If the chest does not rise and epigastric sounds are present, this indicates tracheal placement. Attempt ventilation through the shorter, clear tube. If it has entered the trachea, the chest should rise.

10 Confirm placement by auscultating for breath sounds over the lungs and gastric sounds over the abdomen.

3. Assemble and check equipment **Step 3**.
4. Familiarize yourself with the various tubings in the airway. Identify the long and the short tube prior to insertion.
5. Apply water-soluble lubricant to the tube.
6. Place the patient's head in the sniffing position **Step 4**.
7. Open the patient's mouth with the tongue-jaw lift maneuver and insert the Combitube in the midline of the patient's mouth. Gently insert the tube until the incisors lie between the two reference marks **Step 5**.
8. Inflate line 1 (blue pilot balloon) leading to the pharyngeal cuff with 100 mL of air and remove syringe **Step 6**.
9. Inflate line 2 (white pilot balloon) leading to the distal cuff with approximately 15 mL of air and remove syringe **Step 7**.
10. Ventilate the patient through the pharyngeal (blue) tube first. Look for chest rise, which indicates esophageal placement of the distal tip, and listen for breath sounds and epigastric sounds **Step 8**.
11. *If the chest rises, breath sounds are present, and epigastric sounds are not present* , continue to ventilate through the longer, blue tube.
12. *If the chest does not rise, no breath sounds are present, and epigastric sounds are present* , this indicates tracheal placement of the Combitube. Attempt ventilation through the shorter, clear tube. If it has entered the trachea, the chest should rise. Continue to ventilate through the shorter clear tube **Step 9**.

Figure 6-35 King LT airway.

13. Confirm placement by auscultating for breath sounds over the lungs and gastric sounds over the abdomen **Step 10**.
14. After determining which tube is to be used for ventilating, cover the end of the tube not being used with a glove or the enclosed adapter to ensure ventilation through the proper tube.

Another type of supraglottic airway includes the King LT airway, which is a single-lumen, dual-cuff supraglottic airway that is inserted blindly and functions similar to the Combitube **Figure 6-35**. Also, the cuffed oropharyngeal airway is an OPA with the addition of a high-volume, low-pressure cuff and proximal airway adapter that permits positive-pressure ventilation.

Surgical Airways

If you encounter a patient who cannot be intubated or ventilated, the patient requires placement of an airway by other means. This frequently means some type of surgical airway. First, an adequate understanding of the anatomy of the anterior part of the neck is needed.

The most prominent structure in the anterior part of the neck is the thyroid cartilage (Adam's apple). It is more easily palpable in males than in females. Directly inferior to the thyroid cartilage is the cricoid cartilage. The cricothyroid membrane lies between these two structures. A thin membrane covered only by skin, the cricothyroid membrane is an important landmark to identify in the setting of a surgical airway.

Equipment

The following equipment is needed to provide invasive advanced airway management.

- ET tube or tracheostomy tube (various sizes)
- Scalpel
- Curved hemostats
- Suction equipment
- 14-gauge or larger over-the-needle catheter
- ¼′ tape
- 10-mL syringe
- Three-way stop cock
- Two pieces of standard oxygen tubing, 4′ to 5′ each
- Y-connector
- Oxygen cylinder (coupled with a 50-psi step-down regulator and a needle flow meter)
- Povidone-iodine swabs
- Body surface isolation, including sterile gloves
- Sterile fenestrated drape (hole in center)
- 4″ × 4″ gauze pads
- Bag-mask device
- Guide wire (70 cm)
- Cotton tie or commercial trach holder

Needle Cricothyrotomy

A surgical airway is used to provide temporary oxygenation when intubation by other means is not possible. A surgical airway may be needed in the event of the unusual situation in which the patient cannot be intubated or ventilated. In the pediatric population younger than 12 years, in whom a formal cricothyrotomy is contraindicated, needle cricothyrotomy is the surgical airway of choice in the emergent setting. In a needle cricothyrotomy, a large-bore angiocath (14 to 16 gauge) is placed through the cricothyroid membrane into the trachea. With a transtracheal jet ventilator, it is possible to provide temporary oxygenation. Exhalation is passive and requires supraglottic airway patency. Needle cricothyrotomy does not allow optimal ventilation, only oxygenation, so hypercarbia is an expected complication. It also does not protect the airway or allow suctioning. It is a temporary airway until a more definitive airway can be placed.

Indications for needle cricothyrotomy include:

- Intubation is not feasible
- Intubation does not relieve obstruction
- Field procedure is to establish a temporary airway

Contraindications to needle cricothyrotomy include:

- Patients with severe airway obstruction below the site of the catheter insertion

Complications of needle cricothyrotomy are:

- Hemorrhage
- Subcutaneous emphysema
- Infection
- Misplacement of cannula
- Accidental removal
- Subglottic stenosis
- Mediastinal emphysema
- Tracheal and esophageal laceration
- **Barotrauma**

Skill Drill 6-8 shows the steps for needle cricothyrotomy, which are described below:

1. Use BSI precautions (gloves and face shield) **Step 1**.
2. Attach a 14- to 16-gauge IV catheter to a 10-mL syringe containing approximately 3 mL of sterile saline or water **Step 2**.
3. With the patient's head in a neutral position, palpate for and locate the thyroid cartilage, cricothyroid membrane, and suprasternal notch **Step 3**.
4. Cleanse the area with an iodine-containing solution **Step 4**.
5. Attach the syringe (if preferred) to the needle.
6. Stabilize the larynx and insert the needle into the cricothyroid membrane at a 45° angle toward the feet **Step 5**.
7. Push the needle until it "pops" into trachea. Aspirate with the syringe to determine correct catheter placement **Step 6**.
8. Confirm tracheal placement by noting movement of air.
9. Advance the catheter over the needle until the hub rests against the skin **Step 7**.
10. Place the syringe and needle in a puncture-proof container **Step 8**.
11. Connect one end of the oxygen tubing to the catheter and the other end to the jet ventilator **Step 9**.
12. Open the release valve on the jet ventilator and adjust the pressure accordingly to provide adequate chest rise **Step 10**. If a jet ventilator is unavailable, temporary ventilation can be provided with a bag-valve-mask device by attaching a 15-mm BVM adapter from a 3-0 endotracheal tube to the catheter, or by attaching a 3-mL syringe with the plunger removed and an adapter from a 7-0 tube.
13. Auscultate the apices and bases of both lungs and over the epigastrium to confirm correct catheter placement **Step 11**.
14. Secure the catheter with a 4″ × 4″ gauze pad and tape. Continue ventilations while frequently reassessing for adequate ventilations and any potential complications **Step 12**.

Surgical Cricothyrotomy

There are many techniques for performing a surgical cricothyrotomy. Techniques range from a fully open technique using a scalpel and an ET tube or tracheostomy tube to modified techniques using various premanufactured kits. Availability of kits depends on the state of practice and medical command

physician. The advantages of an open cricothyrotomy are speed of insertion compared with formal tracheostomy and improved oxygenation and ventilation compared with needle cricothyrotomy.

Indications for surgical cricothyrotomy include:

- Intubation is not feasible
- Intubation does not relieve obstruction
- Field procedure to establish a temporary airway Contraindications to surgical cricothyrotomy are:
- Inability to identify anatomic landmarks, usually secondary to trauma
- Pediatric patients younger than 8 years. Children younger than 8 have a smaller cricothyroid membrane that generally cannot accept a larger bore tube, making needle cricothyrotomy the preferred procedure.

Skill Drill 6-8

Performing Needle Cricothyrotomy

1 Use BSI precautions (gloves and face shield).

2 Attach a 14- to 16-gauge IV catheter to a 10-mL syringe containing approximately 3 mL of sterile saline or water.

3 With the patient's head in a neutral position, palpate for and locate the thyroid cartilage,

cricothyroid membrane, and suprasternal notch.

4 Cleanse the area with an iodine-containing solution.

5 Attach the syringe (if preferred) to the needle. Stabilize the larynx and insert the needle into the cricothyroid membrane at a 45° angle toward the feet.

6 Push the needle until it "pops" into trachea. Aspirate with the syringe to determine correct catheter placement.

7 While holding the catheter, slide the catheter off of the needle until the hub of the catheter is flush with the patient's skin.

8 Place the syringe and needle in a puncture-proof container.

9 Connect one end of the oxygen tubing to the catheter and the other end to the jet ventilator.

10 Open the release valve on the jet ventilator and adjust the pressure accordingly to provide adequate chest rise.

11 Auscultate the apices and bases of both lungs and over the epigastrium to confirm correct catheter placement.

12 Secure the catheter with a 4″ × 4″ gauze pad and tape. Continue ventilations while frequently reassessing for adequate ventilations and any potential complications.

Figure 6-36 The Cook critical care Melker cricothyrotomy catheter kit.

Complications to surgical cricothyrotomy include: Hemorrhage

- Infection
- Misplacement of cannula/tube
- Accidental removal
- Subglottic stenosis
- Mediastinal emphysema
- Tracheal and esophageal laceration

There are several types of surgical cricothyrotomies. Open cricothyrotomy involves the incising of the patient's skin and cricothyroid membrane with a scalpel and placing an ET tube or tracheostomy tube. A modified cricothyrotomy is another type of cricothyrotomy. Several commercial modified cricothyrotomy kits are available, many of which use a modification of the **Seldinger technique** to enable placement of the airway. The Seldinger technique uses a needle and guide wire/guide catheter or tube placement in blood vessels or other hollow organs **Figure 6-36**. Other devices for performing cricothyrotomy, such as the Nu-Trake and Pertrach, are commercially manufactured airway placement devices that may be used in the prehospital environment. These devices do not use the Seldinger technique; they use a device that functions both as an introducer and an airway **Figure 6-37**.

Skill Drill 6-9 shows the steps for surgical cricothyrotomy, which are described as follows:

1. Use BSI precautions (gloves and face shield) **Step 1**.

2. Place the patient supine. Ventilate the patient.
3. Check, assemble, and prepare the equipment **Step 2**.
4. Approach the patient from the left side of the neck. With the patient's head in a neutral position, palpate for and locate the cricothyroid membrane **Step 3**.

Figure 6-37 **A.** Nu-Trake kit. **B.** Pertrach kit.

5. Cleanse the anterior part of the neck from the laryngeal prominence to just below the cricoid ring and position a fenestrated drape **Step 4**.
6. Palpate the cricothyroid membrane.
7. Stabilize the thyroid cartilage with your nondominant hand.
8. With a scalpel in your dominant hand, make a 1-to 2-cm vertical skin incision over the cricothyroid membrane **Step 5**.
9. Puncture the cricothyroid membrane and make a horizontal incision 1 cm in each direction from the midline (a shallow incision, so that the posterior tracheal wall is not injured) **Step 6**.
10. Place a curved hemostat through the incision *before* removing the scalpel. Open the hemostats, ensuring that the tips are well within the trachea **Step 7**.
11. Remove the scalpel.
12. With your free hand, insert the ET tube between the tips of the open hemostats, advancing the balloon about 1.0 to 1.5 cm below the lower margin of the incision **Step 8**.
13. Remove the hemostats.
14. Inflate the cuff on the tube with 8 to 10 mL of air and remove the syringe **Step 9**.
15. Attach an ETCO2 detector in between the tube and the bag-mask device **Step 10**.
16. Ventilate the patient and verify tube position by auscultating the chest bilaterally and over the epigastrium **Step 11**.
17. Secure the tube to the neck and reconfirm correct tube placement. Continue to ventilate **Step 12**.

Rapid Sequence Intubation

Rapid sequence intubation (RSI) involves the coadministration of both anesthetic agents and neuromuscular blocking agents to produce a state of unconsciousness and paralysis to allow tracheal intubation. Originally developed in 1946 to facilitate airway management in obstetric patients requiring intubation with a presumed full stomach, it was further refined in the 1960s with the development of the Sellick maneuver (cricoid pressure) to further reduce the risk of aspiration in patients requiring emergent intubation (although this has never been proven). The use of RSI, compared with blind nasotracheal intubation, facilitated intubation using sedation and topical anesthesia or just forcing the tube into place, has proven to have increased success rates and decreased associated complications. It has become the procedure of choice in the emergency department and trauma bay. Its use in the prehospital setting is relatively new. Initially limited to air medical providers, RSI is now being used by ground providers and is not without controversy.

The indications for performing RSI include many of the same indications for ET intubation with the exception of the patient in cardiac arrest who should not require the administration of medications to facilitate intubation. Remember, by administering sedatives and paralytics, you are taking away a patient's ability to protect his or her airway and breathe. You must be able to provide an airway and adequately ventilate and oxygenate your patient. RSI also assumes that patients have eaten prior to needing emergent intubation. By administering medications to sedate and paralyze a patient, the risk of regurgitation and aspiration is minimized, but not eliminated.

Skill Drill 6-9

Performing Surgical Cricothyrotomy

1 Use BSI precautions (gloves and face shield).

2 Check, assemble, and prepare the equipment.

3 Approach the patient from the left side of the neck. With the patient's head in a neutral position, palpate for and locate the cricothyroid membrane.

4 Cleanse the anterior part of the neck from the laryngeal prominence to just below the cricoid ring and position a fenestrated drape.

5 With a scalpel in your dominant hand, make a 1- to 2-cm vertical skin incision over the cricothyroid membrane.

6 Puncture the cricothyroid membrane and make a horizontal incision 1 cm in each direction from the midline (a shallow incision, so that the posterior tracheal wall is not injured).

7 Place a curved hemostat through the incision before removing the scalpel. Open the hemostats, ensuring that the tips are well within the trachea.

8 With your free hand, insert the ET tube between the tips of the open hemostats, advancing the balloon about 1.0 to 1.5 cm below the lower margin of the incision.

9 Inflate the cuff on the tube with 8 to 10 mL of air and remove the syringe.

10 Attach an $ETCO_2$ detector in between the tube and the bag-mask device.

11 Ventilate the patient and auscultate the chest bilaterally and over the epigastrium.

12 Secure the tube to the neck and reconfirm correct tube placement. Continue to ventilate.

The normal contraindications and complications for standard intubation apply for RSI. The most important contraindication is fear of the inability to intubate, and the most devastating complication is not being able to ventilate. This scenario will almost invariably result in a catastrophic patient outcome. The use of RSI requires careful patient selection (which can sometimes be difficult in the emergency and pre-hospital environment) and preparation.

Transport considerations for the patient undergoing RSI as well as any intubated patient are that capnography, preferably continous waveform, should be available, considered mandatory, and used throughout all phases of transportation of the patient.

Equipment for performing RSI includes:

- Gloves, gowns, mask, goggles
- Neuromuscular blocking agents
- Sedative agents
- Cardiac agents
- Syringes
- Needles
- Intubation equipment
- Suction
- Oxygen

RSI is a series of steps to facilitate ET intubation. It begins with preparation. All equipment necessary for intubation, rescue ventilation, and surgical airway must be available, checked, and working prior to use. The patient also requires at least one working IV access (preferably two because one may infiltrate, fall out, or be pulled out inadvertently) for the administration of the appropriate medications.

Special Populations

Children, obese patients, and pregnant patients desaturate much more rapidly.

The next step is preoxygenation. All patients undergoing RSI should be preoxygenated prior to beginning the procedure. In the patient who is spontaneously breathing with adequate tidal volumes, the application of high-flow oxygen via a nonrebreathing mask is sufficient. In the patient with apnea or hypoventilation, assistance with high-flow oxygen via a bag-mask device may be necessary. Bagging with RSI should be used only when indicated in order to avoid gastric insufflation and possible regurgitation.

Preoxygenation with high-flow oxygen saturates the air remaining in the lungs after normal expiration (functional residual capacity, approximately 30 mL/kg) with 100% oxygen. Many RSI protocols recommend administering high-flow oxygen for at least 5 minutes, if possible. This will allow for a prolonged period of apnea without significant desaturation in most patients. Children, obese patients, and pregnant patients desaturate much more rapidly.

The medications used in RSI fall under two broad categories: sedative or induction agents to induce unconsciousness and neuromuscular blocking agents to induce paralysis. The combination of both types of medications is essential to successful RSI and intubation. For both types of medications, the ideal agent would have a rapid onset, a short duration of action, a stable hemodynamic profile, and few if any adverse side effects. Unfortunately, agents that meet all of these requirements do not exist. Also, the use of these agents individually may result in adverse outcomes. The use of sedative/induction agents alone frequently does not result in successful intubation secondary to intact airway reflexes. The use of neuromuscular blocking agents alone may result in a paralyzed yet awake patient. The combination of both sedation/induction and neuromuscular blockade results in significantly greater intubation success with fewer complications.

Skill Drill 6-10 shows the steps for performing RSI, which are described as follows:

1. Prepare and assemble the equipment.
2. Preoxygenate with 100% oxygen **Step 1**.
3. Administer medications to premedicate, sedate, and paralyze the patient. When premedicating:
   - **a.** If your medical director or protocol recommends it, consider a defasciculating dose of a nondepolarizing neuromuscular blocking agent.
   - **b.** Consider lidocaine or opiates to decrease cardiovascular effects and elevations of intracranial pressure associated with upper airway stimulation.
   - **c.** Consider atropine to decrease bradycardia associated with the administration of succinylcholine.
4. When sedating the patient, use an agent that induces sedation and amnesia provided the patient is hemodynamically stable (systolic blood pressure >90 mm Hg).
5. Finally, paralyze the patient using an appropriate agent.
6. Apply posterior cricoid pressure **Step 2**.
7. Intubate the patient **Step 3**.
8. Confirm ET tube placement **Step 4**.
9. Release cricoid pressure.

10. Maintain paralysis and sedation.

Pharmacologic Agents Used in RSI

Sedative/Induction Agents

Table 6-4 lists sedative/induction agents that may be used in RSI, and their doses, onsets, durations, advantages, and disadvantages.

The induction agent chosen for use in RSI must be appropriate for the individual patient. The ultra-short acting barbiturates sodium thiopental and methohexital have a rapid onset of action and a short duration of action, which makes them ideal for use as induction agents, but requires a hemodynamically stable patient because use of these agents may precipitate myocardial depression and hypotension. The adverse hemodynamic profiles of these agents and the emergence of other, more hemodyamically stable agents has led to less use of sodium thiopental and methohexital in areas other than anesthesia. The benzodiazepines midazolam, lorazepam, and diazepam have a slightly longer onset of action and a significantly longer duration of action, which makes them less attractive as induction agents. They also have the ability to cause hypotension secondary to vasodilation. However, they are frequently used for sedation after intubation in the hemodynamically stable patient. Ketamine is an agent that has a stable hemodynamic profile and bronchodilatory properties that make it an attractive induction agent. The use of this agent, however, can increase intracranial pressure (ICP) and has been associated with adverse reactions. Propofol is an agent widely used by anesthesiologists. Its use as an induction agent in situations other than during surgery has been limited by associated vasodilation and hypotension. Many prehospital care providers have begun to use etomidate as the induction agent of choice because of its rapid onset of action, short duration of action, and stable hemodynamic profile.

Other potentially beneficial agents used in RSI are lidocaine and atropine. Lidocaine can be administered at 1.5 mg/kg 2 to 3 minutes prior to intubation. Lidocaine has been shown to have mixed results regarding its ability to blunt the sympathetic response to intubation but it has been shown to blunt the rise in ICP associated with suctioning and laryngeal stimulation; no studies have been performed regarding intubation. Atropine should be administered in select patients receiving succinylcholine. Heightened vagal stimulation in pediatric patients can result in significant bradycardia. Many professionals recommend administering atropine to all children younger than 1 year who will be receiving succinylcholine and to consider adminstration for children between 1 and 10 years old. Also, adult patients receiving a second dose of succinylcholine should receive a dose of atropine prior to receiving additional succinylcholine. Adult patients with a heart rate of less than 60 beats/min should receive atropine prior to receiving succinylcholine and performing laryngoscopy.

Skill Drill 6-10

Performing Rapid Sequence Intubation

1 Prepare and assemble the equipment. Preoxygenate the patient. Administer medications to premedicate, sedate, and paralyze the patient.

2 Apply posterior cricoid pressure.

3 Intubate the patient.

4 Confirm ET tube placement. Release cricoid pressure.

Special Populations

Heightened vagal stimulation in pediatric patients can result in significant bradycardia. It is a good idea to administer atropine to children younger than 1 year who will be receiving succinylcholine and to

have it available for children between 1 and 10 years old.

The dose of atropine for pediatric patients is 0.02 mg/kg IV. The minimum dose is 0.1 mg. The maximum dose is 0.5 to 1.0 mg total. The adult dose of atropine is 0.5 to 1.0 mg IV. Atropine should be administered approximately 1 to 2 minutes before administering succinylcholine and attempting intubation.

Neuromuscular Blocking Agents

There are two types of neuromuscular blocking agents, depolarizing and nondepolarizing. The depolarizing agents act by rapidly depolarizing the neuromuscular end plate causing resistance to further stimulation. The nondepolarizing agents block the binding of acetylcholine to its receptors in the neuromuscular end plate. Both result in paralysis. The only depolarizing neuromuscular blocking agent in use in the United States is succinylcholine. Succinylcholine has several important absolute contraindications for its use. It should not be used in patients who have burns older than 48 hours, crush injuries, stroke, or spinal cord injuries less than 6 months previously, or degenerative muscle diseases (ie, ALS, muscular dystrophy).

There are several nondepolarizing neuromuscular blocking agents utilized in RSI. They are vecuronium, pancuronium, rocuronium, and cisatracurium. These agents are primarily used in three ways as a part of the RSI sequence.

- They can be used as pretreatment agents to prevent the fasciculations encountered with succinylcholine. The defasciculating dose range is 10% to 20% of the intubating dose. The use of defasciculating doses is rare in the prehospital setting. For vecuronium and pancuronium, the range is 0.01 to 0.02 mg/kg; and for rocuronium, the dose is 0.06 mg/kg.

TABLE 6-4 Sedative/Induction Agents

Drug Category	Drug Name	Dose	Onset	Duration	Advantages	Disadvantages
Ultra-short acting barbiturates	Sodium thiopental (Penothal)	3-6 mg/kg	<30 s	5-10 min	Significant anticonvulsant properties, cerebro-protective, can reduce ICP.	Histamine release. A potent vasodilator and myocardial depressant.
	Methohexital (Brevital)	1-3 mg/kg	<30 s	5-10 min		
Benzodiazepines	Midazolam (Versed)	2-5 mg on induction, 5 mg PRN for sedation	30-60 s	15-30 min	Provide amnesia, hypnosis, sedation. Anticonvulsant properties.	Vasodilation, hypotension, myocardial depression.
	Lorazepam (Ativan)	0.03 to 0.06 mg/kg	1-2 min	1-2 hr		
	Diazepam (Valium)	0.3 to 0.6 mg/kg	45-60 s	15-30 min		
Anesthetic agents	Etomidate (Amidate)	0.2-0.6 mg/kg	15-45 s	3-12 min	Usual induction dose is 0.3 mg/kg. Preferred induction agent for RSI secondary to its rapid onset, short duration, and stable hemodynamic profile. Cerebroprotective, reducing cerebral blood flow and metabolism in the setting of elevated ICP.	Injection site pain secondary to the diluent (propylene glycol). Myoclonic movements that may mimic seizure activity. Not FDA approved for use in pediatric patients, although many published reports in pediatric patients report no adverse effects. Plasma cortisol suppression has also been reported with etomidate use in the ICU environment, long term. Short-term use in RSI has not shown cortisol suppression.
	Ketamine (Ketalar)	1-2 mg/kg	45-60 s	10-20 min	Phencyclidine derivative with analgesic, anesthetic, and amnestic properties. Also has a stable hemodynamic profile secondary to catecholamine release and stimulation of the sympathetic nervous system. Also a bronchodilator, making it an ideal induction agent in the setting of bronchospasm.	In the setting of elevated ICP, the use of ketamine may increase ICP further. Emergence reactions are also an occasional complication of ketamine administration. Reactions are rarely an issue when ketamine is used in the setting of RSI because the benzodiazepine used for post RSI sedation attenuates this response.
	Propofol (Diprivan)	1-2 mg/kg	15-45 s	5-10 min	Decreases cerebral oxygen demand and ICP.	Vasodilation and myocardial depression, that may result in hypotension and a subsequent reduction in CPP. Pain at injection site.
Opiates	Fentanyl (Sublimaze)	2-3 µg/kg	3-5 min	30-60 min	Attenuation of the sympathetic response to laryngoscopy.	Hypotension and apnea.

Abbreviations: CPP, cerebral perfusion pressure; FDA, Food and Drug Administration; ICP, intracranial pressure; ICU, intensive care unit; PRN, pro re nata (as needed); RSI, rapid sequence intubation.

- They can be used as the primary paralytic in the event of contraindications to succinylcholine (hyperkalemia).
- Most commonly, they are used to maintain postintubation paralysis.

Neuromuscular blocking agents are summarized in **Table 6-5**.

Tracheostomy Management

Patients receiving interfacility transport may already have a tracheostomy in place for a variety of reasons as follows:

- Facial trauma

- Significant tracheal trauma
- Head injury
- Most commonly, failure to wean/long-term ventilator support

Contraindications to a tracheostomy include coagulopathy, neck tumor, and infection; however, these are relative contraindications, because the alternative is death.

Complications of a tracheostomy include:

- Accidental removal, particularly a "fresh" or nonmature tracheostomy
- Infection
- Hemorrhage Aspiration
- Mediastinal emphysema
- Tracheoesophageal fistula
- Tracheal stenosis
- Tracheomalacia
- Tracheoarterial fistula (frequently from a "low-lying" tracheostomy that erodes into the innominate artery)

Tracheostomy placement does not occur in the field and is therefore usually not in the skill set of the pre-hospital provider. It takes longer to perform than other surgical airways and requires equipment not usually found in the prehospital environment. In general, patients with long-term tracheostomy devices can easily remove and replace them. Endotracheal tubes can be placed in a tracheotomy stoma if a device cannot be replaced or is malfunctioning. In a patient who needs positive-pressure ventilation, the cuff on a tracheostomy device should be inflated or replaced with a cuffed endotracheal tube if ventilation is inadequate.

Mechanical Ventilation

Mechanical ventilation refers to the application of a device that provides patients varying degrees of ventilatory support. These devices range from simple to complex, depending on the needs of the patient and the capabilities of the machine. At one time, the classification and description of ventilators were simple; however, with the increase in biotechnology, the classification of these devices has become more complicated. All ventilators, however, have several common characteristics.

1. Power source: All ventilators require an external power source. The source can be electric or pneumatic (requiring a 50-psi gas source).
2. Cycling: This refers to which variable terminates the inspiratory phase of a breath. Pressure, volume, time, and flow can terminate a breath, depending on the ventilator.
3. Breath delivery: The ventilator can deliver a breath using either negative pressure **Figure 6-38** or postive pressure **Figure 6-39.**
4. Parameters: **Mode,** tidal volume or inspiratory pressure, respiratory rate, flow or **I time**, FIO_2, and PEEP are selected by the clinician. Modes and parameters are discussed in detail later in this section.

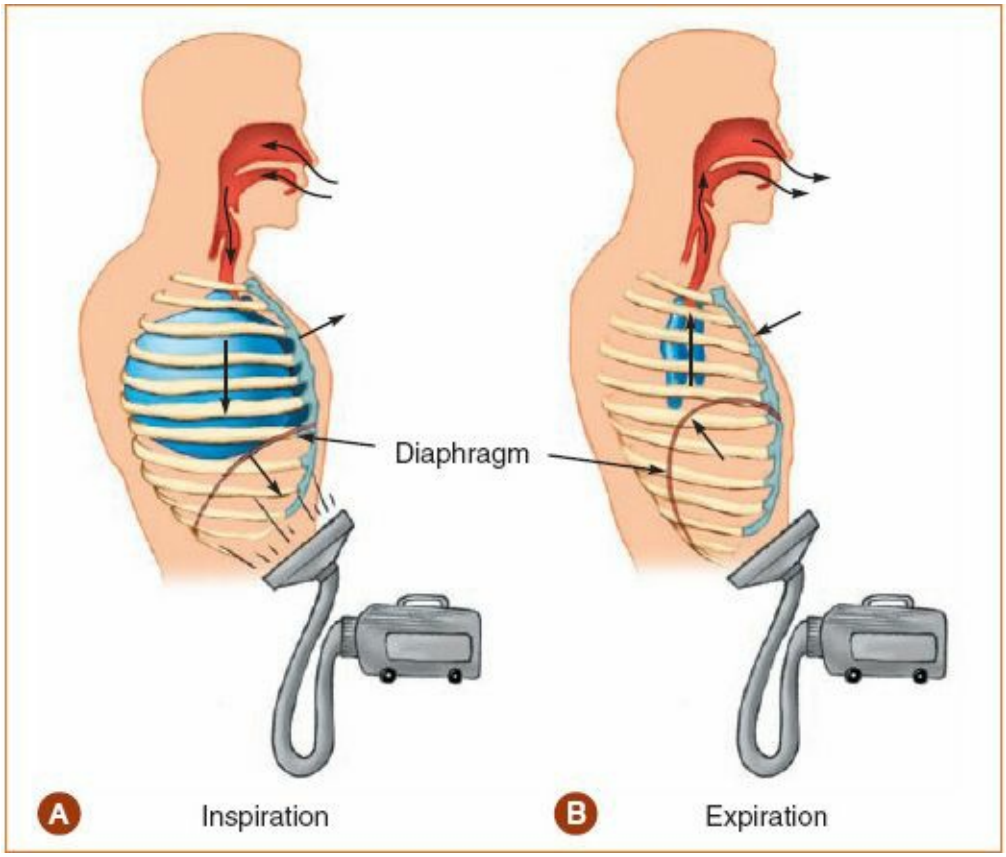


Figure 6-38 Normal ventilation is negative-pressure ventilation, which is similar to a vacuum cleaner. Negative pressure pulls down the diaphragm, causing the lungs to fill **(A).** When the pressure is released, the diaphragm relaxes and the lungs empty **(B).**

TABLE 6-5 Neuromuscular Blocking Agents

Drug Category	Drug Name	Dose	Onset	Duration	Advantages	Disadvantages
Depolarizing neuromuscular blocking agents	Succinylcholine (Anectine, Quelicin)	1-2 mg/kg	< 1 min	5 min	Rapid onset, short duration of action.	Fasciculations. Hyperkalemia. Increased intracrainal pressure, increased intraocular pressure, and increased intragastric pressure. It may cause or worsen bradycardia, particularly in pediatric patients. It has been implicated in malignant hyperthermia and may cause prolonged neuromuscular blockade.
Nondepolarizing neuromuscular blocking agents	Vecuronium (Norcuron)	For intubation: 0.15 mg/kg Postintubation paralysis: 0.01-0.1 mg/kg	90-120 sec	60-75 min	Longer duration means that effects are less likely to wear off during transport.	Possible prolonged paralysis with long-term use, renal or hepatic dysfunction. Possible prolonged paralysis with concurrent use of corticosteroids. No effect on level of consciousness, so they must be administered with adequate anesthesia, analgesia, or sedation. In patients with apnea, establish a patent airway prior to use.
	Rocuronium (Zemuron)	For intubation: 0.6 to 1.2 mg/kg Postintubation paralysis: 0.1-0.2 mg/kg	< 2 min	30-60 min		
	Pancuronium (Pavulon)	For intubation: 0.1 mg/kg Postintubation paralysis: 0.015-0.1 mg/kg	1-2 min	45-60 min		
	Cisatracurium (Nimbex)	For intubation: 0.15-0.2 mg/kg Postintubation paralysis: 0.03 mg/kg	2-3 min	30-40 min		

5. Ventilator circuit: An external circuit, which varies depending on the ventilator, used to connect the ventilator to the patient.
6. Alarms: Varying types of audio and/or visual alarms warn of ventilator malfunction or parameters outside set alarm limits. They should be set for each individual patient and *never* disabled.

Remember that not all ventilators have the same range of characteristics, capabilities, or features. All users need to be familiar with the capabilities of the devices, and no one should use any ventilator without being properly educated on its use and capabilities.

The indications for mechanical ventilation range from apnea, managing the work of breathing, and improving distribution of inhaled gases, to ventilatory and respiratory failure. Use of mechanical ventilation, while lifesaving, can have negative effects on several body systems:

1. Positive-pressure ventilation increases intrathoracic pressure, which can result in barotrauma (pneumothorax).
2. An increase in intrathoracic pressure can result in reduced venous return to the right side of the heart, which may result in poor cardiac output and hypotension.

3. Increased intrathoracic pressure may reduce blood flow to the liver and kidneys.
4. The diminished venous return to the right side of the heart, poor cardiac output, and possible hypotension along with reduced hepato/renal blood flow may fool the body into believing it is volume depleted, which results in various hormonal changes such as increased vasopressin and aldosterone activity and decreased levels of atrial natriuretic hormone. All of these changes result in fluid retention.

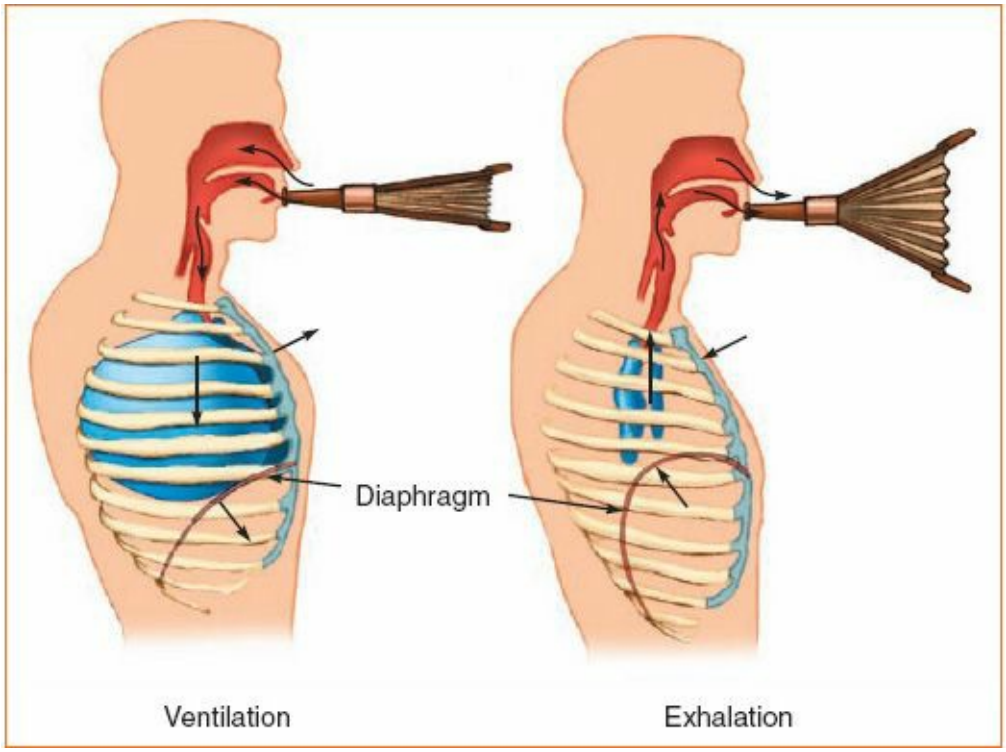

Figure 6-39 With positive-pressure ventilation, air is pushed into the respiratory tract with bag-mask ventilation. This is the opposite of negative-pressure ventilation.

Negative-Pressure Ventilators

During the polio epidemics of the 1950s, iron lungs were common **Figure 6-40**. Recall that in normal spontaneous breathing, a breath is initiated by a drop in the transrespiratory pressure gradient. **Negative-pressure ventilators** operate in the same way. A negative pressure is transmitted by the ventilator to the chest wall, therefore allowing inspiration to occur. The original iron lung is no longer used, but has been replaced by smaller and more convenient devices. The two most common devices are the cuirass, or "turtle shell," and the poncho type. The cuirass resembles a chest plate of armor and is strapped onto the chest. A hose is then connected to the ventilator that sucks on the chest during inspiration. The poncho requires a lightweight frame that is fitted onto the chest with a lightweight airtight jacket placed over the patient's frame. The ventilator hose is then attached to the jacket. Both require that a tight seal be maintained. These devices are not found in acute care facilities, but are used in rehabilitation and long-term care facilities as well as the home. The devices are used chiefly on patients with neuromuscular diseases who still have airway control.

Positive-Pressure Ventilators

Positive-pressure ventilators are more prevalent than negative-pressure ventilators. The tidal volume is delivered at pressures greater than ambient pressure and is therefore paradoxical to spontaneous breathing. There are potential hazards to this type of life support, however, such as pneumothorax, subcutaneous emphysema, and decreased cardiac output. Later on in the chapter, we will discuss

strategies that attempt to minimize these complications. Positive-pressure ventilators come in various sizes, power sources, and capabilities, and can be as small and portable as a laptop computer or as large as a desk. Each institution selects the type of ventilator based on its capabilities and patient needs, as well as cost and operation.

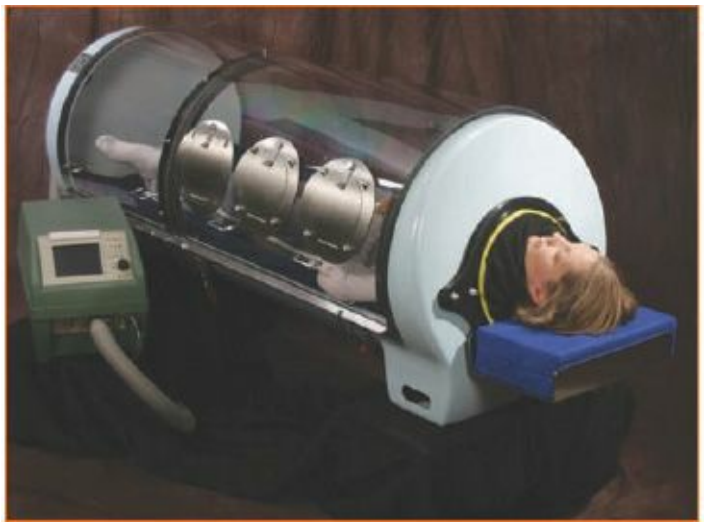

Figure 6-40 An iron lung.

Positive-pressure ventilators are commonly described by which variable terminates the inspiratory phase of the breath. **Pressure ventilators** end the delivery of the tidal volume based on a clinician-selected predetermined pressure. Therefore, the volume is variable. In **volume ventilators**, the breath ends when the predetermined tidal volume is achieved, and therefore the pressure is variable. **Flow-cycled ventilators** end inspiration when a predetermined **flow rate** is achieved, and **time-cycled ventilators** end inspiration after a selected inspiratory time has been achieved. Volume ventilators are the most common ventilator used. When you are using pressure ventilators, remember that the machine terminates inspiration when a preset pressure is achieved. Therefore, if the patient is biting down on the ET tube or is obstructed with mucus, the ventilator still delivers the pressure, but the tidal volume is significantly decreased. Increased airway resistance and decreased thoracic compliance also have the same effect. Careful monitoring of breath sounds, oxygen saturation, $ETCO_2$, visual inspection for adequate chest expansion, and monitoring delivered V_T are essential when pressure ventilation is being used.

Volume ventilators deliver a preset volume using varying pressures. The pressure required by the ventilator depends on the size of the tidal volume, flow rate, airway resistance, and lung–chest wall compliance. Because volume ventilators use varying pressures, it is important that you monitor the **peak airway pressure**. The high-pressure alarm alerts you that excessive pressures are being used to deliver the tidal volume. This alarm is set at approximately 10 cm H_2O greater than the patient's average peak pressure. Secretions, bronchospasm, and a decrease in thoracic/pulmonary compliance will result in increased airway pressures.

All ventilators, regardless of type, rely on an external circuit that connects the ventilator to the patient. Intrinsic to the circuit is some method for exhaled gas to be vented to the environment. On some ventilators, this is accomplished through the exhalation limb of the circuit that is connected to the ventilator. An internal exhalation valve then regulates exhalation as well as PEEP. Other ventilators use an external exhalation valve.

In either case, a closed system must exist between the ventilator and the patient. Any loose connections, cracks, or disconnections will result in ventilator malfunction and can be potentially life threatening. The integrity of patientventilator connection via the circuit should be visually inspected

throughout transport.

Invasive vs Noninvasive Ventilation

For years, conventional ventilation required **invasive ventilation** in the form of placement of an artificial airway, chiefly the ET tube. Because of the hazards and complications of ET tubes, other interfaces began to be used. Mouthpieces and masks of varying sizes and styles were attached to conventional ventilators, giving rise to "noninvasive" ventilation. By definition, **noninvasive ventilation** is any form of mechanical ventilation without an artificial airway. This now includes other devices such as CPAP and **bi-level positive airway pressure (BiPAP)**. The modalities use nasal or full-face masks to deliver a preset pressure to the lungs during spontaneous breathing. In CPAP, the prescribed pressure raises the breathing baseline above ambient pressure. The increased pressure across the entire breathing cycle increases the **mean airway pressure** and stents the airway. The increased mean pressure also increases the functional residual capacity (FRC) and decreases the effort that the patient has to exert to get a full breath, thus improving oxygenation.

BiPAP works similarly, but two separate pressures are used—inspiratory positive airway pressure (IPAP) and PEEP, also called expiratory positive airway pressure (EPAP). IPAP is always set higher than EPAP by at least 4 cm H_2O. BiPAP has the same benefits as CPAP. Additionally, the pressure gradient enhances ventilation. The reduced expiratory pressure makes exhalation easier and increases patient tolerance. Current EMS research indicates that CPAP use in the field is well tolerated and can significantly improve oxygenation and ventilation, potentially avoiding the need for intubation. Both are contra-indicated in patients who cannot protect their airways, have unstable facial fractures, or are uncooperative. Because they augment spontaneous breaths, neither is considered to be "life support" equipment.

Ventilator Modes and Parameters

Ventilator modes describe what types of breaths are delivered to the patient. This chiefly refers to whether the breath is a mandatory or machine breath or a spontaneous breath. The various modes of mechanical ventilation may ensure a particular minute ventilation and control the work of breathing. The result is an alphabet soup of acronyms that can be confusing to the novice ventilator user. Once again, not all ventilators have all the modes available. **Table 6-6** lists the most common modes of ventilation.

Ventilator parameters refer to the other settings that may be adjusted and should be monitored continuously by the clinician. Again, the availability of modes, alarms, and other parameters can vary from machine to machine. The clinician must be familiar with the ventilator being used. Ventilator parameters and alarms are listed in **Table 6-7**. This is not intended to be an all-inclusive list. Some ventilators have many more audio/visual alarms, and the CCTP must understand these prior to transport.

Note that expiratory time is not a set parameter. Expiratory time is a function of set respiratory rate and inspiratory time and is "left over" after inspiration is completed.

PEEP

PEEP, which is not a true mode, occurs at the end of a mandatory machine breath. Instead of exhaling back to ambient pressure, the ventilator is set to stop exhalation at a prescribed pressure. The result is an increase in the amount of air in the alveoli. This increases the FRC and improves oxygenation. PEEP also reduces the shunt fraction and increases lung compliance. Detrimental effects of PEEP include decreased venous return, a resultant decrease in cardiac output, increased ICP, decreased renal and portal blood flow, and increased risk of barotrauma. PEEP is contraindicated in patients with untreated pneumothorax

or bronchopleural fistula. PEEP values are usually determined by the ability to improve the Pa_{O_2} and decrease the F_{IO_2}. An important consideration during transport is to maintain PEEP levels even when using a manual resuscitator (bag-mask device). An external PEEP valve should be attached to the bag. The patient's hemodynamic status, as well as oxygenation, should be carefully monitored when applying and adjusting PEEP.

Special Populations

Pregnant patients at term increase their tidal volume by about 40% and they live in a compensated respiratory alkalosis. Keep this in mind when adjusting ventilator settings.

Nitric Oxide

Nitric oxide (NO, or nitrogen monoxide) has seen and will continue to see increased use during critical care transports. This increase is due in part to the introduction of portable NO administration units and expansion of the patient populations in which NO appears to be effective. Currently in the United States, the only Food and Drug Administration-approved use of NO is for treatment of refractory hypoxemic respiratory failure in term and near term newborns. In neonatal applications when NO is used, the response rate to NO exceeds 60%. Total costs of care are reduced, and the need for extracorporeal membrane oxygenation (ECMO) therapy has been reduced by up to 20%.

TABLE 6-6 Modes of Mechanical Ventilation

Mode	Definition	Indication
Control, or continuous, manual ventilation	Ventilator delivers a specific set respiratory rate and volume, controlled by the ventilator. The patient is not allowed any other breaths.	Used when a specific minute volume is required, such as with a head injury. Can also be used when a patient is fighting or "bucking" the ventilator. The respiratory center is controlled by using neuromuscular blockade and sedation.
Assist/control	The ventilator guarantees a minimum breath rate. The patient is allowed to breathe over the set rate, but each breath is at the preset tidal volume. Necessitates the proper setting of the **sensitivity** (ventilator control that regulates the amount of negative pressure required by the patient to initiate or "trigger" a breath).	Controls the work of breathing, but allows the patient to set his or her own respiratory rate.
Synchronized intermittent mandatory	A set respiratory rate and tidal volume are delivered and synchronized with each patient-initiated breath. Each patient breath is at the patient-initiated volume. The machine will deliver a certain	Allows the patient to assume some or most of the work of breathing, depending upon the mandatory

ventilation	number of mandatory breaths. All other breaths are spontaneous breaths at the patient's own rate and depth.	rate. Can also be used as a weaning technique.
PCV	The machine is set to deliver a preset pressure rather than volume. PIP is set and flow is delivered until the set PIP is reached. Tidal volume may vary significantly with changes in patient pulmonary status.	Used when volume ventilation requires too much pressure, such as in acute respiratory distress syndrome. Commonly used in conjunction with inverse ratio ventilation (see below). One of the lung protective strategies.
Pressure-regulated volume control ventilation	The machine will deliver the desired tidal volume at the least amount of pressure.	Used when both pressure and volume regulation are needed.
Inverse ratio ventilation	The ventilator is set so that the inspiratory phase is longer than the expiratory phase.	Used to increase oxygenation when the F_{IO_2} is too high (> 0.60). Must ensure that all volume is exhaled to prevent breath stacking and hyperinflation. Often used with PCV.
Pressure support	A clinician-selected amount of positive pressure augments a spontaneous breath.	Used to augment a spontaneous breath. The pressure overcomes the superimposed resistance of the airway and ventilator circuit and improves lung compliance.
CPAP	The baseline pressure for spontaneous breathing is raised above ambient, increasing oxygenation and mean airway pressure.	Improves oxygenation during spontaneous breathing.
Bi-level positive airway pressure	CPAP with the ability to sense inspiration and deliver additional positive pressure.	Improves oxygenation and ventilation with spontaneous breathing.
PEEP	The ventilator is set to stop exhalation at a prescribed pressure.	Measured in centimeters of water. Some practitioners use 5 cm of PEEP for every patient, a kind of "physiologic PEEP." PEEP is used to increase the functional residual capacity or the amount of air remaining in the lungs at the end of expiration. Increased PEEP helps keep the alveoli open and improves gas (oxygen) exchange. It is frequently titrated upward in response to hypoxemia in an effort to improve oxygenation and lower high F_{IO_2} levels.

Abbreviations: CPAP, continuous positive airway pressure; FIO_2, fraction of inspired oxygen; PCV, pressure control ventilation; PEEP, positive end-expiratory pressure; PIP, peak inspiratory pressure.

TABLE 6-7 Ventilator Parameters

Parameter	Definition	Setting Range
Tidal volume	Amount of air delivered with each machine breath	Approximately 10 mL/kg of ideal weight; 5–7 mL/kg if poor lung compliance (for example, from acute lung injury or restrictive or obstructive disease) is present. Smaller volumes may be used to prevent alveolar overdistention.
Respiratory rate	Number of breaths delivered in a minute	10–14 based on desired mandatory minute ventilation.
Fraction of inspired oxygen	Percentage of inhaled oxygen expressed as a decimal	0.21–1.0. Titrated to achieve adequate oxygenation (oxygen saturation, 0.90%). For initial management an FIO_2 of 1.0 (100%) is used and then titrated downward in an attempt to maintain adequate arterial saturation at the lowest FIO_2 possible (50% or less) to avoid oxygen toxicity.
Peak flow	Speed at which the tidal volume is delivered	Can vary greatly between 35 and 100 L/min.
Inspiratory time	The time set to deliver the desired flow or tidal volume	Can vary between 0.5 and 1.5 sec.
Peak inspiratory pressure	The peak pressure generated during ventilation. May vary with volume ventilation.	Set parameter with pressure ventilation. Should be maintained at the lowest value possible to minimize barotrauma/volutrauma (trauma from excessive lung inflation volumes).
Inspiratory plateau pressure	The pressure applied in volume ventilation to the small airways and alveoli. This is measured by applying an inspiratory pause.	Plateau pressure should be maintained at less than 30 cm H_2O to minimize volutrauma.
Low-pressure alarm	Alerts clinicians to a leak in the system or a patient disconnect	Set 5–10 cm H_2O lower than the average cycling (peak) pressure.
High-pressure alarm	Alerts clinician that the ventilator is using high pressures to deliver the tidal volume	Set 10 cm H_2O higher than the peak inspiratory pressure.
Power		

failure/low battery/low pressure source alarm	Alerts clinician to ventilator failure due to a loss of power	Varies from ventilator to ventilator.

Research is ongoing, and many institutions have standing agreements with their Institutional Review Boards to allow compassionate use of NO in adults with refractory hypoxemia from a wide range of clinical syndromes. Note that NO is not the same as nitrous oxide.

NO is a gas that increases blood flow by promoting vasodilatation. This mechanism occurs via the endothelial blood vessel linings, which receive the signal from NO for smooth muscle to relax. NO also discourages smooth muscle contraction of the blood vessels. Therefore, when hypoxia results from pulmonary vascular vasoconstriction, NO can significantly improve flow and oxygenation. However, an overabundance of NO can contribute to reperfusion injury, for example if an excess is produced after an ischemic injury.

NO is presently patented and available from a single manufacturer under a business model that charges for gas usage and controls administration devices, gas supply, and disposables used to deliver the gas to ventilator circuits. NO gas is bled into the inspiratory limb of a ventilator circuit at a dilution measured in parts per million. Published studies list effective doses at 0.25 to 80 ppm, although ranges vary by institutional policy and practice. Effects of NO vary and are patient specific.

Parameters for titration of NO need to be defined prior to initiating therapy. Patient assessment modalities vary considerably by institution. Typical measurements that suggest a favorable response to NO include a 20% improvement in oxygenation and/or a 30% decline in pulmonary vascular resistance. In the absence of invasive monitoring capability, improvements in oxygenation, hemodynamic stability, and less frequent desaturations have been used to gauge effectiveness (or lack thereof).

Abrupt discontinuation of NO has been associated with a rebound phenomenon with significant desaturations and hemodynamic instability. CCTPs should be certain to calculate gas volumes and battery lifespan and to ensure that needed equipment will be available to continue NO administration throughout a transport.

NO gas readily reacts with other gases, including oxygen and water vapor found in ventilator circuit tubing. Highly corrosive nitrogen dioxide (NO_2) results from this oxidative process and poses significant risk of acute lung tissue injury with resultant pulmonary edema. NO_2 concentrations are monitored by the commercially available administration device—elevated levels can be remedied by purging the NO gas system or lowering the NO bleed. Health care worker occupational exposure to NO and NO_2 is a theoretical risk of treatment but has yet to be demonstrated in published research.

Methemoglobinemia is another potential complication of NO therapy caused by oxidation of hemoglobin to methemoglobin, a dyshemoglobin that cannot carry oxygen. Monitoring methemoglobin levels at least daily is important to prevent inducing an iatrogenic hypoxia. Pulse carbon monoxide oximeters capable of measuring methemoglobin are helpful for spot assessment or continual monitoring of methemoglobin levels.

NO can be a valuable adjunct for critical care transport of extremely hypoxic patients, to optimize conventional therapies, to continue care started prior to transfer, or as a bridge to more advanced therapies such as ECMO or high-frequency jet ventilation. The greatest dangers during transport are iatrogenic overdoses of NO with resultant acute lung injury and pulmonary edema and/or methemoglobinemia. Abrupt discontinuation of NO therapy due to gas loss or equipment malfunction can result in catastrophic rebound effects. Use of NO during transport requires the CCTP be thoroughly

familiar with NO equipment operation, troubleshooting, and emergency procedures in case of failure.

Ventilator Management

There may be instances when you will use a portable ventilator during patient transport. Indications for using a portable ventilator include:

- Impending or actual respiratory failure
- Inadequate respiratory drive or apnea
- Inadequate gas exchange
- Decrease work of breathing and oxygen cost

Complications of using a portable ventilator include:

- Mechanical failure
- Patient anxiety
- Improper settings
- Increased intrapulmonary pressure
- Cardiovascular compromise
- Gastrointestinal disturbances
- Infection
- Impaired clearance and drying of secretions

Skill Drill 6-11 shows the steps for using a portable ventilator, which are described as follows:

1. Initiate power
2. Attach the ventilator circuit **Step 2**.
3. Adjust continuous flow **Step 3**.
4. Select the ventilator rate, inspiratory rate, flow rate, and oxygen concentrations **Step 4**.
5. Make mode selections: CPAP and PEEP, intermittent mandatory ventilation (IMV)/synchronized IMV (SIMV), assist control **Step 5**.

During transport of the critically ill patient receiving mechanical ventilation, only necessary adjustments to the ventilator should be made. These adjustments usually include maintaining adequate oxygenation and minute ventilation. If mechanical ventilation is instituted, it is recommended that the guidelines listed below be followed after securing a patent airway. In most cases, the CCTP will use the settings already in place. The guidelines should be used by the CCTP who is intubating and establishing the patient on the ventilator. Keep in mind that any occult pneumothorax or pneumome-diastinum may worsen with the initiation of positive-pressure ventilation.

1. Start with an F_{IO_2} of 1.0 and titrate down if possible to maintain an Sp_{O_2} of 92% to 94%.
2. To manage the work of breathing, use the assist/control mode. If the patient is paralyzed and sedated, there is NO difference between assist control (AC) and SIMV.
3. Tidal volumes can be set at approximately 7 to 10 mL/kg of ideal body weight.
4. Set the respiratory rate between 10 and 12 breaths/min.

5. Adjust the peak flow rate or inspiratory time to accommodate the patient's inspiratory flow demand and to allow for sufficient expiratory time and avoidance of **auto-PEEP**.
6. Adjust the sensitivity to –1 cm H_2O.

It is the responsibility of the transport team to ensure that ventilator function and the patient's ventilatory status are maintained during the transport. This can be accomplished by:

- Maintaining a stable and patent airway.
- Verifying and documenting the ventilator settings before, during, and after arrival.
- Ensuring proper power supply and oxygen during the transport.
- Assessing and documenting breath sounds before, during (if possible), and after transport.
- Continuously monitoring pulse oximetry (SpO_2) and $ETCO_2$.
- Having a manual resuscitator (bag-mask device) available if there is any doubt about the functioning of the ventilator.

Skill Drill 6-11

Using a Portable Ventilator

1 Initiate power.

2 Attach ventilator circuit.

3 Adjust continuous flow.

4 Select the ventilator rate, inspiratory rate, flow rate, and oxygen concentrations.

5 Make mode selections: CPAP and PEEP, IMV/SIMV, assist control.

Flight Considerations

When you are using a portable ventilator in the air medical setting, pneumatic-controlled ventilators are not accurate in-flight—electronic-controlled ventilators should be used for air transport. Watch for signs/symptoms of pneumothorax. In interfacility patients with significant respiratory compromise, a trial of 15 to 30 minutes on the transport ventilator prior to departure may be warranted to ensure that the ventilator changes will be tolerated.

Troubleshooting

Troubleshooting ventilator function is not as difficult as it seems. First, it is imperative that a manual resuscitator accompanies every patient on a ventilator. When in doubt of ventilator function, the

resuscitator must be used to ensure the safety of the patient. A good rule of thumb in troubleshooting equipment is to start at the patient and work your way, methodically, toward the equipment/wall.

Although alarms vary from ventilator to ventilator, the more common alarms are:

1. **Low battery/power source**: This alarm sounds when the electrical supply to the ventilator is inadequate or the gas inlet pressure is low. It is corrected by restoring the proper power source.
2. **Low-pressure alarm**: Usually for a leak or disconnect, this alarm may also sound if the cuff on the ET tube or tracheostomy tube is leaking or deflated, resulting in a significant air leak.
3. **High-pressure alarm**: The high-pressure alarm sounds when the ventilator uses too much pressure to deliver the tidal volume. It can be caused by many factors, such as bronchospasm, secretions, kinks in the external circuit or airway, biting on the ET tube, coughing, gagging, breathing asynchronously or "bucking" the ventilator, alveolar overdistention, and improper flow rates and/or I:E ratio. Migration of the ET tube to the esophagus and pneumothorax is the more serious cause. Assess the patient carefully and implement the appropriate intervention.

Skill Drill 6-12

Troubleshooting a Ventilator Low-Pressure Alarm

1 Quickly inspect the ventilator-patient interface for a disconnection. Tighten all connections.

2 If the alarm is still sounding, disconnect the ventilator and bag the patient.

3 Place a gloved finger over the patient ventilator connector and observe the next ventilator breath cycle.

If the manometer attempts to rise and the high-pressure alarm sounds, the ventilator circuit is intact and the leak is with the patient.

Skill Drill 6-12 If the low-pressure alarm sounds, follow the steps as described here:

1. Quickly inspect the ventilator-patient interface for a disconnection. Tighten all connections **Step 1**.
2. If the alarm is still sounding, disconnect the ventilator and bag the patient **Step 2**.
3. Place a gloved finger over the patient ventilator connector and observe the next ventilator breath cycle **Step 3**.
4. If the manometer attempts to rise and the high-pressure alarm sounds, the ventilator circuit is intact and the leak is with the patient.

Summary

Assessing the respiratory system of a critical care transport patient involves a thorough physical assessment as well as a review of the patient history and patient care chart. A thorough report by transferring personnel will help establish the clinical picture.

Establishing a baseline assessment and the ability to differentiate normal and abnormal findings in the respiratory system are paramount to comprehensive respiratory care during transport. Essential skills include auscultating breath sounds, evaluating oxygenation and ventilatory adequacy, and setting up and troubleshooting the ventilator.

Concepts such as tidal volume, minute volume, and anatomic dead space are crucial to understanding respiratory function. Additional devices and laboratory studies are also helpful in monitoring the patient's condition. ABGs, if available, reveal the acid-base balance and blood levels of oxygen and CO_2. Pulse oximetry, capnometry, and ETCO2 detection offer a continuous, noninvasive means of measuring these gases during transport.

Transport of the critically ill patient who is receiving ventilation must be planned to ensure patient safety. First, be familiar with the capabilities of the ventilator but always have a manual resuscitator on hand. Prepare for the transport by having an adequate power supply. Second, know why the patient is being vented and what the settings are prior to transport. Obtain a baseline assessment parameter for the patient and the ventilator before beginning the transport. Continue to monitor ventilator performance and patient response during the transport. Last, ensure the same upon arrival. Verify and document airway patency, respiratory assessment, and parameters at the time of transfer. By observing these guidelines, the transport should be a safe one for you and your patient.

Case Study

YOUR TEAM IS DISPATCHED TO A RURAL HOSPITAL 75 MILES AWAY for a 23-year-old, 70-kg woman in status asthmaticus. She was brought to the emergency department 2 hours ago by local EMS for difficulty breathing. She presented to the emergency department in acute respiratory distress, with audible

inspiratory and expiratory wheezes, intercostal and supraclavicular retractions, and tripod positioning. Her initial vital signs included the following: respiratory rate, 32 breaths/min and labored; heart rate, 126 beats/min; blood pressure, 126/84 mm Hg; and Spo_2, 92% on an 8-L nebulizer.

Brush fires in the area have placed the county under an air quality warning. The patient's attack occurred after she had taken her dog for a walk. The patient's medical history includes asthma, which is controlled with daily use of an Advair inhaler. She has been hospitalized three times prior to this episode. One admission resulted in an intensive care stay for respiratory failure requiring intubation.

A radiograph of the patient's lungs taken upon arrival at the emergency department demonstrated hyperinflation. The initial ABG reading while the patient was receiving a nebulizer treatment using 8 L of oxygen was pH 7.52, $PaCO_2$ 27 mm Hg, and PaO_2 88 mm Hg. A subsequent ABG reading 45 minutes later with the patient on a non-rebreathing mask at 15 L/min was pH 7.46, $PaCO_2$ 33 mm Hg, and PaO_2 79 mm Hg. All other chemistry and blood values were within normal limits.

You and your team arrive at the emergency department 4 hours after the patient's arrival. While your partner obtains her paperwork and speaks with the nurse caring for her, you assess the patient. You observe a young woman who is minimally responsive to verbal stimuli. She exhibits poor air exchange by shallow respirations accompanied by severe intercostal and supraclavicular retractions and minimal air exchange upon auscultation. Current vital signs include the following: pulse rate, 87 beats/min; respiratory rate, 18 breaths/min, labored and shallow; blood pressure, 112/78 mm Hg; Spo_2, 86% on a nonrebreathing mask with oxygen administered at 15 L/min. As you are completing your assessment of the patient, the nurse brings you the most recent ABG results drawn with the patient on the nonrebreathing mask showing pH 7.25, PCO_2 62 mm Hg, and PaO_2 65 mm Hg.

1. Does this patient meet the criteria for intubation?
2. Which factors should be considered when assessing the patient for a difficult airway?
3. Which medications are used during rapid sequence intubation?

Per protocol, you and your partner prepare for rapid sequence intubation. Using the LEMON rule, you determine that the patient should not be a difficult intubation. While your partner provides oxygen to the patient using a bag-mask device attached to 100% oxygen, you prepare the following medications for administration: lidocaine, 70 mg; etomidate, 21 mg for sedation; vecuronium, 0.7 mg as a defasciculating agent prior to paralyzing; and succinylcholine, 140 mg for paralysis. Your partner administers the lidocaine, etomidate, and succinylcholine while you are ventilating the patient and waiting for muscle relaxation. After 90 seconds you notice that the patient still doesn't feel completely relaxed and presents with an intact gag reflex. You follow your protocol and administer a second dose of succinylcholine through another IV line. You are able to intubate the patient without difficulty and confirm tube placement by auscultation, visualization, and use of capnography. The patient is placed on the transport ventilator and prepared for the trip back to your facility. Prior to leaving the hospital you administer an additional 7 mg of vecuronium and 3.5 mg of lorazepam (Ativan) for continued paralysis and sedation during transport. Additional treatment includes a continuous albuterol nebulizer at 10 mg/h, 125 mg of Solu-Medrol IV, and a normal saline drip at 150 mL/h.

Once you have the patient loaded in the back of your helicopter you notice that the patient's end-tidal CO_2 is rising and her oxygen saturation is dropping. Reassessment of the endotracheal tube indicates that the tube has become dislodged and is now ventilating the stomach. You and partner decide to pull the tube and reattempt intubation. After two unsuccessful attempts, you give your partner a chance; your partner is unable to visualize the vocal cords. Your King Airway is retrieved and inserted without difficulty. After confirming placement of the King Airway, you secure the tube with a commercial tube holder, place your

patient back on the ventilator, and continue your transport. You arrive at the receiving hospital approximately 90 minutes later following an uncomplicated trip. A detailed patient report is given to the awaiting staff upon your arrival, which includes a list of all the medications given along with the reason for the insertion of the King Airway.

4. Was it an acceptable practice to administer a second dose of succinylcholine and what are some possible causes for having to repeat the dose?
5. What is a King Airway and why was it able to be inserted without difficulty when the ET tube was not?

Analysis

This patient is a candidate for ET intubation due to her decreased mental status and respiratory failure, as shown by ineffective respirations, minimal air movement, and ABG results. Initially, the patient arrived at the emergency department awake and alert in respiratory distress. The first ABG results showed respiratory alkalosis, a common finding in early stages of an acute asthma attack. The second blood gas analysis came back with close to normal values with the exception of oxygenation. This finding should be a warning sign and should prompt you to reassess the patient to determine whether the condition is improving or the patient is getting tired and bears close watching. Don't let the numbers trick you!

Patient history and assessment play an important role in the preparation of intubation. Questions that can be answered by a review of patient history include the presence of congenital anomalies, recent surgery, trauma, infection, or cancer. Pertinent assessment findings include patients with short necks or those who are obese and patients with dental abnormalities such as an overbite. There are two assessment tools that can be used to guide your decision: the Mallampati method and the 3-3-2 rule.

The Mallampati method ranks the difficulty of intubation (class I is the easiest and class IV is the most difficult) based on how much of the oropharyngeal structures can be visualized in a patient who is seated in an upright position with a fully open mouth. A class I airway is one in which all oropharyngeal structures can be visualized. With a class II airway, the glottis is only partially visible. With a class III airway, the glottis cannot be exposed, but the corniculate cartilages can be seen. Finally, the class IV airway prevents the visualization of any oropharyngeal structures.

The 3-3-2 rule refers to three easy anatomic methods. For the first "3," have the patient open his or her mouth as wide as possible. This opening should allow for a minimum of three finger widths (approximately 5 cm). An opening of less than three finger widths may be an indicator of a difficult airway. The second "3" is a measurement of the length of the mandible. This is measured from the tip of the chin to the hyoid bone. Again, an optimal measurement is one that is the width of at least three fingers. The final measurement, "2," refers to the distance from the hyoid bone to the thyroid notch. An ideal airway would have a distance of at least two finger widths.

Medications administered during rapid sequence intubation are given to premedicate, sedate, and paralyze the patient. Medications given to premedicate the patient include a smaller dose (also known as a defasciculating dose) of a nondepolarizing neuromuscular blocking agent, such as vecuronium (Norcuron); lidocaine, to minimize cardiovascular complications and prevent a rise in intracranial pressure during intubation; atropine, to decrease the bradycardic effects associated with succinylcholine; and a sedative, or induction agent (for example, etomidate [Amidate]) to provide sedation and amnesia.

Succinycholine can be repeated if needed using the same dosing regimen. The most likely reason that the succinylcholine didn't work is due to an infiltrated intravenous line. However, because succinylcholine is temperature sensitive, that particular vial of medication might have been exposed to extreme temperatures for a prolonged period of time, thus contributing to the ineffectiveness of the medication.

The King Airway is a supraglottic airway device that doesn't require the direct visualization of the vocal cords to be inserted. The device is actually inserted into the esophagus, after which a distal and proximal balloon is inflated and the patient's lungs are ventilated through fenestrations located between the two balloons. Even though this is a supraglottic device, the patient can be mechanically ventilated without difficulty.

Prep Kit

Ready for Review

- The goal of the CCTP is to ensure the adequacy of ventilation and oxygenation of the critically ill patient during transport. The CCTP must have a good understanding of respiratory function and assessment.
- An understanding of airway anatomy and physiology, including the structures of the nose, mouth, pharynx, larynx, and trachea, is essential to successful airway management.
- The airway anatomy of pediatric patients is different from an adult's. The small size of the cricothyroid membrane in children younger than 4 years may make needle and surgical cricothyrotomy difficult or impossible. Children also have significantly higher oxygen consumption rates than adults.
- The respiratory system is divided into the conducting zone and the respiratory zone, with the conducting zone further divided into the upper airway and lower airway. An adult lung contains approximately 300 million alveoli, each one in contact with a pulmonary capillary, and the interface is called the alveolar capillary (AC) membrane.
- The pulmonary circulatory system is a low-pressure system, and for gas exchange to occur, blood flow must be in contact with the alveoli.
- Gas exchange occurs as a result of pressure gradient changes across the AC membrane, and with diffusion, the molecules of oxygen move from the alveoli into the blood because there are fewer oxygen molecules in the blood, and the molecules of CO_2 diffuse from the blood into the alveoli because there are fewer CO_2 molecules in the alveoli.
- $\dot{V}/\dot{Q}$ mismatch factors, due to inadequate ventilation, perfusion, or both, can affect the diffusion of gases across the membrane. The mechanics and dynamics of breathing use the concepts of elastance, compliance, resistance, and pressure gradients.
- The total lung capacity of a normal male adult is between 5 and 6 L of gas, which can be further divided into different lung volumes and capacities.
- Diseases that result in difficulty moving air out of the lungs are classified as obstructive diseases, including asthma, COPD, cystic fibrosis, and bronchioectasis, and involve an increase in airway resistance.
- Diseases that result in difficulty moving air into the lungs are defined as restrictive diseases, are the result of loss of chest or lung compliance, either individually or together, and include occupational lung diseases (the pneumoconioses) and idiopathic pulmonary fibrosis, pneumonia, atelectasis, chest wall deformities and injuries, and all the neuromuscular diseases that affect breathing.
- Patient assessment includes visually inspecting the patient with a focus on the chest, using auscultation sites to check breath sounds, assessing respiratory patterns and breathing rate, and using palpation to check the status of the lungs, skin, subcutaneous tissues, and chest expansion. Prior to transport, the

CCTP needs to review the patient care report carefully, noting any medications, underlying disease, or trauma that might compromise ventilation.

- The functioning of the respiratory system is measured using ABG levels, in which blood is obtained from a superficial artery and then analyzed for pH, $Paco_2$ (partial pressure of CO_2 in arterial blood), Pao_2 (partial pressure of oxygen in arterial blood), Hco_3^- (concentration of bicarbonate ion), base excess, and Spo_2 (oxygen saturation of the hemoglobin molecule).
- Respiratory insufficiency is the inability of the respiratory system to keep up with the metabolic demands of the body. Respiratory insufficiency can lead to respiratory depression. Respiratory failure, either oxygenation failure or ventilatory failure, occurs when the respiratory system fails to meet the body's metabolic needs.
- Basic airway skills are the starting point in the initial assessment and treatment of the patient by the CCTP and include positioning the nontrauma victim in the recovery position, using the head tilt–chin lift or the jaw-thrust maneuver or using airway adjuncts such as the OPA or NPA.
- Both the OPA and the NPA are used along with manual airway maneuvers to provide a patent airway.
- Suctioning to remove debris (vomit and blood) and turning the patient to his or her side while using a large-bore suction device can restore airway patency and minimize the potential for aspiration.
- Patients should receive some form of supplemental oxygen based on provider assessment, regardless of documented Spo_2.
- Oxygen delivery may take many forms, including mouth-to-mouth ventilation, barrier device/resuscitation mask, and bag-mask ventilation.
- Definitive airway management is considered to be the placement of an ET tube or tracheostomy tube within the trachea.
- In anticipation of a difficult airway, several factors need to be considered, including patient history and patient assessment. Also, the 3-3-2 rule should be used.
- Advantages of using the LMA are ease of insertion and superior oxygenation and ventilation compared with bag-mask ventilation. Disadvantages for using the LMA are the risk of aspiration and difficulty with obtaining an adequate seal. Use the LMA if the patient is in a deep coma or cardiac or respiratory arrest, or if ET intubation is not possible. LMA is contraindicated for use on patients with a gag reflex or facial or esophageal trauma, or if an airway obstruction by a foreign body is suspected.
- The Combitube, a dual-lumen, dual-cuffed supraglottic airway, may be placed blindly, and once proper placement is verified, the patient must be kept sedated and paralyzed. Use the Combitube when ET intubation is not possible or if intubation as an attempted rescue airway has failed or the patient is in a deep coma or cardiac or respiratory arrest, or to reduce the risk of gastric distention. Combitube contraindications include patients with a gag reflex, an upper airway obstruction or suspected foreign body obstruction, facial or esophageal trauma, known esophageal disease, or possible caustic ingestion. Children younger than 16 years or patients shorter than 4′ should not be intubated with a Combitube.
- When a patient cannot be intubated or ventilated, placement of a surgical airway via needle cricothyrotomy, surgical cricothyrotomy (either open or modified), or RSI is required, which involves the coadministration of both anesthetic agents and neuromuscular blocking agents to produce a state of unconsciousness and paralysis that allow tracheal intubation.
- Some pharmacologic agents used in RSI are sedative/induction agents that include short-acting barbiturates such as sodium thiopental, benzodiazepines such as lorazepam and diazepam, anesthetic

agents such as etomidate and ketamine, opiates such as fentanyl, and lidocaine and atropine.

- Other pharmacologic agents used in RSI are neuromuscular blocking agents, which are either depolarizing or nondepolarizing. Succinylcholine is the only depolarizing neuromuscular blocking agent used in the United States, but there are several nondepolarizing neuromuscular blocking agents used, including vecuronium, pancuronium, rocuronium, and cisatracurium, and they are primarily used either as pretreatment agents, as the primary paralytic, or more commonly, to maintain post-intubation paralysis.
- Mechanical ventilation is the use of a machine that provides ventilatory support, ranging from simple to complex and of varying degree, depending on the capabilities of the machine.
- All ventilators have several common characteristics, including power source, cycling, breath delivery, parameters, circuitry and interface, and alarms, but not all ventilators have the same availability of all these parameters, nor do all ventilators have the same range of features.
- The indications for the need for mechanical ventilation range from apnea, managing the work of breathing, improving distribution of inhaled gases, to ventilatory and respiratory failure.
- In normal spontaneous breathing, a breath is initiated by a drop in the transrespiratory pressure gradient. Negative-pressure ventilators work in this manner by transmitting a negative pressure from the ventilator to the chest wall, thereby allowing inspiration to occur. Negative-pressure ventilators are used mainly on patients in rehabilitation or long-term care facilities or in the home.
- Positive-pressure ventilators use positive-pressure ventilation, in which air is pushed into the respiratory tract. Positive-pressure ventilators are often described by which variable terminates the inspiratory phase of the breath, such as pressure ventilators, volume ventilators, flow-cycled ventilators, and time-cycled ventilators, with volume ventilators being the most common.
- Conventional ventilation requires invasive ventilation in the form of placement of an artificial airway, chiefly the ET tube. Noninvasive ventilation is any form of mechanical ventilation without an artificial airway, but includes other devices such as CPAP and BiPAP, which use nasal or full-face masks to deliver a certain pressure to the lungs during spontaneous breathing.
- Both CPAP and BiPAP are contraindicated in patients who cannot protect their airways, have unstable facial fractures, or are uncooperative.
- Ventilator modes describe the type of breath delivered to the patient (ie, whether the breath is a mandatory machine breath or a spontaneous breath), may ensure a particular minute ventilation, and control the work of breathing.
- PEEP, not a true ventilator mode, occurs at the end of a mandatory machine breath, and instead of exhaling back to ambient pressure, the ventilator is set to stop the exhalation at a prescribed pressure, which results in an increase in the air in the alveoli, thus increasing the functional residual capacity, from which gas exchange occurs, and improving oxygenation. PEEP is contraindicated in patients with untreated pneumothorax or with bronchopleural fistula. During patient transport, few ventilator changes need to be made except for necessary adjustments of FIO_2 to accommodate changes in oxygenation. If ventilation needs to be initiated in the field, the CCTP should follow the recommended guidelines after securing a patent airway. The CCTP is responsible for ensuring proper ventilator function and that the patient's ventilatory status remains stable.
- Indications for using a portable ventilator include respiratory failure, apnea, inadequate gas exchange, decreased work of breathing and oxygen cost.
- The CCTP should be able to troubleshoot ventilator function, and a manual resuscitator should

accompany every patient on a ventilator.

Vital Vocabulary

3-3-2 rule A method used to predict difficult intubation. A mouth opening of less than three fingers wide, a mandible length of less than three fingers wide, and a distance from hyoid bone to thyroid notch of less than two fingers wide indicate a possibly difficult airway.

adventitious breath sounds Abnormal breath sounds that are heard in addition to, or in place of, normal sounds.

agonal respirations Slow, shallow, irregular respirations or occasional gasping breaths; results from cerebral anoxia.

alveolar ventilation (V_A) The volume of air that comes into contact with the alveolar capillary membrane surfaces and participates in the exchange of gases between the lung and blood.

anatomic dead space (V_D) Space in airway structures such as the trachea, bronchi, and bronchioles that does not participate in gas exchange. It is defined physiologically as ventilation without perfusion.

apnea The absence of respiration.

apneustic breathing A condition in which lesions in the respiratory center of the brain stem lead to a breathing pattern characterized by prolonged, gasping inspiration, followed by extremely short, ineffective expiration.

arterial blood gas (ABG) Analysis of the following characteristics of blood: pH, partial pressure of carbon dioxide (in arterial blood), partial pressure of oxygen (in arterial blood), concentration of bicarbonate ion, base excess (indicating whether the patient is acidotic or alkalotic), and oxygen saturation of the hemoglobin molecule.

auto-PEEP The nonintended increase in end alveolar pressure due to air trapping.

barotrauma Injury to the chest or lungs as a result of increased intrathoracic pressure.

bi-level positive airway pressure (BiPAP) The use of two separate pressures—inspiratory positive airway pressure and expiratory positive airway pressure—to raise the breathing baseline above ambient pressure. The pressure gradient enhances ventilation, and the reduced expiratory pressure makes exhalation easier and increases patient tolerance.

Biot's (ataxic) breathing Breathing characterized by three patterns: (1) slow and deep, (2) rapid and shallow, and (3) apnea. Causes include meningitis, increased intracranial pressure, and central nervous system dysfunction.

bradypnea A respiratory rate that is slower than normal.

bronchovesicular sounds A combination of the tracheal and vesicular breath sounds, heard in places where airways and alveoli are found, the upper part of the sternum and between the scapulae.

capnograph The measurement of exhaled CO_2, which in most cases correlates with the CO_2 levels in arterial blood, can be done with two different types of devices—an electronic monitor that displays a waveform or a colorimetric device that should turn yellow during exhalation, indicating proper tube placement.

capnometry The measurement of exhaled CO_2, performed the same way as capnography, but which provides a light-emitting diode readout of the patient's exhaled CO_2.

central neurogenic hyperventilation A pattern of very deep, rapid respirations at rates of 40 to 60 breaths/min, caused by a midbrain lesion or dysfunction.

Cheyne-Stokes respiration A cyclic pattern of increased respiratory rate and depth with periods of apnea. Causes include increased intracranial pressure, renal failure, meningitis, drug overdose, or hypoxia secondary to congestive heart failure.

cluster breathing An abnormal respiratory pattern in which a cluster of irregular respirations that vary in depth are followed by a period of apnea at irregular intervals.

continuous positive airway pressure (CPAP) A means of raising the breathing baseline above ambient pressure. The increased pressure across the entire breathing cycle increases the mean airway pressure, stents the airway, and increases the functional residual capacity, thereby improving oxygenation.

crackle Breath sound produced as fluid-filled alveoli pop open under increasing inspiratory pressure; can be fine or coarse.

esophageal detection device (EDD) A bulb or syringe that is attached to the proximal end of the ET tube; a device used to confirm proper ET tube placement.

eupnea Normal breathing at a rate of 12 to 20 breaths/min in the adult patient.

expiratory reserve volume (ERV) The air that can be expelled from the lungs after a normal exhalation.

face-to-face intubation Performing intubation at the same level as the patient's face; used when the standard position is not possible. In this position, the laryngoscope is held in the provider's right hand and the ET tube in the left.

flow-cycled ventilator A positive-pressure ventilator that ends inspiration when a predetermined flow rate is achieved.

flow rate The speed of the gas at which the tidal volume is delivered.

fraction of inspired oxygen (F_{IO_2}) Percentage of inhaled oxygen expressed as a decimal. For example, 40% oxygen = F_{IO_2} of 0.40.

functional residual capacity (FRC) The amount of air remaining in the lungs after normal expiration; the sum of residual volume and expiratory reserve volume.

hyperpnea A breath that is deeper than normal; can lead to low levels of CO_2.

hypopnea A shallow breath; can lead to increased CO_2 levels and decreased oxygen levels.

I time The time frame for the delivery of the tidal volume.

I:E ratio An expression for comparing the length of expiration to inspiration. The normal ratio is 1:2. This means that expiration is twice as long as inspiration. It is not measured in seconds.

inspiratory capacity (IC) The maximum amount of air that can be inspired; the sum of inspiratory reserve volume and tidal volume.

inspiratory reserve volume (IRV) The amount of air that can be inhaled after a tidal volume is inhaled.

invasive ventilation Application of mechanical ventilation through an artificial airway such as a tracheostomy or ET tube.

Kussmaul's respiration A fast and deep respiratory pattern without any periods of apnea. The rate and depth are greater than the normal rate expected; breathing is labored, with periods of deep breaths punctuated by sighs.

Mallampati classification A system for predicting the relative difficulty of intubation based on the

amount of oropharyngeal structures visible in an upright, seated patient who is fully able to open his or her mouth.

mean airway pressure The amount of positive pressure in the airway, averaged over the inspiratory and expiratory phases of the breathing cycle.

mechanical ventilation The application of a device that provides varying degrees of ventilatory support.

minute volume Total volume of air breathed in and out in 1 minute. It is calculated by multiplying the respiratory rate per minute by the tidal volume.

mode The particular way in which a spontaneous or mechanical breath is delivered.

negative-pressure ventilator A mechanical ventilator that operates using pressure that is less than ambient (atmospheric) pressure.

noninvasive ventilation Application of mechanical ventilation through a mask, mouthpiece, or other interfaces other than an artificial airway.

obstructive diseases Diseases that result in difficulty with moving air out of the lungs, such as asthma, COPD, cystic fibrosis, and bronchioectasis.

peak airway pressure The amount of positive pressure generated by the ventilator to deliver the tidal volume.

pleural friction rub The result of an inflammation that causes the pleura to thicken, decreasing the pleural space and allowing the surfaces of the pleura to rub together.

positive end-expiratory pressure (PEEP) The amount of pressure above ambient pressure present in the airway at the end of the respiratory cycle.

positive-pressure ventilator A mechanical ventilator that operates using pressure that is greater than ambient pressure.

pressure ventilator A type of positive-pressure ventilator that ends the delivery of the tidal volume based on a predetermined pressure; therefore, the volume is variable.

residual volume (RV) The amount of air remaining in the lungs after the expiratory reserve volume is exhaled.

respiratory depression A low respiratory rate (< 12 breaths/min in adults) for a prolonged period of time; also called hypoventilation.

respiratory failure A situation in which the respiratory system fails to meet the body's metabolic needs. If not reversed, it leads to respiratory or cardiopulmonary arrest.

respiratory insufficiency The inability of the respiratory system to keep up with the metabolic demands of the body.

restrictive diseases Diseases that result in difficulty moving air in to the lungs such as occupational lung diseases, idiopathic pulmonary fibrosis, pneumonia, atelectasis, chest wall deformities and injuries, and neuromuscular diseases that affect breathing.

retrograde intubation A technique in which a wire is placed through the trachea and into the mouth with a needle via the cricoid membrane. The ET tube is then placed over the wire and guided into the trachea.

rhonchi Rattling vibrations produced as air flows through mucus or around obstruction in the larger airways.

Seldinger technique A technique for obtaining vascular or other hollow organ access that uses a hollow

bore needle inserted percutaneously followed by placement of a soft-tipped guide wire. The needle is removed and a dilator is temporarily placed. The dilator is removed and the desired catheter is placed over the guide wire. The guide wire is then removed. The catheter is then secured.

sensitivity Ventilator control that regulates the amount of negative pressure required by the patient to initiate or "trigger" a breath.

shunt Perfusion without ventilation.

Spo_2 The noninvasive pulse oximetry measurement of oxyhemoglobin saturation by means of a beam of light applied to a superficial capillary bed such as the digits or ear lobe.

stridor High-pitched sound representing air moving past fluid or mechanical obstruction within or immediately above the glottic opening.

tachypnea An abnormally fast respiratory rate.

tidal volume (V_T) The volume of air moved into and out of the lungs with each respiratory cycle.

time-cycled ventilator A type of positive-pressure ventilator in which the ventilator ends inspiration after a selected inspiratory time has been achieved.

total lung capacity (TLC) The maximal amount of air that can fill the lungs; the sum of tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume.

tracheal breath sounds Breath sounds heard by placing the stethoscope diaphragm over the trachea or over the sternum; also called bronchial breath sounds.

transillumination The act of using a light source placed within the trachea to visualize through the thin tissue that covers the trachea.

ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch A state of inadequate ventilation, perfusion, or both, in which there is inadequate gas exchange.

vesicular breath sounds Softer, muffled sounds in which the expiratory phase is barely audible.

vital capacity (V_c) The maximal amount of air that can be exhaled following a maximal inspiration; the sum of tidal volume, inspiratory reserve volume, and expiratory reserve volume; approximately 80% total lung capacity.

volume ventilator A type of positive-pressure ventilator in which the breath ends when the predetermined tidal volume is achieved.

$\dot{V}/\dot{Q}$ ratio The relationship between alveolar ventilation and alveolar capillary perfusion. The normal value is 0.8.

wheeze A high-pitched musical sound caused by airflow through a narrowed or constricted airway.

Pharmacology

Authors

Andrew Bartkus, RN, MSN, CEN, CCRN, CFRN, NREMT-P, FP-C

Shaun Froshour, NREMT-P

Objectives

1. Outline the principles of medication administration for CCTPs, including patient and medication selection, predicted and desired responses, absorption and elimination principles, side effects or adverse medication reactions, and transport and monitoring considerations (p 188–194).
2. Identify and discuss reliable resources for medication and pharmacology information (p 188).
3. Discuss the significance of medication pharmacokinetics and pharmacodynamics in the critical care transport setting (p 189–190).
4. Identify airway management medications used during critical care transport, including indications, contraindications, dosages, side effects, and interactions (p 195–197).
5. Identify respiratory management medications used during critical care transport, including indications, contraindications, dosages, side effects, and interactions (p 197–201).
6. Identify cardiovascular system medications used during critical care transport, including indications, contraindications, dosages, side effects, and interactions (p 201–210).
7. Identify medications for neurologic conditions that are used during critical care transport, including indications, contraindications, dosages, side effects, and interactions (p 210, 214–215).
8. Identify medications affecting the gastrointestinal system that are used during critical care transport, including indications, contraindications, dosages, side effects, and interactions (p 215, 217–218).
9. Identify any miscellaneous medications that are used during critical care transport, including indications, contraindications, dosages, side effects, and interactions (p 218–222).
10. Understand the sequence for medication infusion and know how to infuse medication with an infusion pump during transport and through changes in altitude (p 222, 224).

Introduction

Pharmacology is defined as the study of the preparation, properties, uses, and actions of medications. Modern health care and modern society are heavily dependent on medication for the management of illness and the alleviation of medical conditions or symptoms. Pharmacology plays a significant role in pre-hospital and critical care medicine and is often an essential component of patient care and transport. The practice of transporting critical care patients requires an enhanced understanding of all aspects of pharmacology in order to provide optimal patient care without causing further patient injury or death. Although this chapter covers a brief review of important basics, it assumes a general understanding of the subject of pharmacology. Many specific medications and medication groups are discussed. This list, however, is not comprehensive. As new medications and approaches to treatment of various conditions emerge, it is essential to balance this new information with proven treatment strategies. As always, follow local regulations, policies, and protocols and consult reliable, current sources when administering any medication.

Pharmacology and Medication Information

CCTPs should stay abreast of newly approved medications and current research. Current, reliable medication information may be obtained from a variety of sources, many of which are available in print and electronic formats **Table 7-1**.

In recent years, the Internet has emerged as a readily accessible source for medication information. Take some time to familiarize yourself with reputable and reliable Internet resources. Software versions of some of these resources, such as Epocrates, are also available for notebook computers, personal digital assistants (PDAs), and pocket personal computers. Regardless of the format used, careful research of the source's accuracy will assist in obtaining reliable information for clinical practice.

A Practical Approach to Medication Administration

Medication administration is a delicate blending of art and science. Many factors assist with medication selection for a particular condition.

The optimal medication for a particular patient may or may not be immediately available during patient transport. Many specialized medications such as antidotes, thrombolytics, and antibiotics are not routinely carried by CCTPs. Expense, storage concerns, and infrequent use are common limiting factors. A sending facility or a transport program's sponsoring hospital pharmacy are potential resources when a necessary medication is needed emergently but not carried by the transport team. Before leaving a sending facility, transport crews should obtain a sufficient quantity of a specialized medication infusion to account for transport time, plus an additional amount to provide a safe margin against unanticipated delays. If a desired medication remains unavailable, the transport team must decide if there is an acceptable alternative.

TABLE 7-1 Sources of Drug Information

Source	Description
American Medical Association *Drug Evaluation*	A nonofficial compendium that provides another source of useful drug information for pharmacists and medical practitioners; includes generic and trade names; information may not be limited to drugs approved for use by the FDA.
Drug inserts	Printed document included in the packaging provided by the drug's manufacturer; generally the same information submitted and approved by the FDA; when available, serves as a valuable reference; should not be confused with the information provided by a pharmacy when a patient receives a prescription, which is useful in obtaining information pertaining to a drug but is not necessarily inclusive.
Hospital formulary	A list of approved drugs, dosage forms, package sizes, and drug strengths stocked by hospitals and pharmacies. Published as a quick reference to assist the physician, registered nurse, pharmacy staff, and adjunctive staff. Divided into four general sections: introduction, therapeutic index, drug monographs, and general reference.
Physician's	Compiles data on most medications available in the United States; uses the information on file with the FDA; includes information regarding indications, dosages, contraindications, and adverse reactions.

Desk Reference	The size of the book makes it difficult for use on an ambulance or aircraft, but CD-ROM and electronic versions make it more accessible in the field. This source provides a vast amount of material on each medication, which may make it difficult to obtain any specific information needed immediately by CCTPs.
USDA Center for Drug Evaluation and Research	The FDA mission is to ensure that safe and effective drugs are available in the United States.
Various commercial medication reference texts and materials	These materials are widely available in print and electronic formats. Educational institutions, industry organizations, and independent publishing companies provide medication information in formats ranging from a simple listing of medications and doses (*Pharmacopeia*), to complex compilations that include an exhaustive list of interactions, overdose/toxicity treatments, pharmacokinetics, and administration guidelines. Select materials may only include medications related to a particular specialty (such as obstetrics, psychiatry, and critical care).

Abbreviations: FDA, Food and Drug Administration.

The scope of practice and monitoring capabilities of the transport team must also be considered when selecting a medication. Many vasoactive medications are best administered with continuous hemodynamic monitoring and require infusion pumps for precise adjustments. The transport team must be adequately trained and equipped to recognize and effectively manage anticipated side effects or adverse reactions associated with a particular medication. Transport teams who do not perform adequate monitoring or are unable to properly administer a medication place that patient at grave risk.

Other considerations include the clinical status of a patient. If immediate, life-saving interventions are required, it would be best to postpone the administration of scheduled, routine medications. Additionally, significant safety or operational priorities related to an aircraft or ambulance overshadow routine medication administration.

CCTPs must consider factors specific to each medication before administration. Indications, pharmacodynamics, pharmacokinetics, side effects, and potential adverse effects must all be considered. A particular medication is indicated when a specific condition requires treatment. Indications are further based on Food and Drug Administration (FDA) approval of the medication. A medication may have numerous, often seemingly unrelated indications.

Pharmacokinetics

Pharmacokinetics is the study of the metabolism and action of medications within the body, with particular emphasis on the time required for absorption, duration of action, distribution in the body, and mechanism of excretion.

Absorption

Absorption of a medication occurs either immediately or shortly after its administration. The route of administration affects how quickly and how much of the dose is absorbed. CCTPs generally use

intravenous (IV), intramuscular (IM), subcutaneous (SC), oral (PO), transdermal, nasal, and sometimes rectal routes for medication administration. Other routes not usually performed by CCTPs include ocular, intra-arterial, otic, and vaginal.

The route of medication administration affects its **bioavailability**, the amount of an administered medication (fraction or percentage) that reaches systemic circulation without any alteration. IV medications consistently have 100% bioavailability. The bioavailability of medications administered orally ranges from 0% to 100%, depending on the substance. Lidocaine, for example, when given orally only reaches approximately 35% bioavailability compared with 100% when given intravenously. Differences in bioavailability illustrate how a dose of a particular medication may be safe when given orally but toxic or lethal when given intravenously. For example, significant differences between the oral and IV dose exist for beta-blockers and calcium channel blockers. Nasal, sublingual, and rectal routes provide safe, alternative access for select medications when IV access cannot be established. The bioavailability of medications administered by these routes and other nonintravenous routes is based on numerous factors, including perfusion, membrane pH, and surface area along with variations based on the type of medication, chemical, or method of preparation.

Distribution

Once absorption has occurred, medication distribution to the tissues is highly variable. Blood is the primary distribution vehicle. Substances will distribute into the body based on the size of the molecule, ionization, binding to tissues or plasma proteins, lipid or water solubility, and perfusion to a region. Placental and brain barriers restrict distribution of certain substances into fetal and brain tissue, respectively. Highly lipid-soluble medications tend to cross these barriers where other medications would not readily cross. The solubility of a medication also affects dosage calculations for weight-based medications.

First-pass effect (also called first-pass metabolism) occurs with orally administered medications, in which the concentration of a medication is reduced as it passes through the liver before it enters systemic circulation. The medication undergoes biotransformation, elimination, or both. The kidneys and urinary system are the main routes of elimination. Patients with acute or chronic renal disease require careful consideration when medications are administered. Other routes of elimination include the lungs (usually highly volatile substances or gases), sweat, saliva, stool, and breast milk.

Biotransformation

The liver is the primary site for biotransformation, but many body tissues and cells have the ability as well. Four possible events occur during biotransformation of a medication. An active drug may be changed into an inactive metabolite. This new substance causes no new effects and is then ultimately eliminated. An active drug can also be changed into an active metabolite, for example procainamide into *N*-acetylprocainamide, that causes continued or new clinical effects. An active medication may also biotransform into a reactive metabolite that has a greater potential for action than its parent substance (for example, acetaminophen into *N*-acetyl-p-benzoquinoneimine). Finally, an otherwise inactive substance undergoes biotransformation into an active, potentially toxic substance (codeine changed into morphine). Active (and reactive) metabolites can complicate the clinical situation and require special consideration when selecting certain medications. The presence of active (and reactive) metabolites becomes particularly important when considering a medication half-life or monitoring a medication plasma level. Larger tertiary care centers often have the ability to assess medication metabolite levels in addition to plasma levels of the medication itself.

Elimination

Substances or medications undergoing elimination follow one of two possible patterns. If a substance follows **zero-order elimination**, a fixed amount of substance is eliminated over a time period, regardless of the amount of substance present in the plasma. Ethanol follows zero-order elimination. Regardless of how much ethanol is present, only a relatively fixed amount gets excreted each hour. Most medications and other substances follow **first-order elimination.** In first-order elimination, the amount of substance eliminated over a period of time is proportional to the plasma concentration. Medication half-lives reflect first-order kinetics. A medication **steady state** occurs when administration of a medication equals the rate of elimination, which is desirable with antibiotics and anticoagulants.

Factors affecting biotransformation and elimination include perfusion, liver and kidney status, metabolism, and the manner and extent of absorption. Biotransformation and elimination are also influenced by chronic exposure to a particular medication or chemical.

Enzyme systems in the liver perform biotransformation. The cytochrome P450 system, present in the liver and in other tissues, is the main pathway responsible for biotransformation of many medications and chemicals. This system is also manipulated by many medications and chemicals, leading to altered patterns of biotransformation in select persons. Common agents such as nicotine, grapefruit juice, and broccoli have a significant impact on the functioning of the cytochrome P450 system. The list of medications that either promote or inhibit the action of the cytochrome P450 system on other medications is exhaustive.

Pharmacodynamics

Pharmacodynamics is the way in which a medication produces the response intended, also known as the **mechanism of action**. It encompasses the factors that may alter the intended response and any side effects or unexpected effects.

Theories of Drug Action

Medications are chemicals that are administered to cure or treat a disease, symptom, condition, or other anomaly. When these chemicals act upon the body to achieve a particular goal, four basic mechanisms may occur. A medication may bind with a receptor site on a particular cell to either promote or inhibit a specific activity of that cell. A medication may also affect the physical property of a cell, which in turn alters the functioning of that cell. A medication may combine directly with other chemicals within the body to alter or limit the effects of this chemical or allow it to be removed. Finally, a medication may alter a metabolic pathway in order to achieve a desired result.

Medications that bind to a receptor site are the most prevalent, particularly in the prehospital setting. Receptor sites are specialized proteins on a cell that receive chemical mediator messages to stimulate a particular response. For example, when acetylcholine attaches to receptor sites in the heart, it causes the heart rate to slow. Cellular responses can be wide ranging depending on the chemical mediator and the cells being stimulated. A medication molecule will have one of two effects when it attaches to a receptor site. It may stimulate the receptor site to cause the response it normally does (agonist), or it may block the receptor site from being stimulated by other chemical mediators and inhibit the normal response (antagonist). Some medications can also act as agonist-antagonists, or partial agonists, by performing both roles. In any event, the medication molecule must compete with the naturally occurring chemical mediator. In order for a medication to work effectively, the medication molecule must have a higher affinity for the receptor than the intrinsic chemical mediator does. In addition, more than one medication may vie for the same receptor.

Once the medication is bound to the receptor site, it initiates a chemical change that produces the expected effect by direct binding or by release of a second compound (known as a second messenger) that causes the intended effect. Cyclic adenosine monophosphate (cAMP) is the most common second-messenger chemical related to pharmacology. Once cAMP is produced in the cell, it triggers the release of still other enzymes, which then carry out their own functions.

The number of available receptors is inconsistent and can be affected by the actual number of sites present, the number already occupied by another chemical mediator, and the number occupied by another medication. As medication molecules bind to the receptor sites, the number of receptors decreases, a process known as down-regulation. However, some medications can increase the number of available receptor sites, a process known as up-regulation.

Drug-Response Relationship

Once the medication finds the target tissue, it needs to accumulate to a sufficient concentration to produce its desired effect. The drug-response relationship correlates the amount of medication given and the response it causes. Most of this information comes from the plasma-level profiles, which describe the length of onset, duration, and termination of action. These profiles allow pharmacologists to determine the minimum effective level of a medication and the level at which the medication would be toxic to the patient. When a medication is administered, the **onset of action** is defined as the amount of time it will take for the concentration of the medication at the target tissue to reach the minimum effective level. The CCTP also needs to know how long the medication can be expected to remain above that minimum level to provide the intended action (ie, the **duration of action),** which is defined as the amount of time that the medication can be expected to remain above that minimum effective level. The **termination of action** is the amount of time after the concentration level falls below the minimum level to the time it is eliminated from the body.

All of these factors affect the **therapeutic index**—the ratio of a drug's lethal dose for 50% of the population (LD_{50}) to its effective dose for 50% of the population (ED_{50}). In other words, the therapeutic index gives an indication of a medication's margin of safety. The plasma profile also provides information about the medication's biologic **half-life (T½)**—that is, the time it takes the body to eliminate half of the drug. Despite the name, a medication is not eliminated in two "half-lives." During the second half-life period, only half of what remained after the first half-life is eliminated. After three half-lives, approximately one eighth of the medication still remains. In many instances the duration of action of a medication is unrelated to its half-life. Aspirin, for example, has a half-life of 15 minutes, yet produces antiplatelet effects that last for 7 days. Typically, a medication has no effect after five to seven half-lives.

Factors Affecting Drug Responses

Patient characteristics affect the action of a drug. Patients differ with respect to how they react to medications. Age, gender, weight, heredity, and clinical condition each have an impact on medication choice, medication response, required dose, and elimination characteristics.

Age

Patients of different ages may have vastly different responses to the same drug. Older people, for example, tend to be much more sensitive to the effects of drugs and often require smaller doses than younger patients. Elderly patients frequently exhibit declining renal function and decreased muscle mass, which interfere with the reliability of creatinine clearance when determining an appropriate medication dose. Additionally, changes in body water content, relative to body fat content, change the distribution of water- and lipid-soluble medications, requiring dosage adjustments. Changes in or a reduction of certain

neurotransmitters further complicates medication dosing in the elderly. A person's metabolism will vary significantly at different ages throughout life. Pediatric patients generally have an increased metabolic rate compared with adult and elderly patients and often require an increase in either dose or frequency of administration. It is not, however, solely a matter of dose. Some drugs have different effects altogether in different age groups.

Sedative-hypnotic agents tend to exhibit a more profound or prolonged effect in older patients. Excitement, rather than sedation, is also possible when elderly patients receive certain medications. Barbiturates, for example, act as sedatives in most adults, but may produce excitement or agitation in older patients. Pediatric patients frequently experience paradoxical drug reactions in which sedative agents cause hyperactivity and agitation, further complicating the clinical situation. Diphenhydramine, chloral hydrate, and certain benzodiazepines are frequently the cause of paradoxical medication reactions in children.

Weight

Many drugs are formulated for an average adult, usually considered to be a 154-lb (70-kg) person. However, the ultimate drug concentration will be quite different if the same dose is administered to a 106-lb (48-kg) person and a 300-1b (136-kg) person. Therefore, body weight must be taken into consideration by calculating dosages in milligrams or micrograms per kilogram of the patient's body weight (mg/kg or µg/kg, respectively). The nature of a particular drug, including receptor sites and tissue distribution, will determine whether the medication dosage is based on a patient's ideal body weight rather than actual body weight.

Special Populations

Pediatric and geriatric patients often have slower medication absorption and elimination times, necessitating modification of the doses of many drugs administered to these patients. Pregnant patients are limited in the medications they can take because of the risk to the fetus.

Special Populations

Almost all medications require lower doses for elderly patients because of diminished renal clearance. CCTPs should be aware of this when administering drugs. Additionally, medications that have a high first-pass metabolism rate through the liver can require additional medication doses to obtain the optimal serum levels. Consult a specific, reliable reference for each medication that is being considered for oral administration, and be sure to rely on medical direction at all times.

For example, digoxin should be administered according to a patient's ideal body weight. Lidocaine should be administered according to a patient's actual body weight. Research is limited on many other weight-based medication dosages; in practice, critical care medications are administered and titrated based on effect. Clinicians should consider tissue binding, protein binding, and perfusion when administering weight-based medications. Ideal body weight in adults is calculated as follows:

- **Males (kg):** 50 + (2.3 times patient's height in inches over 5′)
- **Females (kg):** 45.5 + (2.3 times patient's height in inches over 5′)

Gender

General differences in body mass between males and females affect reactions to medications. Some

medications can have varying effects in the different sexes, particularly when they are based on hormones.

Environment

The environmental milieu can influence a medication's reaction because of the psychological and physiologic stresses imposed on the patient. In addition, a particular reaction to an environmental factor, such as seasonal allergies, can alter response to a medication.

Time of Administration

The time at which a patient is given a medication may affect the reaction. If a patient takes an oral medication immediately after eating, the time of onset is likely to be slowed compared with taking the same drug on an empty stomach or during physical activity such as exercise.

Condition of the Patient

The patient's overall health also affects the response to many drugs. If the kidneys are not working properly, for example, medications may not be excreted efficiently, and the concentration of a drug may build up inside the body until it reaches toxic levels. Liver and kidney failure significantly alter the metabolism and elimination of many medications. *Consult a reliable medication reference or seek medical direction before administering medications to patients with significant liver or kidney dysfunction*. If the patient is in shock, it may take hours before the patient absorbs a drug that has been injected. In a situation such as profound anaphylaxis, it may be necessary to administer medications intravenously that are normally administered intramuscularly or subcutaneously. Medications may also not be effective in hypothermic patients. IV medications are often withheld if a patient's core temperature has fallen below 80°F (30°C) and given at greater intervals when hypothermic patients have a core temperature above 80°F (30°C). Chapter 18 provides a more detailed discussion of medication administration for the treatment of hypothermia.

Genetic Factors

A patient's genetics may affect the reaction to a medication. If a patient lacks necessary enzymes or has a lower metabolism, the response to a medication might be significantly delayed. Glucose-6-phosphate dehydrogenase deficiency is a common genetic disorder affecting hundreds of millions of people worldwide. The administration of oxidant medications (such as antimalarials), sulfonamides, nitrofurantoin, and phenazopyridine and exposure to naphthalene (mothballs) cause a potentially life-threatening hemolytic anemia in these patients. Other genetic disorders such as primary pulmonary hypertension and sickle cell disease have specific concerns related to pharmacology and hemodynamics. Medications with vasoconstrictor properties will adversely affect lung perfusion in patients with pulmonary hypertension. Any medication that causes hypoxia, vasospasm, or dehydration can precipitate or worsen a sickle-cell crisis.

Pregnancy

Medication administration in pregnant patients has special risks. Medications pass from the pregnant woman's bloodstream into the placenta and ultimately affect the fetus. During pregnancy, patients also experience impaired respiratory excursion, hemodilution, and altered hemodynamic parameters. There is evidence that catecholamines such as norepinephrine and epinephrine have an adverse impact on placental perfusion, but these medications are generally limited to use in extreme situations, such as profound shock or cardiac arrest. Ephedrine, because of its beta-2 and alpha-1 properties, is the preferred vasopressor for maternal shock. The FDA has established five categories to indicate a drug's potential for causing abnormal prenatal development. **Table 7-2** lists the categories and their implications.

Psychological Factors

The relationship between psychological factors and medication administration during critical care transport cannot be overstated. In several research studies, subjects were given a placebo, a pill with no therapeutic or medicinal properties. Some subjects began to exhibit effects as if they were taking real medication. This is known as the placebo effect, which has been noted in up to 10% of the subjects in some studies.

Psychological factors need to be considered when medications are administered for analgesia and sedation. Patient positioning, temperature regulation, and proactive communication can optimize the effects of analgesia or sedative medications, possibly decreasing the overall amount of each medication required. Occasionally, patients with psychiatric disorders require excessive amounts of sedatives for the desired effect or demonstrate a paradoxical medication reaction similar to children with select medications, especially with benzodiazepines.

TABLE 7-2 FDA Pregnancy Risk Categories

Pregnancy Category	Implications
A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.
B	Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal-reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
C	Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (eg, if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
X	Studies in animals or human beings have demonstrated fetal abnormalities, there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Predictable Responses

Because of the extensive research that goes into developing and testing a medication before it is approved, generally there is a good idea of potential patient responses to a particular drug. CCTPs should also anticipate unexpected drug responses beyond the desired effect, called **side effects**. Side effects are reactions that can manifest as signs or symptoms that are not the desired effects, but nevertheless are expected based on how the medication works. All medications have some side effects—even oxygen.

CCTPs need to be able to evaluate the benefits compared with the risks associated with the side effects. If the patient's condition will improve more so than deteriorate from side effects, the CCTP will likely administer the medication. Conversely, if the risks for side effects outweigh the benefits of drug treatment, it is best to withhold drug administration. This concept is known as the risk-benefit ratio. The risk-benefit ratio is evaluated separately for each patient and his or her particular clinical situation. A side effect that is insignificant for one group of patients may have life-threatening implications for another group of patients, such as genetically susceptible, immunocompromised, or hemodynamically unstable individuals. For example, if a medication causes hypotension as a side effect, it should be avoided in patients with shock. If a medication alters immune response, it may place immunocompromised patients at significant risk. Patients with G6PD deficiency, a genetic disorder discussed previously, may experience hemolytic anemia as a side effect of sulfonamides and oxidant medications. The risks associated with medication side effects should not be underestimated in high-risk or critically ill patients.

Iatrogenic Responses

When the administration of drugs leads to symptoms that mimic naturally occurring disease states, it is known as an **iatrogenic response**. An iatrogenic response is an adverse condition inadvertently induced in a patient as a result of treatment. For example, a urinary tract infection may develop after insertion of an indwelling catheter, or Stevens Johnson syndrome is a potentially fatal complication of treatment that may develop with medications such as penicillin, sulfa antibiotics, anticonvulsants, and at least one cyclooxygenase-2 inhibitor. Although Stevens-Johnson syndrome is often tough to predict or anticipate, the consequences of this syndrome and other iatrogenic drug responses are devastating and potentially fatal.

Unpredictable Responses

Even though the doses of medications have been carefully tested and designed for specific conditions, some patients have adverse effects that have not been anticipated. The most common unpredictable response encountered in the prehospital setting is an allergic reaction. An allergic reaction occurs when the patient is extremely sensitive, or hypersensitive, to the medication, or one of the ingredients used in its particular form or preparation. Because the patient is hypersensitive, the drug activates the immune system. Allergic reactions are unpredictable—unless the patient has had an allergic reaction to the same drug in the past—and may lead to life-threatening anaphylaxis. Allergic reactions should be anticipated with any drug. Severe reactions to an antibiotic that is penicillin-based may indicate a greater chance of reaction to another antibiotic that is penicillin-based. Patients with egg or soy allergies are not candidates for sedation with propofol (Diprivan). An allergy to bananas or avocados is highly suggestive of a latex allergy. There are numerous other allergy patterns between food, environmental, and medication allergies that CCTPs should evaluate prior to administering a medication to patients with known allergies.

In rare cases, the patient may experience a completely unique response that is specific to that person; it is not seen in other patients. This situation is known as an **idiosyncrasy** and is unrelated to the pharmacologic action of a medication or the dose administered.

Patients who take a particular medication for an extended period can build up **tolerance** to it. In these cases, the patient will often require higher doses than normal to achieve the desired response. Patients may also develop a tolerance to one medication as a result of prolonged administration of another medication, known as **cross-tolerance**. This phenomenon is often seen in patients who take several pain medications. A patient who is taking a medication such as oxycodone may become tolerant to opiate-based medications. Therefore, if morphine is administered for pain, the patient may not have the desired response because of cross-tolerance. **Tachyphylaxis** is a condition in which the patient rapidly becomes

tolerant to a medication. With tachyphylaxis, increasingly higher doses of a medication are required to achieve desired effects. This can occur with just a couple of doses and is most often seen with **sympathomimetic** agents. It is important to keep in mind, however, that toxic thresholds may remain unchanged. With prolonged administration of a medication, a patient can become drug dependent. In this case, the person will have significant symptoms if he or she stops using the medication.

All medications need to reach a minimum concentration in the target tissue before they become effective; that concentration is reached by providing a specific dose. If several doses are given in a relatively short time, the patient may experience a **cumulative effect**, which is an increased effect when a medication is given in several successive doses, possibly resulting in therapeutic or nontherapeutic effects.

Many patients take multiple medications at one time. It is possible for the effects of one medication to alter the response of another medication, a phenomenon known as a **drug interaction**. The interaction may not always be anticipated. For example, if the patient is taking two sympathomimetics, it does not necessarily mean the patient will experience a more dramatic sympathetic response. It is possible to see the opposite response or a completely unrelated response. When the patient is taking more than one medication, one medication could block the body's response to another medication. This is called **drug antagonism**. For example, if a patient has taken an opiate-based drug such as morphine, another medication, naloxone, can be administered to block the response to the morphine.

A **summation effect** occurs when two drugs given to the patient have the same effect, which doubles the response exhibited by the patient. When the patient receives two drugs that have the same effect but produce a response greater than the sum of their individual responses, the result is known as **synergism**. At times, the interaction between two medications can cause one drug to enhance the effect of another, known as **potentiation**. For example, acetaminophen (Tylenol) and alcohol interact. It is well known that high doses of acetaminophen are damaging to the liver. When alcohol is ingested along with acetaminophen, more of the medication is taken up into the liver and may result in acute liver failure. This phenomenon is referred to as the alcohol-acetaminophen syndrome. Some potentiation effects are known and can be exploited to achieve a desired effect; in other cases, potentiation may occur unexpectedly. A direct biochemical interaction that takes place between two drugs is referred to as **interference**. **Inhibition** is the opposite of potentiation, where one medication limits the effects of another.

Avoiding Medication Errors

Medication errors related to selection, administration, or monitoring are responsible for thousands of deaths annually. The risk of a medication error leading to an adverse patient outcome is high. CCTPs, in addition to ensuring the right patient, right drug, right dose, right route, right time, and right formulation, must evaluate medication decisions made by sending facility staff for potential errors. It is essential that CCTPs confirm the accuracy of any medication infusion that they are continuing during transport. Proper labeling of transport medications and infusions is essential for CCTPs when accepting a patient and turning over patient care. Additionally, line incompatibility should be considered for any patient receiving multiple IV medications. Numerous medications will either chemically interact or precipitate (take on a solid form) when combined in the same IV line, causing unpredictable or dangerous consequences for the patient.

Medication Management

Medication Storage

Many medications can be altered due to extremes in temperature, exposure to direct sunlight, or excessive humidity. In most cases, the potency of the medication is decreased, and, in some cases, the actual molecular components can be degraded and made inactive. Each manufacturer must provide guidance on the proper storage for each medication that is approved by the FDA. This information can be found on the drug insert or in the *United States Pharmacopeia*. In general, medications should be kept out of direct sunlight and stored in temperatures between 55°F (13°C) and 85°F (29°C). During transport, CCTPs and vehicles are exposed to temperature extremes. It is essential that medications remain within their required temperature range. Medications such as cardizem (Diltiazem), various neuromuscular blocking agents (succinylcholine and rocuronium), and lorazepam (Ativan) require refrigerator storage. These medications are only stable at room temperature for a limited period of time. Consult the manufacturer's guidelines for adjusted expiration dates with room temperature storage and anticipate frequent replacement of these medications if they are stored at room temperature.

Transport vehicles require special consideration for medication storage. CCTPs should monitor the temperature of transport vehicles when they are exposed to extremes of heat or cold. Medications may need to be removed while the vehicle is parked. Smaller electronic devices are now available that can record the temperature of a vehicle and identify periods of deviation from safe medication storage temperatures. CCTPs should be conscious of these general guidelines, use their best judgment, and ensure that medications are stored in areas that are not routinely or constantly exposed to poor climate conditions. Every department should have a written protocol or procedure for the specific handling of all medications, fluids, or diluents on the vehicle or in the station as a guide on how best to store and handle medications used in daily practice. In addition, CCTPs should check the expiration dates on medications on the transport vehicle at least monthly and dispose of the expired lots.

Security of Controlled Medications

Nearly every medication used in the prehospital setting is a prescription medication; however, some are controlled substances and have more stringent control guidelines. State and federal governments heavily regulate the acquisition, storage, usage, and disposal of controlled medications. State pharmacy boards and the US Drug Enforcement Agency have specific regulations that CCTPs must follow in these situations. Minimum requirements for the storage of controlled substances include a securely locked, substantially constructed cabinet with no sign or any other indication that the cabinet is used for the storage of controlled substances. Cabinets constructed of materials that are fragile and/or allow visualization, such as glass or plastic, are considered inappropriate for this purpose. A controlled substance disposition record must be maintained, and thorough documentation must be completed for any use of a controlled substance, including the disposal of any leftover waste medication not administered during patient care. Any expired controlled substances must be returned to the agency or departmental officer in charge of maintenance and dispersal of controlled substances and must also be documented in the disposition record(s). These are general guidelines. Every department must have a written protocol and procedure for the use, storage, disposition, and documentation of controlled substances.

Specific Medications Used in Critical Care Transport

Individual medications and medication families common to critical care transport are examined here, but this list is far from complete. CCTPs should be prepared to encounter many additional medications in clinical practice and have a strategy in place to responsibly administer or monitor patients who have received these medications. Conversely, not every medication or medication family here may be relevant to providers who only perform critical care transport of specialty populations (for example, high-risk obstetric or neonatal populations). Each medication or medication family is organized based on its most

common use. It is common for medications to have accepted uses in multiple categories. The dosages, kinetics, and related materials for each medication may vary slightly from one reference source to another. As always, follow local system or organizational protocols regarding administration guidelines for each medication.

Medications Used in Airway Management

Definitive airway management in critical care transport combines techniques for airway device placement with medications designed to facilitate placement. Sedative-hypnotic agents are administered with chemical paralytics to create the best patient condition possible for invasive airway procedures. Ideally, the patient should have no gag reflex, no trismus, relaxed facial/airway muscles for maximal visualization, no awareness of the procedure, and no memory of the procedure. These goals can be accomplished with the proper use of the medications described in this section. Various airway management protocols also include mucolytics for secretion control, IV analgesic medications, and anesthetic use, which are discussed later in this chapter.

Ultra-Short-Acting Nonbarbiturate Hypnotic Agents

For patients who require endotracheal intubation, ultra-short-acting nonbarbiturate hypnotic agents are quickly becoming the gold standard. Etomidate (Amidate) is the drug of choice in this category for intubation because of its effective action and few side effects. Etomidate depresses the reticular activating system by stimulating the gamma-aminobutyric acid (GABA) receptors. It decreases oxygen consumption and cerebral blood flow, which makes it ideal in cases of increased intracranial pressure. Administered at a dose of 0.3 mg/kg, etomidate reaches peak effect in 1 minute and provides anesthesia for about 3 to 5 minutes. There are no absolute contraindications for the use of etomidate for rapid sequence intubation. However, a high incidence of uncomfortable myoclonic muscle movement is associated with its use. Recent studies suggest that even a single dose of etomidate may result in adrenal suppression, which has caused some to reconsider its use in critically ill patients.

Ketamine, a phencyclidine (PCP) derivative, is another option for rapid sequence intubation and general anesthesia. Ketamine is also ideal because of its rapid onset of 1 minute or less and duration of action of 10 to 15 minutes. The drug makes the patient unaware of his or her surroundings and fall into a trance-like state. It works by interrupting pathways between the cortex, which is responsible for higher functions such as language and perception, and the limbic system, which provides emotions and memories. By interrupting these pathways, ketamine is believed to provide its dissociative, analgesic, and sedative properties. Typically given at a dose of 1 to 4 mg/kg, ketamine produces anesthesia, analgesia, and amnesia. This drug is abused in the general population so increased security is required for this medication.

Ketamine tends to cause an increase in blood pressure, pulse, and cardiac output. This can be both a benefit and a drawback depending on the cardiovascular state of the patient. Patients with uncontrolled hypertension could be further compromised by the effect of ketamine, whereas patients who are in a state of hypoperfusion may benefit. Ketamine has also been found to have bronchodilatory effects. The exact mechanism of this effect is unclear, but it has been found to be beneficial in patients with bronchospasm. CCTPs should anticipate an emergence reaction, which includes hallucinations, agitation, irrational behavior, and delirium, following ketamine administration. These reactions can be minimized or prevented by premedication with benzodiazepines such as lorazepam (Ativan) or midazolam (Versed).

Sedative-Hypnotic Agents

Propofol (Diprivan) is another sedative-hypnotic agent used in airway management. The normal adult dose is 1 to 2.5 mg/kg for induction; some providers administer 40 mg every 10 seconds until induction is

accomplished. Propofol provides both anesthetic and amnesic effects beginning about 20 seconds after administration and lasting for 10 to 15 minutes. In certain states it is outside the registered nurse and paramedic scope of practice to use propofol as an induction agent, but acceptable for use as a maintenance sedative in the intensive care unit (ICU) and during patient transport. The maintenance dose ranges from 5 to 50 μg/kg/min. Many alternate dosing regimens are available for pediatric patients, elderly patients, general anesthesia, and select compromised patients or situations. Consult a reliable reference for specific dosing parameters for these patients. In addition to use as a sedative-hypnotic agent, propofol has some powerful anticonvulsant properties. It may be useful in patients with status epilepticus who have resisted frontline anticonvulsant medications such as phenytoin and benzodiazepines. Propofol may also be the maintenance sedative of choice for short-term use in hemodynamically stable neurologic patients who are predisposed to seizure activity.

Propofol decreases myocardial activity and systemic vascular resistance. Patients could experience a decrease in oxygen delivery to vital organs, most notably the brain (evidenced by significant drops in blood pressure). Propofol should be used with caution in patients who would experience the devastating impact of hypotension (such as traumatic brain injury). Decreased blood pressure from propofol administration may prove beneficial in patients who are experiencing hypertension from the effects of sympathomimetic drugs. Additionally, propofol has been shown to have a greater effect on depressing pharyngeal and laryngeal muscle tone, possibly facilitating endotracheal intubation.

Propofol requires a strict aseptic technique during preparation and administration. The lipid-based preparation serves as a great breeding ground for invasive microorganisms. Additionally, propofol infusions should not be continued for longer than 48 hours. High doses of propofol or prolonged infusions have caused patient fatalities from propofol infusion syndrome, which includes metabolic acidosis, rhabdomyolysis, cardiac and renal failure, and several other serious conditions. Propofol has numerous medication interactions, through either alteration of the cytochrome P450 system or action to potentiate other central nervous system (CNS) and respiratory depressant medications and chemicals.

Benzodiazepines

Many airway management protocols include the use of benzodiazepines either during the initial induction or as a maintenance sedative. Benzodiazepines include common critical care medications such as diazepam (Valium), lorazepam (Ativan), and midazolam (Versed) along with oral medications for long-term home use, including oxazepam (Serax) and clonazepam (Klonopin). These medications have anxiolytic, sedative, and anticonvulsant properties. The three common critical care benzodiazepines are all pregnancy class D, which indicates a strong risk to the fetus. These medications should only be used in life-threatening situations in which no safer medication alternatives exist. Benzodiazepines have been linked to fetal anomalies and neonatal floppy baby syndrome.

Benzodiazepines are believed to affect the inhibitory neurotransmitter GABA in the brain, although their exact mechanism of action is not fully understood. Benzodiazepine molecules bind to a receptor near GABA binding sites, which is thought to enhance their affinity for GABA. This increased affinity causes brain activity to slow.

Like propofol, benzodiazepines should be used with caution in patients with hypotension or potential hypotension.

Of the three most popular benzodiazepines, midazolam (Versed) is the most common choice for rapid sequence intubation or induction because of the relatively fast onset time when compared to other benzodiazepines at 1 to 5 minutes when administered at a dose of 2.5 to 10 mg IV in adults. Midazolam should generally be used as an adjunct to other sedative-hypnotic agents rather than as the sole medication for induction. It has a 60-minute duration of action and peaks in approximately 30 minutes. If midazolam is to be used as the sole induction agent, it must be administered 3 minutes prior to proceeding with any

chemical paralytic agents. In addition, midazolam has a beneficial potent amnesic effect, which inhibits the patient's ability to recall the procedure.

Midazolam is believed to carry out its effect by altering the neurotransmitter GABA. As such, midazolam acts as a CNS depressant, but it also has hypnotic and anterograde amnesic properties. Although patient recovery time is dose dependent, patients can take as long as 2 hours to recover. Some interfacility transport systems may use a narcotic premedication, such as fentanyl, when using midazolam in order to gain a potentiation effect.

Diazepam (Valium) is a moderately long-acting benzodiazepine with a duration of action of 30 to 90 minutes, but has a slower onset than midazolam, at approximately 5 minutes, when patients are given between 2 and 10 mg IV. Lorazepam (Ativan) is a benzodiazepine medication that is gaining popularity. This medication has a rapid onset of 1 to 5 minutes, but a variable peak effect.

Diazepam and lorazepam are excellent first-choice anti-convulsants. Midazolam works well, but not as well as diazepam and lorazepam for seizure control. In critical care transport it is possible that only one of these medications may be available for use. Benzodiazepines are administered emergently for active seizure activity and supplemented by other anticonvulsants in patients who do not initially respond.

Midazolam, diazepam, and lorazepam are used routinely at reduced dosages for anxiolysis before and during transport. Use caution when administering these medications to patients who are predisposed to paradoxical or bizarre medication reactions, such as children, the elderly, and psychiatric patients.

In the event a patient has excessive levels of benzodiazepines, the use of flumazenil (Romazicon) may be necessitated. Flumazenil is used to treat benzodiazepine overdoses by antagonizing the benzodiazepine receptors. Adult patients are given an initial dose of 0.2 mg by IV catheter over 30 seconds. After 30 seconds of observation, a second dose of 0.3 mg can be administered over 30 seconds. If the desired effect is not yet achieved, 0.5 mg can be administered every minute, up to 3 mg total. Pediatric patients can receive 0.002 to 0.02 mg/kg IV every minute. Extreme caution must be exercised with the use of this medication. Flumazenil should be avoided in patients who have overdosed on any medication with the potential to cause seizures, patients with any unknown drug overdoses, patients with a history of seizures, any patient likely to experience a seizure (such as traumatic brain injury or intracranial hemorrhage), and any patient who has been taking benzodiazepines long-term. With all of these contraindications, the use of flumazenil in critical care transport is limited.

Paralytic Medications

Chemical paralytic medications inhibit muscle activity (and resistance) in patients who require airway and respiratory muscle relaxation to facilitate airway adjunct placement or mechanical ventilation. Intubation success rates are improved as a result of increased visualization of airway anatomy following chemical paralysis. **Acetylcholine (ACh)** is the neurotransmitter that bridges the synapse at the neuromuscular junction. An influx of calcium in the nerves stimulates the release of ACh, which moves across the synapse and binds with the **nicotinic receptors** on the muscle cells. When ACh makes that connection, depolarization of the muscle takes place and the intended movement or action takes place. A paralytic medication can be grouped into one of two categories depending on how it interacts with ACh and the nicotinic receptors: depolarizing or nondepolarizing.

Special Populations

Remember to reference a length-based resuscitation tape (such as the Broselow tape) for resuscitation medication dosages for children. Medication dosages and other pediatric topics are covered in Chapter 23.

Depolarizing Agents

Depolarizing paralytics work by acting as an agonist in the nicotinic receptor and mimicking the activity of ACh. The medication stimulates muscle depolarization but then remains bound to the receptor, thereby preventing it from repolarizing and being triggered again. Succinylcholine (Anectine) is the only depolarizing chemical paralytic agent in widespread clinical practice. In addition to activity on the nicotinic receptors, succinylcholine also stimulates cardiac muscarinic receptors, leading to bradycardia, especially in children. At a dose of 1 to 2 mg/kg, patients will experience muscle relaxation in about 30 seconds, with total paralysis occurring in about 45 seconds. The rapid onset time, coupled with the duration of action at 7 to 10 minutes, makes succinylcholine an ideal paralytic agent for medication-assisted airway management.

Succinylcholine is not without its drawbacks. It has a tendency to increase serum potassium levels, which can cause significant problems in the presence of chronic or acute conditions in which potassium levels may be altered. Acute injuries such as burns, crush injuries, and spinal cord injuries should be treated with alternative medications if they are available. Chronic conditions affecting potassium, such as renal failure, should also receive an alternative medication. Succinylcholine can also cause a transient increase in intracranial pressure (ICP). Although the increased ICP from laryngoscopy is of greater concern, the medication-induced ICP must be considered and accounted for in cases of closed-head injury. The most common side effect is muscle fasciculations, which is the twitching activity seen as the muscles depolarize. Although the twitching may not appear overly dramatic, care should be given to ensure the patient does not experience any further injury or inadvertently pull IV lines. Many rapid-sequence intubation or induction (RSI) protocols include a reduced dose of a nondepolarizing muscle relaxer prior to succinylcholine to prevent or reduce any fasciculations.

Succinylcholine can cause malignant hyperthermia and therefore is contraindicated in patients who have a known history or family history of this condition. Malignant hyperthermia is discussed in greater depth in Chapter 20. Also, expect a much longer than normal duration of action of succinylcholine when it is administered to any patient exposed to acetylcholinesterase inhibitors, found in chemical nerve agents and pesticides. This is the result of inhibition of acetylcholinesterase, the enzyme that breaks down ACh. A nondepolarizing muscle relaxer may be preferred in these situations.

Nondepolarizing Agents

Nondepolarizing agents work by competitively antagonizing ACh at the postsynaptic receptors. In doing so, the ACh is unable to cause stimulation, and muscle depolarization cannot occur. A few different nondepolarizing medications are available, and some are more desirable for medication-assisted airway management than others. Overall, the major drawback in using nondepolarizing medications is that they tend to have a slower onset time and longer duration of action when compared with succinylcholine.

Rocuronium (Zemuron) has the fastest onset time of the nondepolarizing paralytics, at 60 to 90 seconds. It is generally administered at a dose of 0.5 to 1 mg/kg, but at that dose the medication lasts for as long as 45 minutes. A higher initial dose (1 mg/kg) permits the shorter onset time in RSI procedures. Subsequent maintenance doses can be reduced to 0.5 mg/kg. In the event that definitive airway management cannot be established, providers are then required to manage an apneic patient for an extended period of time. Heated debate persists whether rocuronium or succinylcholine is the preferred medication for emergent chemical paralysis during RSI procedures. The side effects of succinylcholine are weighed against the longer duration of rocuronium. Several other nondepolarizing muscle relaxers are available for ongoing chemical paralysis during patient transport or in a critical care unit.

CCTPs may encounter other nondepolarizing muscle relaxers. Vecuronium (Norcuron), pancuronium (Pavulon), cisatracurium (Nimbex), and atracurium (Tracrium) each have the same mechanism as rocuronium. The onset, duration, and certain side effects will vary among these medications. Long-term

chemical paralysis has many serious implications for CCTPs and other health care providers. Muscle weakness and neuropathies can persist long after chemical paralytic medications have been discontinued. These conditions can impair ventilator weaning, can prolong ICU admissions, and will further compromise patient recovery. It is essential that patients only receive chemical paralytic agents for the shortest duration and lowest possible dose. Intensive care providers can use a train of four measurement, post-tetanic count, or double-burst stimulation to assess for the correct level of medication in patients receiving long-term chemical paralysis. Special instruction is required before CCTPs perform or interpret these tests. Proper utilization of these tests will prevent excessive dosing of paralytic medications, which will minimize the risk and severity of long-term complications. *Train of four and other paralytic monitoring does not at all reflect the underlying level of sedation and analgesia in chemically paralyzed patients*. It is imperative that CCTPs and other health care providers carefully evaluate the level of sedation and analgesia in any patient who is chemically paralyzed. In many patients, particularly those with unstable hemodynamics, assessment of sedation and analgesia through vital signs is unreliable. Conversely, it is common for hypertension and tachycardia to be incorrectly treated with vasoactive medications when the underlying cause is undersedation and pain. *Inadequate sedation and analgesia in chemically paralyzed patients is commonplace in intensive care and critical care transport*. CCTPs must take careful steps to avoid this situation in any patient who is transported.

Patients undergoing chemical paralysis are also at high risk for decompensation or death when CCTPs do not carefully match ventilation settings with patient needs. Hyperventilation, evidenced by increased minute ventilation, is often a compensatory mechanism in critically ill patients. Once a patient is chemically paralyzed, disastrous consequences can occur if inadequate ventilator settings are used.

Airway medications used in critical care transport are summarized in **Table 7-3**.

Medications Used in Respiratory Management

Effective respiration requires both the movement (ventilation) of air into and out of the lungs as well as gas exchange at the alveolar-capillary level. When respiration becomes compromised, numerous medications are available to augment either of these two functions. Beta-agonist medications act upon receptors in the lower airways to improve airflow into and out of the lungs. Additional medications improve oxygenation and ventilation through further bronchodilation, inflammation reduction, and secretion control.

Various inhaled gases and exogenous surfactant appear to improve oxygen delivery and exchange in patients with respiratory disorders. The research continues regarding the safety and efficacy of these approaches. Specialized training and equipment are required for these medications and chemicals to be used in ICUs or during critical care transport, beyond the scope of this text.

Beta-Agonist Medications

Beta receptors play a significant role in the management of respiratory disease. There are two types of beta receptors in the sympathetic nervous system. Beta-1 receptors are found in the cardiac tissue and increase the heart rate, cause cardiac muscle to contract, produce automaticity, and trigger cardiac electrical conduction. Beta-2 receptors are found in the peripheral vasculature and in the respiratory tract. They stimulate vasodilation and bronchodilation. Stimulation of the beta-2 receptors allows treatment of asthma and other diseases that cause excessive narrowing of the bronchioles, such as respiratory syncytial virus, bronchitis, or emphysema.

TABLE 7-3 Airway Medications for Critical Care Transport

Indications	Mechanism of Action	Commonly Used CCT Medications and Route of Administration	Side Effects Common to This Medication Class	Special Considerations
Ultra-short-acting nonbarbiturate hypnotic agents: etomidate type				
Induction agent to facilitate airway device placement	Depresses the reticular activating system by stimulating GABA receptors	Etomidate (Amidate): IV	Adrenal suppression, apnea, hypotension, hypertension, tachycardia, bradycardia, myoclonus, nausea, vomiting	Multiple doses increase the likelihood of adrenal suppression. Avoid extravasation.
Ultra-short-acting nonbarbiturate hypnotic agents: ketamine type				
Induction agent to facilitate airway device placement	Interrupts pathways within the cortex and limbic system; prompts release of endogenous catecholamines	Ketamine (Ketalar): IV or IM	Hypertension, emergence reactions, increased ICP, vivid dreams, tremors	Consider premedication with benzodiazepines to prevent an emergence reaction. Ketamine may be the preferred induction agent in patients with respiratory failure.
Sedative-hypnotic agents				
Induction agent to facilitate airway device placement; short-term maintenance sedative for intubated patients; anticonvulsant medication used for refractory status epilepticus	Alkyl-phenolic compound with anesthetic properties; exact mechanism is unclear, but it is unrelated to other common opioid or sedative agents	Propofol (Diprivan): IV	Including but not limited to: hypotension, apnea, hypertension, cardiac arrhythmias, propofol infusion syndrome, iatrogenic infections, tachycardia, bradycardia	Use with caution in any patient who would experience devastating consequences to hypotension, even transient (such as in patients with traumatic brain injury). Use strict aseptic technique when handling medication or IV tubing. Avoid prolonged use. Administer at the minimum dose possible.
Benzodiazepines				
Sedative agents, often administered to facilitate airway device placement; maintenance sedative agents; anxiolytic agents; first-line anticonvulsant agents	Binds with benzodiazepine receptors on GABA neurons; enhances GABA inhibition of the CNS resulting in CNS cellular depression	Diazepam (Valium): IV, IM, PO, rectally Lorazepam (Ativan): IV, IM, PO Midazolam (Versed): IV, IM, PO	Sedation, respiratory depression, apnea, hypotension, ataxia, vasodilation	Benzodiazepines may cause paradoxical reactions in children. They are not ideal for use as a sole agent for anesthesia induction. They may produce desirable amnesia effects. The antagonist flumazenil (Romazicon) is available for use is situations involving benzodiazepine overdose. Use with caution in any patient with hypotension or potential hypotension.
Depolarizing muscle relaxant agent				
Short-term chemical paralytic to facilitate airway device placement	Activates, binds, and then occupies with acetylcholine receptor sites at the	Succinylcholine (Anectine): IV; may be given IM in extreme (emergency)	May cause or worsen hyperkalemia, causes a transient increase in	Consider pretreatment with atropine in patients prone to

airway device placement	receptor sites at the neuromuscular junction, preventing further activation, leading to chemical paralysis	extreme (emergency) circumstances. Onset: 30–45 s Peak effects: 1–3 min Duration: 7 to 10 min	transient increase in ICP; may cause bradycardia (especially in children), muscle fasciculations, or malignant hyperthermia	patients prone to bradycardia. Do not administer succinylcholine in repeat doses or as an IV drip. Avoid or use with caution in patients with acetylcholinesterase poisoning. Use with caution in patients with neuromuscular disease. Provides no analgesia or sedation; must be accompanied by analgesic and sedative medications.
Nondepolarizing muscle relaxant agents				
Short-term chemical paralytic to facilitate airway device placement; chemical paralytic agents for patients who require ongoing chemical paralysis for transport and certain modes of mechanical ventilation	Competitively antagonizes acetylcholine at receptor sites of the neuromuscular junction, causing extended chemical paralysis	Rocuronium (Zemuron): IV bolus or infusion. Onset: 60–90 s Duration: 45 min Vecuronium (Norcuron): IV bolus or infusion. Onset: 30 s Peak effects: 2.5–3 min Duration: 25–30 min Pancuronium (Pavulon): IV bolus or infusion. Onset: 30 s Peak effects: paralysis in 3–5 min Cisatracurium (Nimbex) IV bolus or infusion. Onset: 2–3 min Peak effects: 3–5 min Duration: 25–90 min Atracurium (Tracium): IV bolus or infusion. Onset: 2–3 min (dose dependant). Peak effects: 5–7 min Duration: 60–70 min	Apnea in unventilated patients, hypotension, hypertension, tachycardia, or bradycardia; atracurium may cause bronchospasm or excessive secretions	Use in caution in patients with neuromuscular disease. These medications provide no analgesia or sedation and must be accompanied by analgesic and sedative medications.

Abbreviations: CNS, central nervous system; GABA, gamma-aminobutyric acid; ICP, intracranial pressure; IM, intramuscular; PO, oral.

Beta-2 agonists may produce some beta-1 effects as well. As the dose of a medication increases, beta selectivity decreases. Beta-2 antagonism serves no clinical purpose; there are no circumstances in which the goal is to reduce the amount of air getting to the lungs via bronchoconstriction. Bronchoconstriction becomes a concern with beta-antagonist (beta-blocking) medications (discussed later) as the dose is increased and beta selectivity disappears.

Albuterol is a common sympathomimetic (mimics the body's sympathetic response) beta-agonist medication used in the treatment of respiratory disorders. Albuterol is considered a selective beta-2 agonist because it affects beta-2 receptors with little or no effect on beta-1 receptors. At a typical dose of 2.5 to 5 mg via nebulizer, albuterol relaxes the smooth muscles in the airway, thereby reducing constriction. Following inhalation or nebulization, the medication is deposited directly at the affected airway tissue, which provides a faster onset with reduced systemic effects. Caution must still be taken, however, because side effects, although fewer, may still occur. Although albuterol is a selective beta-2 agonist, we can still see beta-1 agonism in the way of increased chronotropic and inotropic effects. Cardiac manifestations occur frequently. These increased effects can increase myocardial oxygen demand in a situation in which there is a reduced oxygen supply. Cardiac manifestations range from mild tachycardia and hypertension to chest pain, arrhythmia, angina, myocardial ischemia, and even hypotension. Additionally, agitation, insomnia, dizziness, and irritability are common. In younger, healthy patients, the benefits tend to outweigh the drawbacks because the medication is intended to ultimately

increase oxygen supply. As patients get older with concomitant diseases, the risks and benefits of albuterol should be carefully considered. Despite the potential risks of the many side effects described, albuterol is well tolerated by most patients.

Patients with severe asthma, chronic obstructive pulmonary disease, or other reactive airway disease exacerbations are often placed on a continuous albuterol nebulizer regimen. Increased or prolonged administration places patients at risk for a variety of serious medical conditions, including metabolic acidosis, severe hypokalemia, and many of the cardiac manifestations previously discussed.

Levalbuterol (Xopenex) is a newer, more expensive alternative for patients at high risk for adverse reactions or side effects from albuterol. Headaches, nervousness, and dizziness are the most common side effects. Cardiac manifestations are relatively rare, with tachycardia occurring most frequently. Levalbuterol inhalation solution does not contain lecithin, a preservative used in some albuterol inhalation preparations that may trigger an allergic response in patients with a peanut allergy.

Terbutaline (Brethine) is a beta-2 agonist that is used as a bronchodilator and is commonly used as a tocolytic but is not FDA approved. As a beta-2 agonist, this medication also relaxes the airway smooth muscles to reduce constriction. With a dose of 0.25 mg SC every 20 minutes, this medication has been shown to begin improving respiratory status in as little as 5 to 6 minutes, but the peak effect is generally not seen for 20 to 30 minutes. The side effects are consistent with other beta-2 agonists, which include tachycardia, high blood pressure, trembling, and anxiety. Additionally, terbutaline may decrease serum potassium levels, which has the potential to cause cardiac arrhythmia, although this appears uncommon. Terbutaline should not be used for patients with tachycardia as a result of cardiac arrhythmias.

In more critical cases, it may be necessary to use a nonselective beta-agonist medication. In this case, epinephrine is used and can be administered subcutaneously or via a nebulizer. In either event, the dose should be 0.3 mg of epinephrine of a 1:1,000 (1 mg/mL) concentration. If nebulized, the medication should be diluted with 2.5 mL of normal saline. Racemic epinephrine is also available commercially as a single-dose ampule, premixed for nebulization. Subcutaneous administration requires no dilution. Although either route of epinephrine administration can be expected to have a rapid onset, both carry a significantly higher incidence of side effects. In such cases, the benefits must outweigh the risks of tachycardia, increased myocardial oxygen consumption, and peripheral vasoconstriction.

Mucokinetic and Bronchodilator Medications

In addition to the beta-agonist medication, a handful of other classifications of medications may be used to dilate the patient's lower airway.

The anticholinergic medication ipratropium bromide (Atrovent) is often used concurrently with albuterol. As an anticholinergic medication, ipratropium antagonizes the parasympathetic nervous system to reduce mucosal secretions in the airway and dilate the airway, although to a lesser extent compared with beta-agonists. Ipratropium tends to have a long onset time of 20 minutes and a half-life of 2 hours. It is most commonly administered via nebulizer at a dose of 0.5 mg every 20 minutes for 3 doses. The side effects are consistent with anticholinergic medications; they include nervousness, gastrointestinal (GI) upset, dizziness, and headaches. This medication should be avoided in patients with narrow-angle glaucoma.

Although not commonly used in the acute setting, theophylline is another non–beta-agonist option. The method by which theophylline functions remains uncertain. It is thought to stimulate a release of catecholamines and stimulate the diaphragmatic muscles. In critical care settings, the recommended dose is 6 mg/kg over 20 to 30 minutes for a loading dose, which is followed by a maintenance infusion of 0.5 to 0.7 mg/kg/h. Theophylline has numerous side effects and drug interactions. The most serious adverse reactions include respiratory arrest, seizures, and cardiac arrhythmias. Patients may also experience GI upset, headaches, agitation, tachycardia, and palpitations. Patients taking several types of antibiotics or

thyroid medications should not receive theophylline.

Corticosteroids

The treatment of inflammation, especially in the airway, is anchored by the use of corticosteroids. Corticosteroids work as anti-inflammatory agents but also have been found to increase the number of beta receptors in bronchial smooth muscle. A medication in this classification should be used in most severe and moderate cases of bronchial constriction. Pharmacologists remain unclear on exactly how corticosteroids carry out their functions, but do know that they reverse increased capillary permeability and thereby reduce inflammation.

Prednisone and methylprednisolone (Solumedrol) are commonly used in emergency and critical care settings. Both medications have a prolonged time of onset that can be as long as 4 to 6 hours. Corticosteroid treatment should be withheld in patients suspected of having many different types of infectious disease processes. A mild respiratory illness that accompanies or precipitates a reactive airway disease exacerbation is not generally a contraindication to corticosteroid therapy. The typical dose for prednisone is 40 to 60 mg/d, whereas the one-time dose for methylprednisolone is 125 mg. GI upset, hyperglycemia, and electrolyte imbalances tend to be the most common side effects.

Dexamethasone (Decadron) is also a corticosteroid used for inflammatory disorders, including airway edema, increased ICP, and high-altitude pulmonary edema. The use of dexamethasone has somewhat waned in recent years as the result of associated complications, including severe infections, hyperglycemia, hypokalemia, and myasthenia gravis. It is typically administered at a dose of 4 mg. Adverse reactions include appetite and mood changes, hyperglycemia, and anxiety.

Prednisolone is a corticosteroid that has the lowest percentage of placental crossing. It is sometimes used when absolutely necessary in pregnancy. The dose is 1 mg/kg per os (by mouth) in pediatrics and 40 to 60 mg per os in pregnant adults.

Respiratory medications used in critical care transport are summarized in **Table 7-4**.

Medications Affecting the Cardiovascular System

The cardiovascular system is complex. This section of the chapter discusses the variety of medications commonly encountered when treating the cardiovascular system. The cardiovascular system is made up of the pump (the heart), the container (the vasculature), and the fluid (the blood). The medications used to treat problems with each of the three components are examined.

When looking at the heart, CCTPs should have three main areas of concern: the **chronotropic** aspect, the **inotropic** aspect, and the cardiac rhythm. Each of these is vital to the effective functioning of the heart. Some medications have effects on two or three of the aspects, whereas others have effects limited to only one aspect. Occasionally clinicians and reference sources mention the **dromotropic** aspect, which relates to intracardiac conduction and can be altered by certain medications as well. Dromotropy becomes a concern when multiple cardioactive medications are administered simultaneously. Medications such as catecholamines, beta-blocking agents, calcium channel–blocking agents, and anticholinergic agents may simultaneously affect the heart and blood vessels. Other medications involved in the management of cardiovascular conditions include anticoagulants and thrombolytics, phosphodiesterase inhibitors, and diuretics.

Alpha-Adrenergic Antagonists (Alpha-Blockers)

Alpha receptors are present in vascular smooth muscle and cause vasoconstriction when acted upon by endogenous catecholamines, particularly epinephrine and norepinephrine. Numerous medications antagonize alpha receptors as an unwanted side effect. Haloperidol (Haldol is discussed later in this chapter) and trazodone (Desyrel) are two psychiatric medications that possess alpha-antagonistic

properties causing hypotension, often postural, as a side effect. The alpha-blocker class of medications has been developed to treat hypertension, benign prostatic hyperplasia, glaucoma, and pheochomocytomas (catecholamine-producing tumors) by blocking alpha receptors in the vasculature and select organs (such as the eyes, intestines, or bladder). Clonidine (Catapres) and phentolamine (Regitine) are alpha-blocking medications encountered periodically during critical care transport. Numerous other alpha-blocking oral medications are in use clinically and may be observed as a patient's personal medication. These include terazosin (Hytrin), doxazosin (Cardura), and methyldopa (Aldomet). Labetolol is a medication used in critical care medicine with both alpha-antagonistic and beta-antagonistic properties.

TABLE 7-4 Respiratory Medications for Critical Care Transport

Indications	Mechanism of Action	Commonly Used CCT Medications and Route of Administration	Side Effects Common to This Medication Class	Special Considerations
Beta-agonist medications				
Reactive airway disease, bronchospasm	Activate beta-2 receptors in the respiratory tract, causing bronchodilation	Albuterol (Ventolin): Nebulization, metered-dose inhaler Levalbuterol (Xopenex): Nebulization, metered-dose inhaler Terbutaline (Brethine): SC Epinephrine (Adrenaline): Nebulization, SC, IM, IV	Tachycardia, hypotension, hypertension, chest pain, CNS stimulation, irritability, nervousness, headache, palpitations	Prolonged use of albuterol may cause metabolic acidosis. Use with caution in patients with cardiovascular disease.
Anticholinergic bronchodilator medications				
Reactive airway disease, bronchospasm	Block acetylcholine at bronchial smooth-muscle receptor sites	Ipratropium (Atrovent): Nebulization, metered-dose inhaler	Palpitations, bronchitis	Administered only every 6-8 h.
Theophylline derivatives				
Reactive airway disease, bronchospasm	Block phosphodiesterase and stimulate the release of endogenous catecholamines	Theophylline or Aminophylline: PO and IV	Tachycardia, nervousness, restlessness, nausea, vomiting	Numerous food and medication interactions may occur.
Corticosteroids				
Inflammatory disorders, airway edema, cerebral edema, high-altitude pulmonary edema	Suppress immune response; restore normal capillary permeability; limit neutrophil migration	Methylprednisolone (Solumedrol): IM or IV Prednisone: PO Dexamethasone (Decadron): PO and IV Prednisolone: PO	Insomnia, nervousness, immunosuppression, hyperglycemia	Use with extreme caution or avoid in patients with many active infections. Numerous side effects may occur, especially with long-term administration. Numerous medication interactions may occur.

Abbreviations: CNS, central nervous system; IM, intramuscular; PO, oral; SC, subcutaneous.

Clonidine is given during a hypertensive crisis, 0.1 to 0.2 mg orally. Common side effects of clonidine include dry mouth, dizziness, drowsiness, weakness, and orthostatic hypotension. The onset is typically ½ to 1 hour with effects lasting from 6 to10 hours.

Phentolamine should be carried by any transport provider who administers any IV medication with alpha-adrenergic properties (such as norepinephrine, epinephrine, and dopamine). These medications ideally should be administered through well-placed central venous access. In many situations, only peripheral IV access is available or possible to obtain. If inadvertent peripheral extravasation of alpha-adrenergic medication occurs, the resulting tissue necrosis can be devastating. Diluted phentolamine is injected into affected tissues near the site of extravasation to prevent local vasospasm and cell or tissue death. Effective therapy is demonstrated by normal skin color return within 1 hour.

Labetalol (Trandate, Normodyne) is a medication with both alpha- and beta-blocking (antagonist) properties. It can be given orally or intravenously for the management of chronic or emergent hypertension, respectively. It is contraindicated in pregnancy, although it has been recommended for use in moderate to severe preeclampsia. Avoid administering beta-blockers, including labetalol, when a patient has a high-degree (greater than first-degree) heart block or sick sinus syndrome. Heart failure and cardiogenic shock are other situations in which labetalol is contraindicated. The initial IV dose is 0.25 mg/kg, with escalating doses up to 40 to 80 mg each to a maximum total dose of 300 mg. Labetalol can also be administered as a continuous IV infusion of 2 mg/min (also to a maximum total dose of 300 mg). Effects begin in less than 5 minutes following an IV dose and last up to 4 hours.

Angiotensin-Converting Enzyme Inhibitors

Angiotensinogen is a blood plasma protein component and is acted upon by renin, which is released from the kidneys in response to decreases in blood pressure, to form angiotensin I. Angiotensin-converting enzymes, also found in the bloodstream, transform angiotensin I into angiotensin II. Angiotensin II is a formidable vasoconstrictor, but its creation is slowed by medications that inhibit angiotensin-converting enzymes, or ACE inhibitors. ACE inhibitors also block the breakdown of the vasodilator bradykinin, which also improves blood pressure. These medications are contraindicated if patients have any history of an angioedema reaction to prior administration of an ACE inhibitor.

Captopril (Capoten) is a popular ACE inhibitor found in the critical care setting. In addition to its use for hypertension, captopril may be used for congestive heart failure and acute myocardial infarctions. Typically given at a dose of 12.5 to 50 mg orally, patients should be monitored for hypotension, dizziness, and electrolyte imbalances. The drug effects peak in 1 to 1.5 hours and have a half-life of less than 3 hours.

The critical care paramedic may also use enalapril (Vasotec) to control a patient's blood pressure. It is often given intravenously to patients with hypertension or heart failure. Enalapril is also a common ACE inhibitor and works similarly to captopril, but it has a much longer half-life at 11 hours. Enalapril begins working in approximately 1 hour and peaks in 3 to 5 hours. Enalapril is given at a dose of 0.625 to 1.25 mg IV every 6 hours and has side effects similar to captopril.

Antiarrhythmic Medications

Patients with cardiac rhythm disturbances create a considerable challenge for CCTPs. In extreme circumstances, these rhythm disturbances can deteriorate into a complete loss of organized cardiac activity. The management of cardiac arrhythmias involves several classes of antiarrhythmic medications, many of which create additional risk for catastrophic and lethal rhythm disturbances. For a review of cardiac action potential, see Chapter 13.

The classification of antiarrhythmic medications is a general, broad-based class that is broken down further based on the medication's mechanism of action according to the **Vaughan-Williams classification scheme**. Class I antiarrhythmic medications all work by blocking sodium channels. In doing so, the medication reduces the phase 0 slope and the peak of the action potential. Class I drugs are further divided into IA, IB, and IC based on their strength and degree of phase 0 reduction. Class IA is considered moderate, class IB is weak, and class IC has a strong reduction. The general principle behind sodium channel blockades is to reduce the rate and magnitude of depolarization by decreasing conduction velocity in non-nodal tissue. Recall that nodal tissue generates the initial electrical impulse. Non-nodal tissue receives stimulation from nodal tissues or neighboring cells to initiate depolarization. With the advent of newer medications with several simultaneous mechanisms of action (amiodarone, for example), the Vaughan-Williams classification system has significant limitations.

Class I Antiarrhythmic Medications

Class IA medications have been found to increase the effective refractory period (ERP). This term refers to the interval within the cardiac cycle during which cardiac cells (and muscles) are chemically unable to reenergize. During this time additional action is impossible. By increasing the ERP, the medication interrupts reentry mechanisms by decreasing the cells' ability to recharge and depolarize as quickly. The class IA medications tend to be anticholinergic medications such as quinidine, procainamide, and disopyramide. There are some significant drawbacks with this class, however, particularly pertaining to the effects on patients with preexisting infarctions or structural heart diseases. They also tend to have significant adverse reactions, including lupuslike syndromes (inflammation of the heart tissue including the valves and pericardium), in as many as 30% of long-term procainamide users.

Of the class IA medications, procainamide is the medication most commonly encountered in the acute setting. Given as an infusion, the typical dose is 20 to 30 mg/min, with a maximum dose of 17 mg/kg. When administering procainamide, the CCTP must also be mindful of the clinical endpoints of a 50% widening of the QRS complex, the arrhythmia being suppressed, or the patient becoming hypotensive. Along with the lupuslike syndromes, the patient may also experience widening of the PR and QT intervals, atrioventricular blocks, seizures, and CNS depression.

Class IB medications are slightly different in that they carry out their functions by decreasing the ERP and the action potential duration (APD). The APD is the amount of time that the action potential cycle takes to occur. When the ERP and APD are decreased, the automaticity is decreased, which reduces the tendency to depolarize in a disorganized fashion. These medications are indicated for ventricular fibrillation, ventricular tachycardia, and ventricular irritability. Lidocaine has a greater impact on ventricle cells with longer action potentials than atrial cells with shorter action potentials. Lidocaine is the prototypical class IB medication. At a dose of 1 to 1.5 mg/kg and a repeat dose of 0.5 to 0.75 mg/kg, lidocaine remains a treatment option for patients experiencing cardiac arrhythmias originating in the ventricles. Some clinicians and organizations such as the American Heart Association have decreased the emphasis on lidocaine in favor of amiodarone (discussed later) for treatment of certain ventricular arrhythmias. The medication reaches peak effect in about 5 minutes but has a highly variable duration of action. Caution should be exercised so as not to exceed the maximum dose of 3 mg/kg.

Class IC medications work by suppressing the phase 0 repolarization. Class IC medications differ from the other class I medications in that they have virtually no effect on the action potential. By suppressing repolarization, the conductivity is reduced through the heart. Class IC medications are used for life-threatening arrhythmias originating in the ventricles. Some studies have indicated a propensity for ST-segment elevation with the use of class IC medications. Flecainide is a prototypical class IC medication. This oral medication is not routinely used in critical care transport. Interestingly enough, medications in this class can be proarrhythmic as well. They can precipitate ventricular arrhythmias, heart failure, and cardiac arrest, seemingly in the case of an acute myocardial infarction within the previous 2 years.

Class II Antiarrhythmic Medications/Beta-Adrenergic Blocking Agents

The class II antiarrhythmics are comprised of the beta-blocking medications. The cardiovascular system is influenced by the sympathetic nervous system, particularly by epinephrine and norepinephrine binding to the adrenergic beta-1 and beta-2 receptors. Beta-blocking medications work to antagonize the beta receptors by competitively binding to the beta receptor sites to inhibit stimulation. Earlier beta-blocking medications were considered nonselective because they indiscriminately blocked both beta-1 and beta-2 receptors. More recent versions are relatively selective for beta-1 receptors, although some beta-2 binding occurs, particularly with higher doses. These sympathetic nervous system blocking medications, or sympatholytics, have several uses, including the treatment of arrhythmias, hypertension, acute myocardial infarctions, and congestive heart failure. In the event the medication causes an excessive

blockade, the patient may experience bradycardia, heart failure, hypotension, and atrioventricular blocks. Especially with the use of nonselective beta-blocking medications, bronchoconstriction and hypoglycemia may occur. Propanolol is a common nonselective beta-blocking medication.

Metoprolol (Lopressor) is a selective beta-1 blocking drug that decreases the automaticity of the heart tissue. This effectively decreases cardiac output and systemic blood pressure. Metoprolol should be given at a dose of 5 mg IV every 2 to 5 minutes for three doses. The medication should then be titrated to achieve the desired effect of a heart rate between 60 and 90 beats/min and a safe blood pressure level. Metoprolol should not be used for patients with severe congestive heart failure, bradycardia, or cardiogenic shock. In addition to close monitoring of the patient's pulse rate, blood pressure, and respirations, particular attention should be given to the blood glucose level because metoprolol may reduce signs and symptoms of acute hypoglycemia. Furthermore, patients withdrawing from this medication may experience severe thyroid complications.

When a patient with supraventricular tachycardia, A-fib/A-flutter, or hypertension needs a shorter-acting beta-blocking medication, esmolol (Brevibloc) may be an appropriate choice. The effects of esmolol last approximately 10 to 30 minutes (except following cumulative doses), which makes adjustments easier when compared with longer-acting medications. Esmolol should be given with a loading dose of 250 to 500 μg/kg over 1 to 3 minutes. The patient should then be administered 50 μg/kg/min over 4 minutes. The infusion is either maintained at 50 μg/kg/min or increased by 50 μg/kg/min every 4 minutes (or longer) until the desired effect is achieved, to a maximum esmolol infusion rate of 200 μg/kg/min. Patients with atrioventricular blocks and uncompensated congestive heart failure should not receive this medication. There are many medication interactions that the provider must consider when administering this medication, including nonopiate pain medications and most other cardioactive medications. Extravasation can cause tissue necrosis.

Class III Antiarrhythmic Medications

The third class of antiarrhythmic medications is composed of the potassium channel blockers. Potassium channels open immediately after cardiac cell depolarization and allow for repolarization to occur. Potassium channel–blocking medications work by blocking these potassium channels, thereby delaying the phase 3 repolarization of the cardiac cells. When this occurs, we find an increase in the action potential duration and the effective refractory period. Because the medication increases the refractory period, we tend to see prolonged QT intervals on the patient's electrocardiogram (ECG). This effect makes potassium channel–blocking medications particularly useful for treating re-entry tachycardias and arrhythmias occurring as a result of cellular depolarization due to excessive excitability.

Amiodarone (Cordarone) is the most common class III antiarrhythmic medication, even though it also has properties that are consistent with other categories. As with the other antiarrhythmic medications, the class III medications can be proarrhythmic as well as antiarrhythmic. Amiodarone can precipitate torsade de pointes, atrioventricular (AV) blocks, and bradycardia, which make it contraindicated in the presence of bradycardia or AV blocks. The initial dose for patients in cardiac arrest is 300 mg IV rapid by push (if no pulse is present) followed by a repeat dose of 150 mg IV. Patients who are not in cardiac arrest may benefit from an initial dose of 150 mg IV given over 10 minutes. Numerous other dosing patterns are used for different indications. The onset of action is variable, and peak effects may not occur for days or weeks. Consult a reliable medication reference source for dosing in other (noncardiac arrest) situations.

Class IV Antiarrhythmic Medications/Calcium Channel–Blocker Medications

To conclude the Vaughan-Williams classifications, the class IV antiarrhythmic medications consist of the calcium channel blockers. Calcium channel–blocking medications bind to the L-type calcium channels in the cardiac and vascular smooth muscle cells. L-type calcium channels play a primary role in cardiac

nodal automaticity and phase 0 of the action potential. In other words, the L-type calcium channels influence the impulse generating and depolarizing activities of the sinoatrial and atrioventricular nodes. By blocking the calcium channels, these medications cause vasodilation, negative inotropy, negative chronotropy, and negative dromotropy (decreased electrical conduction velocity). Although calcium channel–blocking medications decrease the automaticity of aberrant pacemaker sites, the greatest influence comes in their ability to decrease the conduction velocity through the AV node. This factor makes class IV antiarrhythmic medications useful for tachyarrhythmias originating in the atria.

Currently, there are only two calcium channel–blocking medications used for treating arrhythmias: verapamil (Calan) and diltiazem (Cardizem). Each medication is effective in reducing atrial tachycardias, but diltiazem has been shown to have less risk of hypotension than verapamil. Verapamil is typically given at a dose of 2.5 to 10 mg IV over 2 minutes. The dose can be repeated at 5 to 10 mg after 15 to 30 minutes. Diltiazem is given at a dose of 0.25 mg/kg IV over 2 minutes. Neither medication should be given to patients who have preexisting bradycardias, Wolff-Parkinson-White syndrome, or heart failure. Additionally, patients taking a beta-blocking medication may experience a potentiation effect and should not receive calcium channel blockers.

Adenosine

Adenosine is a different type of antiarrhythmic. It is classified as an endogenous nucleoside, meaning it is a naturally occurring protein that is a substantial part of cellular metabolism. This medication works to interrupt re-entry pathways through the AV node. The AV nodal conduction is slowed, and the AV nodal refractory period is prolonged. In doing so, it can restore a sinus rhythm in patients who have paroxysmal supraventricular tachycardia. Adenosine is not effective in converting atrial fibrillation, but may be used as a diagnostic tool when differentiation between atrial fibrillation and supraventricular tachycardia cannot be made because of the rate. Because adenosine is quickly absorbed by vascular endothelial cells, it has an exceptionally short duration of action of around 12 seconds. It must be given as a rapid IV bolus followed by a rapid IV bolus of at least 10 mL of normal saline through an IV site no more distal than the antecubital fossa. Once adenosine is administered at an initial dose of 6 mg, you can expect the patient to exhibit a brief period of profound bradycardia or even asystole. This pause, although disconcerting, is brief and usually well tolerated. Communicating with the patient and other bystanders to anticipate this occurrence will mitigate much of the stress. If successful, this period should be followed by a sinus rhythm. Unsuccessful conversion will result in the heart rate returning to near the original rate, at which time a second and third dose of 12 mg IV can be administered. The side effects of the medication include flushing, chest pressure, and light-headedness. Adenosine should be avoided or used with extreme caution in patients taking dipyridamole (Persantine) and carbamazepine (Tegratol) because of likely potentiation effects. Adenosine can be administered for paroxysmal supraventricular tachycardia associated with Wolff-Parkinson-White syndrome, but CCTPs should have a cardioverter or defibrillator immediately available if the patient's condition or rhythm suddenly deteriorates.

Anticholinergic Medications

Anticholinergic medications have a wide variety of clinical uses. Diphenhydramine, a potent antihistamine, and various histamine-blockers are discussed later. Other anticholinergic medications are administered therapeutically to treat nausea and vomiting, excessive secretions from a variety of organs, abdominal cramps, and excess vagal tone leading to bradycardia or asystole.

Atropine is classified as an anticholinergic medication because it blocks the ACh receptors in the parasympathetic nervous system. Under normal circumstances, the parasympathetic nervous system causes the heart rate to slow following activation of these receptors. Atropine antagonizes these receptors to allow the heart rate to increase in response to endogenous sympathetic stimulation already present and

available within the body. When endogenous catecholamines are depleted or when bradycardia is not a result of increased parasympathetic stimulation, atropine is not likely to be very effective. Atropine, administered at a dose of 0.5 to 1 mg, with a maximum dose of 0.4 mg/kg, is the best treatment option for patients who are not experiencing myocardial ischemia or acute hemorrhage. The drug can be expected to begin working immediately, with a duration of action of 2 hours. Patients who receive atropine must be monitored for dizziness, palpitation, GI upset, arrhythmias, anticholinergic effects (blurred vision, dry mouth, and urinary retention), and paradoxical bradycardia when the medication is administered at low doses or too slowly. Atropine remains the medication of choice because it has predominantly chronotropic effects and little to no inotropic effects. CCTPs should be aware that atropine is not likely to be effective for increasing the heart rate in patients who have second- and third-degree heart blocks. In second- and third-degree heart blocks, CCTPs should anticipate the need for cardiac pacing instead of using atropine or when atropine is determined to be ineffective. Many RSI protocols include atropine as a prophylactic medication to prevent bradycardia from succinylcholine administration and airway manipulation, especially in pediatric patients.

Atropine, in addition to its use as the treatment for bradycardia and asystole, is essential for the emergent treatment of acetylcholinesterase inhibitor toxicity following exposure to certain pesticides and chemical nerve agents. A patient with this condition may require hundreds of milligrams of atropine. Tachycardia is not a contraindication for additional atropine in this situation.

Catecholamines and Sympathomimetic Agents

Dopamine, epinephrine, and norepinephrine are substances produced within the body to activate the sympathetic nervous system, which in turn initiates the fight or flight response from body cells, tissues, organs, and systems. These substances stimulate alpha- and beta-adrenergic receptors, resulting in many changes in the body. In healthy people, blood vessels constrict, cardiac output increases, blood coagulation increases, skeletal muscles strengthen, and large airways increase in diameter along with a myriad of smaller changes designed to improve the performance and efficiency of the human body. Collectively, dopamine, epinephrine, and norepinephrine are referred to as sympathomimetics or catecholamines based on their chemical structure. Each endogenous chemical described has been replicated pharmacologically for use in critical care and during patient transport.

Dopamine is available commercially for use as an IV infusion. In its natural endogenous form, it is a precursor to both norepinephrine and epinephrine within the body. Dopamine has positive inotropic effects by stimulating beta-1 receptors. In addition, dopamine stimulates alpha-1 receptors when given at a higher dose, which causes peripheral vasoconstriction. Dopamine also affects dopaminergic receptors. Dopaminergic receptors are found in the CNS as well as the pulmonary artery and atrias of the heart. Stimulation of the dopaminergic receptors increases myocardial contractility and cardiac output. The wide range of effects found with dopamine allow for a variety of uses. Patients may receive dopamine at a low dose in order to achieve a renal effect, up to 3 μg/kg/min, although the benefits remain undocumented. The intent is to increase the renal output and decrease fluid volume in the body. Slightly higher doses, between 3 and 5 μg/kg/min, will optimize the beta effects to increase cardiac output. Still higher doses of 5 to 20 μg/kg/min will provide the alpha effects to increase and maintain blood pressure. Patients may exhibit adverse reactions, including cardiac arrhythmias, hypertension, and increased myocardial oxygen demand. Dopamine typically has a peak effect around 5 to 10 minutes, and the effect terminates moments after the infusion is discontinued. In the event extravasation occurs, dopamine may cause tissue necrosis.

Epinephrine is another sympathomimetic with widespread effects. It can be used to support respiratory function by opening up larger airways. It augments blood pressure by increasing vascular tone. Epinephrine has chronotropic effects, but has even more inotropic effects on the heart. During cardiac

arrest resuscitation efforts, it is given at a dose of 1 mg IV every 3 to 5 minutes to enhance myocardial perfusion. When given intravenously, the onset can be expected within a few moments, with the duration lasting less than 10 minutes. Patients may exhibit hypertension, arrhythmias, pulmonary edema, and anxiety with administration. In various clinical situations, epinephrine is given as an IV bolus, an IV infusion, inhaled, nebulized, administered IM or SC, or administered via an endotracheal tube. Consult a reliable reference for dosing instructions when epinephrine is indicated.

For patients in cardiac arrest, the first or second dose of epinephrine can be replaced with vasopressin. Vasopressin is a naturally occurring hormone referred to as an antidiuretic hormone. The medication, when given at high doses, up to 40 units IV, has significant peripheral vasoconstrictive effects. It also has a much longer duration of action; therefore, no repeat dose is necessary and epinephrine should not be resumed for 10 to 15 minutes. Some evidence shows that vasopressin may also cause coronary artery constriction; therefore, caution should be exercised when using the medication in patients with profound cardiovascular disease. Vasopressin is an additional option, although not FDA approved, for patients in severe shock resulting from vasodilatation (such as sepsis). A vasopressin infusion is initiated at 0.0005 U/kg/h and titrated to clinical effect. Vasopressin is also administered for the treatment of diabetes insipidus and certain types of gastrointestinal hemorrhage.

Norepinephrine (Levophed) is another sympathomimetic that has significant beta-1 and alpha-1 agonist effects. It also is most commonly used for blood pressure control, although it should not be used for patients who are hypotensive as the result of acute hemorrhage. When norepinephrine is administered, patients may exhibit arrhythmias, tachycardia, hypertension, and decreased peripheral blood flow. When the drug is administered at an infusion rate of 0.5 to 1.0 μg/min, the peak effects can be seen after about 3 minutes and last less than 1 minute after the infusion is discontinued. The maximum safe dose of norepinephrine is 20 μg/min, although some tertiary care centers titrate infusions up to 40 μg/min.

Phenylephrine (Neo-Synephrine) is another treatment option for increasing a patient's blood pressure. The medication is classified as an alpha-agonist and causes vasoconstrictive effects by binding to, and stimulating, the alpha receptors in the vascular smooth muscle. By definition, phenylephrine is a sympathomimetic, but not a catecholamine, because of its pure alpha-agonist activity. Caution must be exercised because the vasoconstriction includes coronary arteries. Patients with impaired coronary circulation may experience myocardial ischemia. Phenylephrine is typically given as an infusion at a rate of 40 to 60 μg/min. It may be necessary to start the infusion at 100 to 180 μg/min until the blood pressure increases. Phenylephrine is ideal for situations in which vasomotor tone is lost, without simultaneous impairment of myocardial contractility.

Dobutamine (Dobutrex) is a frequently used sympathomimetic in critical care transport. Dobutamine stimulates beta-1 receptors to increase myocardial contractility. The major difference between dobutamine and dopamine or norepinephrine is that dobutamine has minimal chronotropic effects when compared with the other two medications. Peak effect is reached after 10 minutes, and the effects last for about 2 minutes after the infusion of 2 to 20 μg/kg/min is discontinued. Caution must be exercised because dobutamine may cause an increase in infarction size in patients experiencing an acute myocardial infarction. It may also precipitate cardiac arrhythmias, hypertension, and premature ventricular complexes. Dobutamine is known for worsening an already tenuous blood pressure. Consider starting treatment with dopamine to stabilize the patient's blood pressure before administering dobutamine to improve cardiac output in patients who require inotropic support.

Direct Vasodilator Medications

Hydralazine (Apresoline) acts directly on arterioles to produce vasodilation and lower blood pressure. It appears to be safe for use as an emergent antihypertensive in pregnant patients with preeclampsia. Additional uses include congestive heart failure, primary pulmonary hypertension, and malignant

hypertension. Numerous reported side effects include angina, reflex hypertension, and tachycardia. Blood pressure reduction begins in 5 to 20 minutes following IV administration and persists up to 4 hours. The initial dose for adults with hypertension is a 10-mg slow IV push reduced to a 5-mg slow IV push in pregnant patients.

Diuretic Medications

Diuretic medications can remove excess fluid from the circulating blood volume, alter the distribution of fluids within the body, enhance urinary elimination of harmful substances, and increase (or maintain) adequate flow through jeopardized kidneys. Treatment with diuretic medications is desirable in situations such as fluid volume overload, cerebral edema, hyperkalemia, and rhabdomyolysis.

The most common diuretic is furosemide (Lasix). Furosemide is a loop diuretic, which means it carries out its functions on the loop of Henle as well as the proximal and distal convoluted tubule. Furosemide inhibits the reabsorption of sodium and potassium salts, which in turn remove (excess) water. There is also evidence that furosemide produces renal vasodilation, which theoretically would improve hemodynamics in patients with fluid overload, although similar research disputes this claim. Several modifications to the dosing recommendations for furosemide have occurred over the past several years; doses may range from a 40- to 120-mg IV bolus and may include a constant infusion. Caution needs to be exercised because of the possibility of dehydration, hypotension, severe electrolyte imbalances, and alkalosis. The IV onset of action occurs in approximately 5 minutes, and the effects typically last about 2 hours. Recent recommendations for the treatment of acute heart failure de-emphasize the use of diuresis, noting that up to 40% of patients with acute heart failure are volume depleted. The relatively rapid effects of loop diuretics do not appear evident in critically ill patients; the effects of furosemide may not be seen for up to 2 hours after administration. Ultimately, routine use of loop diuretics in acute heart failure results in a longer hospital stay and increased mortality.

Some patients may receive a different diuretic called bumetanide (Bumex). Bumetanide is a loop diuretic that works similarly to furosemide. It should be given 1 to 2 mg IV over 2 minutes and repeated in 2 to 3 hours to achieve effect. The dose of bumetanide must be individualized in accordance with an FDA warning regarding excessive electrolyte and fluid depletion. Patients with preexisting electrolyte imbalances should not receive bumetanide. Most of the side effects are related to the electrolyte and fluid imbalances.

Mannitol is a common treatment choice for increased ICP in patients who have experienced a traumatic brain injury. Mannitol is an osmotic diuretic and is used because it pulls water out of the brain tissue into the vasculature. From there, mannitol causes an increase in renal output to rid the body of excess fluid. This diuretic is also used for enhanced urinary elimination of certain toxins, treatment of anuria from acute renal failure, and as a genitourinary irrigant. Mannitol has a rapid onset and a duration of 2 to 6 hours. It is commonly administered at a dose of 0.25 to 2 g/kg every 4 to 6 hours. Caution should be exercised because this medication can cause significant changes in electrolyte levels, which can have negative effects. However, the effects are generally much less than those caused by loop diuretics such as furosemide.

Nitrates

A traditional first-line medication for ischemic heart disease is nitroglycerin. Nitroglycerin also treats hypertension. This nitrate works as a vascular smooth-muscle relaxant, thereby allowing for a decrease in preload on the heart and an increase in vascular space into which fluid can move. Nitroglycerin is primarily a venous dilating agent, with limited effects on arteries, including coronary arteries. Typically given at a standard dose of 0.4 mg sublingually during the initial phase of treatment, some small-scale studies have shown potential benefit in doubling that dose in acute cases that involve pulmonary edema.

Beyond the initial phase of treatment, a nitroglycerin infusion can be used to maintain the decreased preload and vasodilation, often at a dose of 5 to 200 µg/min. Adverse reactions include headache, hypotension, dizziness, and reflexive tachycardia.

Sodium nitroprusside is a nitrate medication. Nitroprusside is not as commonly used to control blood pressure as other hypertensive medications, as a result of the increased chronotropic effects on the heart, but it can be effective at maintaining vasodilation. Nitroprusside is an arterial and venous dilator, which makes it more potent than nitroglycerin. Patients receiving this medication at an infusion rate of 0.5 to 10 µg/kg/m in require close monitoring because it can cause a precipitous decrease in blood pressure. The adverse reactions are similar to nitroglycerin but also include muscle twitching, acidosis, and cyanide-type poisoning in cases of accumulation after prolonged infusions.

Phosphodiesterase Inhibitors (Inodilators)

Milrinone (Primacor) can be used by CCTPs to improve cardiovascular performance. It is classified as a phosphodiesterase enzyme inhibitor, which means that it inhibits the cyclic adenosine monophosphate (cAMP) phosphodiesterase. This medication increases cardiac output by increasing the inotropic effect (cardiac contractility). Increased output occurs without increasing the heart rate or chronotropic effect. The medication simultaneously dilates blood vessels, which is helpful in patients with heart failure. Milrinone is considered to be a safer formulation than inamrinone, with less tendency to cause bone marrow or liver toxicity. Each can precipitate arrhythmias. Milrinone is given with a loading dose of 50 µg/kg over 10 minutes followed by a maintenance dose of 0.375 to 0.75 µg/kg/min. There is no evidence to support the use of milrinone for more than 48 hours, although patients with endstage heart failure may be maintained on long-term continuous infusions of milrinone. Ventricular arrhythmias, including ventricular fibrillation, are possible side effects in addition to hypotension and supraventricular arrhythmias. Serum potassium levels should be monitored in patients receiving this medication.

Anticoagulants, Fibrinolytics/Thrombolytics, and Blood Components

CCTPs will encounter situations that require dissolution of blood clots with thrombolytics, prevention of blood clots with anticoagulants, or expansion of the circulating blood volume with crystalloid and colloid medications. Each medication has the potential for significant harm from improper administration or inadequate monitoring. It is essential that CCTPs consider atypical causes of clinical signs and symptoms before administering anticoagulant or thrombolytic medications. Aneurysms and hemorrhagic events frequently mimic the clinical presentation of thrombus and embolus occlusion of the same organ. Aneurysms can cause chest discomfort and changes on an ECG. A cerebral hemorrhage can mimic a cerebral thrombus or embolus. Anticoagulant or thrombolytic medication use in these patients would likely be fatal.

Anticoagulant Medications

In many instances, it is necessary to prevent the coagulation of blood and the subsequent development of blood clots. The use of anticoagulant medications is common in the transport of critical patients. Aspirin is considered to be a first-line anticoagulant medication and is technically considered an antiplatelet medication. Aspirin works by inhibiting the enzyme cyclooxygenase. Cyclooxygenase is responsible for producing thromboxane A2, which activates platelets. By inhibiting cyclooxygenase, platelets are unable to bind and form a clot. Aspirin does not dissolve a clot that is already present, however, but will aid in the prevention of clot expansion. Every patient being transported for acute coronary syndrome or myocardial infarction should be considered for aspirin administration if the patient is not already receiving the medication.

Special Populations

Older trauma patients who have received anticoagulation medication need special attention during critical care transport. These patients are at increased risk for serious bleeding if they are inadvertently injured from being dropped, falling, or becoming involved in a vehicle crash. Use adequate patient restraint systems and care when moving the patient from one stretcher or bed to another.

Patients who have been administered too much of an anticoagulant medication should not receive rapid reversal if levels become elevated. Unusual bleeding or bruising and elevated coagulation studies on laboratory test results indicate excessive amounts of anticoagulant medications. It is essential to consider the risks of over-anticoagulation compared with the risk of excessive reversal. In many cases, the risk of blood clot formation exceeds the likelihood of spontaneous bleeding.

Medication options are available for high-risk patients who are unable to receive aspirin. Ticlopidine (Ticlid) and clopidogrel (Plavix) reduce platelet aggregation by blocking APD receptors on platelets without affecting prostaglandin metabolism as aspirin does. Ticlopidine has considerably more significant side effects than clopidogrel and appears to be losing favor among clinicians.

Clopidogrel has also demonstrated significant mortality benefits in patients with myocardial infarctions and is often given in conjunction with aspirin therapy. Depending on the situation, clopidogrel is given either 75 or 300 mg orally. Antiplatelet effects begin in about 2 hours and persist for 3 to 7 days. Gastrointestinal side effects predominate, but numerous other CNS, cardiovascular, and hematologic side effects are possible.

Emerging IV antiplatelet medications are becoming increasingly popular in the treatment of cardiac conditions and critical care transport. Glycoprotein IIB-IIIA inhibitors further undermine platelet activity in patients with acute coronary syndrome, especially prior to revascularization procedures. They disrupt the final common pathway for platelet aggregation. At the risk of oversimplifying their role and mechanism, it may be helpful to consider IIB-IIIA inhibitors as "super-aspirins." Abiximab (Reopro), eptifibatide (Integrilin), and tirofiban (Aggrastat) are each administered via IV infusion after an IV loading dose. As with any antiplatelet medication, a careful risk-benefit analysis of bleeding and other risks is essential prior to administration. Bleeding is the most common or obvious concern with these medications. Hypotension, bradycardia, and mild CNS side effects occur with varied frequency in these three medications. Consult a reliable medication reference source of individual dosing and administration information.

Heparin is another common anticoagulant medication. Heparin works by inactivating several blood factors to prevent fibrin formation. It also inactivates thrombin to prevent activation of more blood factors, giving it both anticoagulant and antithrombotic properties. Heparin is infused at a rate based on U/kg/h, depending on disease process and treatment goals. Most institutions administer a loading dose prior to infusion, but CCTPs will occasionally encounter situations in which the maintenance infusion is given without a loading-dose bolus. There are drawbacks to heparin administration, including the need for frequent determinations of partial thromboplastin time (PTT) or heparin level, as well as the lack of available oral form. CCTPs should review the latest lab values and the PTT prior to transport. Great care must be exercised when monitoring the patient for bleeding problems because controlling such hemorrhage is extremely difficult and life threatening. Many health care institutions require that at least two clinicians confirm the order and dose before heparin is administered to a patient. Heparin is also used SC as deep vein thrombosis prophylaxis in immobile, hospitalized patients. Many long-term indwelling vascular devices are flushed with heparin when they are not in use, as are short-term, temporary hemodialysis catheters. Be careful not to inadvertently flush large quantities of heparin into a

patient when accessing these indwelling catheters. Changes in a patient's neurologic status during transport create the concern for spontaneous intracranial hemorrhage and are an indication to discontinue heparin and any other anticoagulant infusions during transport.

Heparin has serious additional side effects. Heparin-induced thrombocytopenia (decreased platelet count)/thrombosis (blood clot), also known as HIT/T, is a syndrome with potentially lethal consequences for patients receiving heparin therapy. The mortality rate exceeds 30% in unrecognized or untreated patients. HIT/T syndrome can be distinguished from nonimmune-mediated (mild) thrombocytopenia because HIT/T appears between 4 and 14 days after beginning heparin therapy. Nonimmune-mediated thrombocytopenia appears within 4 days of starting heparin therapy. Twenty percent of thromboses associated with HIT/T occur in arteries, resulting in acute limb ischemia, cerebrovascular occlusion, and myocardial infarction. A thrombosis also frequently occurs as an extension or increase in the size of the original thrombosis that was being treated by heparin, significantly complicating the clinical situation.

HIT/T should be suspected whenever the platelet count decreases by more than 50% following heparin therapy. The diagnosis is confirmed by specialty laboratory tests, but the platelet decrease is highly suggestive of HIT/T, especially in the absence of other potential causes. HIT/T can occur with low-dose heparin administered SC and enoxaparin therapy. Heparin (or enoxaparin) administration should be immediately discontinued when HIT/T is suspected. The treatment for HIT/T includes the use of lepirudin (Refludan) and argatroban alternate anticoagulants and is best monitored by clinicians experienced in managing this syndrome.

Enoxaparin (Lovenox) is a low-molecular-weight heparin and can be used as an adjunct to thrombolytic medications in patients experiencing myocardial infarctions. It can also be used for patients with unstable angina and several other conditions. Similar to the standard heparin, enoxaparin inhibits various blood factors that form fibrin as well as increase antithrombin activity. Enoxaparin is administered at a dose of 30 mg IV bolus followed by 1 mg/kg SC, not to exceed 100 mg per dose. Twelve hours later, a second dose of 1 mg/kg can be given SC. Alternate dosing patterns are also available for various clinical situations. As with other forms of anticoagulant medications, it should not be administered to patients with bleeding problems or thrombocytopenia. There is no need to monitor PT or PTT values in these patients.

Warfarin (Coumadin) is an additional anticoagulant medication. Warfarin works by inhibiting the creation of vitamin K–dependent coagulation factors in the liver. A single dose can have effects that last as many as 5 to 7 days. Given typically at a dose between 2 and 10 mg (sometimes higher), warfarin carries significant and potentially fatal bleeding risks. It should not be administered to patients with bleeding tendencies, and a cumulative effect can occur in patients taking other anticoagulant, antiplatelet, and thrombolytic medications. Warfarin levels are monitored by obtaining an international normalized ratio, which involves a lab test result that reports the time it takes for blood to clot and compares it to the average time, and PT measurements. Medication doses and administration patterns are continuously adjusted to a target range for either of these values.

CCTPs frequently encounter patients on warfarin who have experienced devastating effects from inadequate monitoring and dose adjustments. It is not uncommon for a cerebral hemorrhage to occur when the anticoagulant effects of warfarin are potentiated by numerous medications, chemicals, and nutritional products. In severe over-anticoagulation situations, phytonadione (vitamin K, aquaMEPHYTON) can be given to counteract some of the anticoagulant effects. This situation should be approached cautiously. The reversal of anticoagulation can be equally as dangerous as over-anticoagulation in high-risk patients.

Thrombolytic or Fibrinolytic Medications

Thrombolytic medications differ from anticoagulants in that these medications break down an existing clot rather than prevent propagation. Thrombolytics convert plasminogen to plasmin. Plasmin is a natural

fibrinolytic that breaks down the fibrinogen and fibrin that compose clots. These medications should not be administered to patients who have undergone recent surgery or experienced problems with intracranial hemorrhage. Relative contraindications include hypertension, GI hemorrhage, and recent trauma.

Alteplase, also referred to as tissue plasminogen activator, or tPA, is identical to natural human plasminogen activator, which is used by the body to prevent excessive thrombus development. Alteplase is commonly used to break down clots that caused acute myocardial infarctions and acute ischemic cerebral vascular accidents. Patients who should not be given alteplase include those who have had recent strokes, intracranial or other internal hemorrhage, and severe hypertension. The typical dosing schedule is 15 mg as an IV bolus followed by an infusion of 0.75 mg/kg over 30 minutes without exceeding 50 mg. That schedule is followed by a maintenance infusion of 0.5 mg/kg over 60 minutes without exceeding 35 mg. If the patient weighs more than 65 kg, the dose changes slightly. The initial loading dose remains 15 mg, but the following infusion is given at 50 mg over 30 minutes, which is subsequently followed by 35 mg over the next 60 minutes. The total overall administration of all three doses should not exceed 100 mg. Alteplase has a short half-life of only 5 minutes, which often necessitates the concurrent administration of heparin to prevent the recurrence of the thrombus.

A close relative to alteplase, retaplase (Retavase) works similarly by producing plasmin. Retaplase, however, has been shown to diffuse throughout the clot with greater efficiency than alteplase and also has a half-life that does not necessitate infusion. The medication is given at a dose of 10 units IV over 2 minutes and can be repeated after 30 minutes if needed. The side effects and contraindications are the same as those found with alteplase. It is common for the second dose of retaplase to be administered during critical care transport, as the patient is en route to a tertiary cardiac care center. Signs of serious bleeding require withholding the second dose of retaplase.

Tenecteplase (TNKase) is a single-dose, weight-based thrombolytic that CCTPs are also likely to encounter. The mechanism and side effects are similar to the other thrombolytics previously discussed. Tenecteplase is given in combination with aspirin and heparin.

Streptokinase, another thrombolytic medication option, does not activate plasminogen. Instead, it binds to existing plasminogen to create additional plasmin. Streptokinase is derived from streptococci and carries some significant untoward effects, such as fever. It has a half-life of about 20 minutes and cannot be safely administered more than once in a 6-hour period as a result of the high antigenic properties. The dose ranges from 250,000 to 1.5 million units over 30 to 60 minutes, depending on the thrombus being treated. The untoward effects often necessitate discontinuation prior to therapeutic levels being reached. This medication appears to be less popular with clinicians, so its use in critical care transport is limited.

Blood Volume–Expanding Solutions

When intravascular volume is lost, it is necessary to replace the lost blood and other plasma fluids in order to maintain adequate circulation and perfusion to vital organs. As of the writing of this text, prehospital use of blood products and blood substitute products is still in the investigational stage and interfacility products is not yet commonplace. CCTPs must rely on other fluids to replace missing blood volume. There are predominantly two options for fluid resuscitation: crystalloid solutions and colloid solutions.

Crystalloid Solutions

Crystalloid solutions remain the most common choice for fluid replacement. A crystalloid is defined as a substance that forms a true solution and passes freely through a semipermeable membrane. In other words, the concentration of water and electrolytes is consistent with that of typical blood concentrations. There are three types of crystalloid solutions: isotonic, hypertonic, and hypotonic solutions. The categories are

based on the fluid's tonicity, or the amount of solutes dissolved in the fluid.

Isotonic solutions have the same tonicity as human blood. As such, the osmotic pressure does not cause fluid or electrolytes to shift into or out of the intravascular space. Instead, the solution will diffuse equally throughout intravascular and extracellular spaces. Isotonic solutions are advantageous in that they have been found to be safe because they tend not to create pressure and concentration gradients between the various fluid compartments within the body. Additionally, they are inexpensive and readily available in virtually every acute health care setting. As long as an isotonic solution is applied within the appropriate parameters, it can produce numerous beneficial effects for patients, including replacement of lost circulating intravascular volume, which increases tissue perfusion, promoting renal excretion of waste products and toxins; and replacement of cellular and interstitial fluids, which promotes cell, tissue, and organ functioning. The body requires two to three times more isotonic solutions when compared with colloid solutions to achieve similar volume expansion. Because the osmotic pressure is equal, crystalloid solutions easily transition into the interstitial spaces, which will cause pulmonary edema in the case of overadministration or heart failure. Normal saline and lactated Ringer's solution are the most common fluids used in this category. Providers of different medical specialties tend to have a particular preference to one of these solutions over the other.

Hypotonic solutions have lower concentrations of electrolytes when compared to the human body. As a result of the lower concentrations, the osmotic pressure moves fluid out of the intravascular space and into the intracellular space. These fluids, such as 0.45% sodium chloride solution, are not useful for hypovolemia because they will cause further collapse of the cardiovascular system. These solutions are usually only used in select situations and require careful monitoring for unintended alterations of body fluid distribution. Hyponatremia, cerebral edema, and death are possible with inappropriate administration of hypotonic IV solutions. CCTPs should note that 5% dextrose in water becomes hypotonic when the dextrose component is consumed by body tissues.

Hypertonic solutions have higher concentrations of electrolytes when compared to blood. When the solutions are administered, the osmotic pressure causes fluid to move out of the intracellular and extravascular spaces and into the intravascular space. Sodium chloride solutions, 3% and 5%, are included in the hypertonic solution category, but the use is limited because of the decreased intracellular fluid volume and inconclusive evidence regarding benefit vs mortality rates. Hypertonic saline is being investigated for numerous purposes, including sepsis management, trauma resuscitation, and treatment of tricyclic antidepressant overdoses. The safety and efficacy in these situations is still being evaluated.

Colloid Solutions

Colloid solutions contain a higher concentration of dissolved electrolytes than do typical blood concentrations. The resulting increased osmotic pressure causes interstitial fluid to be drawn into the intravascular space, thereby increasing the net fluid volume beyond the actual amount administered. This can be particularly problematic in the presence of increased capillary permeability. With this condition, the electrolytes can pass into the interstitial space and draw fluid out of the intravascular space. Life-threatening conditions occur when the permeability increases across the alveolar capillary membranes.

The debate continues as to whether colloid solutions are beneficial, indifferent, or harmful. Several studies have been conducted on the topic, and all three options have been demonstrated at one point or another. Most of the current literature discourages the use of colloids, citing an increase in mortality when these solutions are used.

Blood Products

Albumin falls into another classification of volume-expanding fluids: blood products.

Albumin is a colloid solution derived from human blood donations, processed to prevent infection

and then used for hypovolemia, burns, and certain surgical procedures. Albumin increases intravascular oncotic pressure, drawing extravascular fluid into the blood vessels. The role of albumin in many critical illnesses remains heavily debated. When vascular permeability is increased with certain critical illnesses, albumin has a tendency to leach out of blood vessels into interstitial spaces. The direction of oncotic pressure is reversed, drawing intravascular volume into interstitial spaces, dramatically complicating the clinical situation. In patients who are otherwise well hydrated, albumin is typically administered in a 25% solution. In patients with poor hydration, the concentration should be diluted down to 5% because the albumin will draw fluid from the interstitial spaces. For cases of hypovolemia, adults are commonly given 100 to 200 mL of the 25% solution with the option to repeat the administration in 10 to 15 minutes if needed. The dose administered to burn patients is based on their current hemodynamic status. Side effects are rare, but may include urticaria and nausea. Profound anemia and heart failure are contraindications to albumin administration. The use of sterile water as a diluent can cause fatal renal failure or hemolysis. Acceptable diluents include normal saline and 5% dextrose in water.

Hetastarch is a synthetic colloid solution that is designed to expand the plasma volume. A variety of electrolytes are contained in hetastarch, which in combination retain fluid in the vasculature to substitute depleted blood plasma. When using hetastarch, consideration must be given to the possibility of pulmonary edema, fluid overload, and congestive heart failure. Adult patients typically receive 500 to 1,000 mL based on the hemodynamic state. Pediatric patients should not be given hetastarch. Hetastarch should also be avoided in individuals with allergies to corn or corn products.

Dextran is another volume expander that CCTPs may encounter. It is used in situations when blood products are not immediately available or to prime the tubing of various external medical devices that sequester large amounts of blood. Initial dextran therapy should not exceed 20 mL/kg during the first day, with decreased dosing on subsequent days. Infusion should not exceed 20 to 40 mL/min in adults. An infusion pump is required for dextran administration.

Cardiovascular medications used in critical care transport are summarized in **Table 7-5**.

Medications Used for Neurologic Conditions

Neurologic illnesses, diseases, and conditions are commonly seen during critical care transport. Severity can range from mild anxiety or discomfort to devastating situations such as paralysis, brain injury, intractable seizures, or full brainstem herniation. Neurologic conditions can present following trauma, a myriad of illnesses, or toxic or environmental exposures, or as a consequence of interventions performed before or during critical care transport. Analgesia, anxiolysis, sedation, and seizure control are the main purposes of neurologic medications administered by CCTPs. Various medications with these properties are discussed in other sections of this chapter as well. Benzodiazepines, discussed in the airway medication section, are extremely versatile, treating anxiety, controlling seizures, and providing sedation in a vast array of clinical situations. Propofol, also discussed in the airway section, has potent sedative and anticonvulsant properties. Mannitol, a powerful diuretic medication, is often used to treat cerebral edema and may be a last alternative to save a patient from impending brainstem herniation. Magnesium sulfate, discussed later in this chapter, is effective in controlling seizures in preeclamptic and eclamptic obstetric patients. Medications commonly used in critical care transport to manage or prevent various neurologic conditions are also discussed.

Anesthetic, Antianxiety, Sedative, and Hypnotic Medications

Patient sedation may be warranted in a variety of situations. Several classifications of medications that provide sedation are available, whether the medication is being administered to patients experiencing anxiety or those requiring endotracheal intubation, and each has advantages and disadvantages. Benzodiazepines, which were discussed in the airway medication section, should be considered first-line

anxiolytic and sedative medications during critical care transport.

Haloperidol

Haloperidol (Haldol) is an antipsychotic medication that can sedate combative patients and those experiencing a psychotic episode. Although the exact mechanism of action remains unknown, it is believed that haloperidol works by selectively antagonizing dopamine D_2 receptors to produce a tranquilizing effect. Haloperidol generally has an onset of 10 minutes, with the peak effect usually occurring between 30 and 45 minutes, but possibly occurring later. This medication is not approved for IV administration, but is often used intravenously off label when emergent control of agitation is desired. Usual intramuscular dosing is 2 to 10 mg. The goal is to achieve sedation with the lowest possible dose because of the potential for a fatal condition known as neuroleptic malignant syndrome, which is discussed in Chapter 20. Additionally, providers should be prepared for the potential onset of extrapyramidal symptoms, which are involuntary muscle contractions of the face, neck, trunk, and/or extremities. Treatment for this condition follows individual agency guidelines, usually including intravenous benzotropine (Cogentin), diphenhydramine (Benadryl), or benzodiazepine medications. Respiratory and cardiac compromise is possible with haloperidol, especially with higher doses, and particularly with IV administration Also, an increased risk for prolongation of the QT interval exists, which may lead to torsade de pointes ventricular tachycardia.

Dexmedetomidine

Patients can be given a medication that antagonizes the alpha-2 adrenergic receptors. These neurotransmitters are inhibited, causing sedation for patients who are already intubated and ventilated. Dexmedetomidine (Precedex) is an alpha-2 agonist that may potentially be encountered by CCTPs. In addition to its use in intubated patients, dexmedetomidine has also been approved for sedation in nonintubated patients who undergo various invasive procedures. One benefit of dexmedetomidine is the 6-minute half-life, which may permit easier ventilator weaning or extubation. It is reported that this medication provides the sedative effects without the cardiovascular and respiratory compromise seen in other classes of sedatives. The typical loading dose is 1 μg/kg over 10 minutes followed by the maintenance dose of 0.2 to 0.7 μg/kg/h. Adverse reactions, although less frequent than other medications, include cardiovascular (hypotension and occasional bradycardia or atrial fibrillation) and potential respiratory system compromise. Infusions of dexmedetomidine should not be given for longer than 24 hours.

Anticonvulsant Medications

Although the exact mechanism behind various anticonvulsant medications is not completely clear, these drugs are believed to work by inhibiting the influx of sodium into cells. This halt of sodium transport decreases the ability of cells to depolarize and propagate the seizures. Several other types of drugs fall into the category of anticonvulsants based on the use and intended effect, including benzodiazepines, barbiturates, hydantoins, and valproic acid.

TABLE 7-5 Cardiovascular Medications for Critical Care Transport

Indications	Mechanism of Action	Commonly Used CCT Medications and Route of Administration	Side Effects Common to This Medication Class	Special Considerations
Alpha-adrenergic antagonists				
Hypertension, unwanted vasoconstriction from exogenous or endogenous catecholamines, pheochromocytoma	Block alpha receptors in vascular smooth muscle, preventing vasoconstriction from catecholamines	Clonidine: PO Phentolamine (Regitine): SC, IM, IV Labetolol (Trandate): PO, IV	Hypotension, tachycardia, dizziness, weakness, dry mouth, flushing, weakness	Phentolamine is infiltrated into subcutaneous tissues affected by extravasation of vasoconstrictor medications to prevent tissue necrosis.
ACE inhibitors				
Hypertension, left ventricular dysfunction, congestive heart failure	Prevent conversion of angiotensin I to angiotensin II, a potent vasoconstrictor; reduce aldosterone secretion	Captopril (Capoten): PO Enalapril (Vasotec): PO, IV	Hypotension, tachycardia, chest pain, palpitations, cough, hyperkalemia, angioedema	Numerous medication interactions occur. Be alert for ACE inhibitors causing sudden, unexpected angioedema, even in patients who have been previously taking ACE inhibitors.
Antiarrhythmic class I medications				
Treatment of various atrial or ventricular arrhythmias (different class I agents are appropriate for different types of arrhythmias)	Block fast sodium channels; inhibit depolarization of neuronal cells, decrease myocardial conduction velocity and automaticity	Procainamide: IV Lidocaine: IV, endotracheal tube	Hypotension, nausea, vomiting, unwanted conduction disturbances, cardiovascular collapse, numerous others	Correct any electrolyte disturbances. Avoid use in patients with any significant cardiac conduction abnormality without an appropriately functioning pacemaker.
Antiarrhythmic class II medications (beta-adrenergic blocking agents)				
Treatment of certain cardiac arrhythmias, hypertension, acute myocardial infarction, acute coronary syndrome; also used for tremors, certain psychological disorders, migraines	Competitively block beta receptors in heart, blood vessels; may affect other beta receptors at higher doses	Metoprolol (Lopressor): PO, IV Labetolol (Trandate): PO, IV Esmolol (Brevibloc): IV	Hypotension, bradycardia, conduction abnormalities, dizziness, hypoglycemia	Avoid use in patients with cocaine toxicity due to risk of unopposed alpha stimulation. Beta selectivity is lost following high doses or overdose. Avoid administration of IV calcium channel blockers with beta blockers within a short period of time.
Antiarrhythmic class III medications				
Various atrial or ventricular arrhythmias	Block potassium channels, which delay phase 3 repolarization and increase the effective refractory period	Amiodarone : PO, IV	QT interval prolongation, hypotension, bradycardia, other conduction abnormalities, flushing, edema, numerous cardiac arrhythmias, cardiovascular collapse, numerous additional side effects	Amiodarone affects sodium, potassium, and calcium channels along with alpha- and beta-blocking properties. Amiodarone has an exhaustive list of side effects and medication interactions.
Antiarrhythmic class IV medications (calcium channel blockers)				
Hypertension, certain types of tachycardia, migraines; also used for myocardial	Block L-type calcium channels especially in the SA and AV nodes;	Diltiazem (Cardizem): PO, IV Verapamil (Calan): PO, IV	Hypotension, bradycardia, conduction	Avoid administration of IV calcium channel blockers with beta-

hypertrophy, certain psychological disorders, and tocolysis	inhibit calcium influx into cells in arterial walls, decreasing systemic vascular resistance		disturbances, edema, flushing	blockers within a short period of time.
Antiarrhythmic medications				
Paroxysmal supraventricular tachycardia with or without Wolff-Parkinson-White syndrome	Replicate endogenous nucleoside, which slows or interrupts reentry pathways through the AV node	Adenosine (Adenocard): IV	Flushing, headache, dyspnea, hypotension, ECG changes, hyperventilation; prolonged asystole is possible	Administer rapidly through the largest proximal vein possible. Expect a significant sinus pause immediately following IV administration. Warn patient, family, or other bystanders of this event. Several significant medication interactions occur with adenosine.
Anticholinergic medications				
Bradycardia, asystole, acetylcholinesterase inhibitor toxicity may be given to prevent bradycardia in patients undergoing rapid sequence intubation; may also be used as a mucolytic agent in certain circumstances	Block acetylcholine receptors in the parasympathetic nervous system; counteract excessive vagal stimulation	Atropine: IM, IV, endotracheal tube	Arrhythmias, flushing, tachycardia, dry mucous membranes (may be beneficial), various CNS changes	Extreme quantities may be required for severe acetylcholinesterase inhibitor toxicity. Tachycardia is not an indication to withhold atropine in patients with acetylcholinesterase inhibitor toxicity.
Catecholamines and sympathomimetic agents				
Bronchospasm, airway edema, cardiac arrest, allergic or anaphylactic reactions, profound hypotension, profound bradycardia; certain medications may also be used when inotropic support or renal perfusion is needed	Mimic various effects and functions of the sympathetic nervous system through stimulation of alpha, beta-1, beta-2, and dopamine receptors in blood vessels, tissues, and organs	Dobutamine (Dobutrex): IV Dopamine (Inotropin): IV Ephedrine: IV Epinephrine (Adrenaline): Nebulized, SC, IM, IV, endotracheal tube Phenylephrine (Neo-Synephrine): IV Norepinephrine (Levophed): IV	Hypertension, tachycardia, worsening CHF, increased myocardial oxygen consumption, cardiovascular collapse, peripheral vasoconstriction/ischemia, anxiety, nervousness, restlessness (numerous others)	Continuous hemodynamic monitoring is essential for any of these medications. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis if the IV line infiltrates. Many vasoactive medications will worsen myocardial performance in compromised patients. Avoid using sodium bicarbonate in the same IV lines.
Direct vasodilator agents				
Hypertension, congestive heart failure, primary pulmonary hypertension	Cause direct dilation of arterial wall smooth muscles	Hydralazine (Apresoline): PO, IM, IV	Tachycardia, hypotension, rebound hypertension, vascular collapse, flushing, nausea, vomiting	Certain individuals may experience more profound hypotensive effects than others.
Diuretic medications				
Fluid volume overload, cerebral edema, various toxic exposures, hyperkalemia	Various depending on medication; may use either osmotic gradients or otherwise prevent	Furosemide (Lasix): PO, IM, IV Bumetanide (Bumex):	Hypovolemia, significant electrolyte abnormalities, dizziness, numerous	Closely monitor fluid volume and electrolyte status during and after administration. Do not

hyperkalemia, rhabdomyolysis	or otherwise prevent renal reabsorption of water, electrolytes, and waste products	PO, IM, IV Mannitol (Osmitrol): IV	dizziness, numerous additional abnormalities	administration. Do not use in patients who are physiologically unable to produce urine, such as those with severe chronic renal failure.
Nitrates				
Ischemic cardiac disease, hypertension; useful in patients who require preload reduction, afterload reduction, or vasodilation	Direct action on arterial and venous smooth muscles; nitroglycerin has primary effects on veins; each has effects on coronary and systemic arteries	Nitroglycerin (Nitrodur): Sublingual, transdermal, IV Sodium nitroprusside (Nitropress): IV infusion only	Hypotension, flushing, tachycardia, headache, light-headedness, dizziness, syncope	Thiocyanate toxicity is possible with sodium nitroprusside, especially during prolonged infusions. Monitor vital signs, acid-base status, and cyanide and thiocyanate levels during prolonged treatment.
Phosphodiesterase inhibitors				
Indicated in situations in which both vasodilation and inotropic support are required	Inhibit cAMP in myocardial and vascular tissues	Milrinone (Primacor): IV infusion (after loading infusion)	Hypotension, arrhythmias, nausea, vomiting	Do not use during or immediately after an acute myocardial infarction.
Anticoagulant medications				
Indicated in patients who are at high risk for the development of blood clots; also used to prevent extension of existing blood clots	Various: antiplatelet medications impair platelet aggregation or activation ability; other anticoagulant medications impair blood fibrin formation	Abciximab (Reopro): IV infusion Acetylsalicylic acid (Aspirin): PO Clopidogrel (Plavix): PO Enoxaparin (Lovenox): SC, IV Heparin (Hep-Lock): SC, IV Tirofiban (Aggrastat): IV infusion (after loading infusion)	Potentially life-threatening bleeding disorders, especially in high-risk patients; each medication can cause hematologic disorders; refer to a reliable medication reference prior to administration	Heparin and enoxaparin can each cause blood clot formation in addition to anticoagulation.
Thrombolytic medications				
Given in select situations in which coronary, cerebral, or systemic blood clots place patients at significant risk	Convert plasminogen to plasmin, which breaks down fibrinogen and fibrin in blood clots	Alteplase (Activase, tPA): IV bolus then infusion Reteplase (Retavase): IV bolus x2 Streptokinase (Streptase): IV infusion Tenecteplase (TNKase): IV bolus x1 Urokinase (Kinlytic): IV infusion (after loading infusion)	Potentially life-threatening bleeding disorders	A careful risk-benefit evaluation is essential prior to administration of any of these medications. Catastrophic or lethal complications can occur from uncontrolled hemorrhage following administration. Avoid any unnecessary invasive procedures or trauma in these patients.

Abbreviations: ACE, angiotensin-converting enzyme; AV, atrioventricular; cAMP, cyclic adenosine monophosphate; CHF, congestive heart failure; CNS, central nervous system; ECG, electrocardiographic; IM, intramuscular; PO, oral; SA, sinoatrial; SC, subcutaneous.

Initial pharmacologic treatment of seizures in prehospital and critical care transport should be done with IV benzodiazepines. Rectal diazepam is also an option if it is available for a patient without IV access. Diazepam and lorazepam are the preferred medications, but midazolam has unlabeled use as an anticonvulsant in status epilepticus as well. If seizures persist, if seizures are likely to recur, or if the patient has an illness or injury prone to seizures (such as toxic ingestion or traumatic brain injury), the patient should receive either phenytoin or fosphenytoin. Seizure activity, which is refractory to the previously discussed medications, should be treated with IV barbiturates (phenobarbital or pentobarbital) followed by propofol if necessary.

Phenytoin and Fosphenytoin

Dilantin, generically known as phenytoin, is an anticonvulsant medication prescribed to patients with seizure disorders. It can also be used in the patient with acute status epilepticus by administering 15 to 20 mg/kg IV, infused at a rate no faster than 50 mg/min or 1 mg/kg/min. It should not be used for patients with

cardiac arrhythmias, including AV blocks and bradycardia, though phenytoin is a treatment for arrhythmias in digoxin toxicity. Phenytoin can cause cardiac arrhythmias, including ventricular fibrillation and AV conduction abnormalities, and can cause hypotension as well. It may also cause significant tissue necrosis if extravasated. Extravasation of IV phenytoin causes a "purple glove syndrome," which has required limb amputation in severe situations. Oral phenytoin loading is much safer than administration of IV phenytoin and should be contemplated for conscious, stable, low-risk patients. Oral loading will take approximately 6 hours to reach a therapeutic plasma level. Meticulous dosing consideration is necessary when patients who are already taking phenytoin present following a seizure with a subtherapeutic plasma phenytoin level.

Fosphenytoin (Cerebyx) is a chemically modified form of phenytoin. It is designed to be modified by the body (biotransformed) into phenytoin, which makes it a prodrug of phenytoin. Because it transforms into phenytoin, the dose is documented as milligrams of phenytoin equivalents (PE). The dose for fosphenytoin is 15 to 20 mg PE/kg and should be administered at a rate of 100 mg PE/min. If seizure activity has not resolved, the dose can be increased to 30 mg PE/kg. The remaining information is the same as that for phenytoin. Plasma phenytoin levels will not be accurate until at least 2 hours after fosphenytoin administration.

Barbiturate Medications

Barbiturates are sedative medications, often used for anesthesia, with strong anticonvulsant properties. These medications are not routinely carried by CCTPs, but there is certainly the potential for CCTPs to monitor or administer these medications to patients with intractable seizures who require interfacility transport. These medications possess the ability to decrease cerebral metabolism and cerebral oxygen consumption in at-risk patients.

Phenobarbital is used as an anticonvulsant, although it falls into the barbiturate classification. It is given at a dose of 10 to 20 mg/kg IV for patients exhibiting status epilepticus. As a result of its barbiturate properties, it can cause respiratory and CNS depression. Effects begin in 5 minutes and peak in 30 minutes following IV administration. Both phenobarbital and phenytoin have small margins between therapeutic and toxic serum drug levels, which necessitate close monitoring.

In the event that the patient remains refractory to other medication treatments, pentobarbital may be administered as a last resort. Pentobarbital is a short-acting barbiturate that works as an anticonvulsant but also has sedative and hypnotic properties. Patients are administered a loading dose of 2 to 5 mg/kg and a maintenance dose of 0.5 to 3 mg/kg/h IV infusion. Patients with liver failure should not receive pentobarbital, and those who concurrently consume alcohol may experience an additive effect or death. Like most barbiturate medications, quick cessation of the medication should be avoided. These patients typically require endotracheal intubation for airway protection and ventilator support. Onset of this medication should occur in approximately 1 minute following administration.

Analgesic and Antagonist Medications

Pain is common during critical care transport. Patients experience pain resulting from an illness or injury, or as an unintended consequence of many therapeutic interventions performed by the CCTP. The use of morphine and other opiate-based medications is an essential component of patient care during these transports. Analgesia is the absence of the sensation of pain. Medications that relieve pain are referred to as analgesics. Opiate-based medications are not the only medications with analgesic qualities that are used by CCTPs. Ketamine, discussed earlier, acetaminophen, and various nonsteroidal anti-inflammatory drugs (NSAIDs) are frequently available to CCTPs as well. Sometimes the analgesic itself is not sufficient to relieve pain, in which case an adjunct medication may be given to enhance the effects of the analgesic. When an opiate-based medication is used in conjunction with a benzodiazepine, the dose of

each drug should be lowered to avoid the risk of respiratory depression, unless the patient has an adequately protected airway and supported respiration.

The most common class of medications used for analgesia in the critical care setting is the opioid agonist class. Opioid agonists, either created synthetically or derived from the opium plant, bind to opiate receptors. By blocking these receptors, they prevent the neurons from sending pain signals. Opioid medications are widely abused in society for their euphoric properties.

These medications are also CNS and respiratory depressants. Opioid toxicity or overdose can readily be identified by the triad of respiratory depression, sedation, and pinpoint pupils. The diagnosis of opioid intoxication is frequently confirmed with reversal of these symptoms by an opioid antagonist medication, discussed later.

Fentanyl, Sufentanil, and Morphine

Fentanyl (Sublimaze) is a popular opioid agonist because it is rapid acting, is very potent, and has a relatively short duration of action. It is a synthetic opiate that is said to be anywhere from 75 to 200 times the potency of morphine and also has minimal cardiovascular effects, although bradycardia, tachycardia, and arrhythmias have been reported. Hypotension is also possible, especially when sympathetic stimulation from pain is artificially maintaining an increased blood pressure. It is common for hemodynamic, CNS, and respiratory status to decline when painful stimulation is suddenly eliminated by opioid medications. With high IV doses of fentanyl, chest wall "rigidity" has been reported. The actual incidence of this in clinical practice is debated, but CCTPs should be aware that it may occur. When given at a dose of 0.5 to 2 μg/kg, the patient will experience analgesia within about 90 seconds, with an effective duration lasting approximately 30 minutes.

Sufentanil (Sufenta) is a similar medication to fentanyl, which also has significant analgesic effects with minimal cardiovascular effects. It is most commonly used in surgical settings, but it is possible for CCTPs to encounter patients receiving this medication. The dose is started at 1 to 2 μg/kg (up to 8 μg/kg) for analgesia and increased up to the dose range of 10 to 25 μg/kg when used as an anesthesia induction agent in pediatric patients. Doses greater than 8 μg/kg are considered induction doses. As with other opioid agonists, patients with respiratory compromise should not receive sufentanil unless their airway and ventilations can be supported. The adverse reactions are consistent with fentanyl, including chest wall rigidity, cardiac arrhythmias, and respiratory depression.

Morphine has long been popular for the prehospital induction of analgesia. It is commonly administered at a dose of 0.05 to 0.1 mg/kg, and it alleviates pain through CNS depressant actions. It also suppresses fear and anxiety centers in the brain and brain stem respiratory centers. It has a tendency to increase peripheral venous capacitance and decrease venous return, which decreases preload and afterload and ultimately decreases myocardial oxygen demand. Although this decrease in oxygen demand is typically considered a benefit, care must be exercised to prevent hypotension. Morphine can also cause respiratory depression and somnolence. It should not be given to patients who have respiratory compromise, including patients with asthma, or those who are hypotensive or hypovolemic. Patients frequently report a flushed or itchy feeling with morphine, which is a histamine release, not a true allergic reaction. Morphine may also precipitate (or worsen) nausea or vomiting. It should be avoided in supine patients, in patients who are likely to vomit, and in turbulent aircrafts.

Other Opiate-Based Analgesic Medications

Hydromorphone is a potent analgesic medication that is also well known by the trade name Dilaudid. This medication has a particularly high abuse potential. There is also a notably higher risk of respiratory arrest and death when combined with alcohol or other CNS depressants.

Nubain, or generically known as nalbuphine, is an opioid agonist-antagonist that has a much shorter

list of miscellaneous side effects, although the typical respiratory depression, hypotension, and somnolence still exist. Nalbuphine is typically given at a dose of 10 mg IV, IM, or SQ every 3 to 6 hours.

Naloxone and Other Opioid Antagonists

Opioid antagonists reverse the effects of opioid drugs. They work by competitively binding with the opiate receptors in an antagonistic manner, meaning they do not stimulate the receptor to initiate its action. As a result of this binding, the opioid molecules cannot get to the receptor. The most common opioid antagonist used in the prehospital and critical care transport setting is naloxone (Narcan). Given at a dose of 0.4 to 2 mg, the medication takes effect quickly, but has a shorter half-life than most opiate-based products, which could necessitate repeat administrations. Many opioid overdoses require much more than 2 mg. After 10 mg total without improvement, opioid intoxication is unlikely to be the cause of apnea or unresponsiveness. Patients with apparent opioid intoxication should only receive enough naloxone to restore effective respiratory functioning. Excessive naloxone in opioid-addicted individuals will cause violent withdrawal symptoms, placing the patient, CCTPs, and other health care providers at risk, with potentially lethal consequences. Patients should receive small doses of naloxone at short intervals, while airway and respirations are supported, until adequate reversal of symptoms occurs. The risk of withdrawal symptoms in at-risk individuals should not be underestimated.

NSAIDs

NSAIDs are an alternative to opioid-based analgesic medications. The natural reaction to injury or infection in the body is to promote inflammation in the area(s) involved in an effort to build up the defense and rebuilding cells. This promotion is carried out by prostaglandins, which also have involvement in fevers and platelet activities. Prostaglandins are created by an enzyme found in the cells called cyclooxygenase, or COX for short. Several NSAIDs work by blocking the COX enzymes and thereby decreasing the inflammation-causing prostaglandins.

Ketorolac is the generic name for Toradol. Ketorolac is a medication used for pain management that is in the NSAID category. It is typically administered at a dose of 30 mg IV or 60 mg IM. It is an effective and popular pain medication, but several important details exist pertaining to the use of this drug. It should only be used for short-term or acute pain and not for minor or chronic pain complaints, and it should not be used for more than 5 days total. Ketorolac has been found to cause severe GI ulcers, bleeding, and/or perforations. It can precipitate significant cardiovascular events, including thrombosis, and should not be used for patients with advanced renal impairment. It is also strongly contraindicated for use in patients with hemorrhagic risks and patients in labor.

Neurologic medications used in critical care transport are summarized in **Table 7-6**.

Medications Affecting the GI System

The role and significance of GI medications in critical care transport is easy to underestimate. Aircraft or vehicle turbulence, certain toxic exposures, medication side effects, and numerous clinical conditions can cause nausea or vomiting that requires treatment during transport. GI bleeding is an often lethal condition, requiring critical care transport and the administration of specialized medications. During or after a severe illness or injury, many patients require parenteral nutrition that is often continued during critical care transport. CCTPs will find themselves frequently administering GI medications.

TABLE 7-6 Neurologic Medications for Critical Care Transport

Indications	Mechanism of Action	Commonly Used CCT Medications and Route of Administration	Side Effects Common to This Medication Class	Special Considerations
Anesthetic, antianxiety, sedative, and hypnotic agents				
Patients who require sedation for comfort or safety during transport	Haloperidol blocks postsynaptic dopaminergic receptors, depresses the reticular activating system, and slows the release of hypothalamic hormones. Dexmedetomidine antagonizes alpha-2 adrenergic receptors, inhibiting neurotransmission.	Haloperidol (Haldol): PO, IM, IV (IV is common but unapproved) Dexmedetomidine (Precedex): IV infusion (after loading infusion)	Sedation, hypotension, bradycardia, nausea. Haloperidol has numerous significant side effects, including paradoxical agitation, ECG changes, neuroleptic malignant syndrome, and extrapyramidal symptoms.	Numerous side effects and medication interactions associated with haloperidol significantly limit its usefulness.
Hydantoin anticonvulsants				
Patients in status epilepticus or those who are at high risk for seizure activity (ICH, TBI)	Decrease cellular sodium levels in the motor cortex of the CNS; increase effective refractory period in neural cells; also possess antiarrhythmic activity.	Phenytoin (Dilantin): PO, IV Fosphenytoin (Cerebyx): IM, IV	CNS depression, cardiovascular collapse, tachycardia, nausea, cardiac arrhythmias (especially with phenytoin), venous irritation, Stevens-Johnson syndrome.	IV fosphenytoin is considered safer for administration than phenytoin. IV phenytoin should not be infused any faster than 50 mg/min in adults. Monitor IV sites closely for signs of infiltration.
Barbiturates				
Used periodically for sedation or for status epilepticus in patients refractory to first-line anticonvulsants	Depress the sensory cortex, which slows cerebral metabolism and decreases cerebral oxygen consumption.	Phenobarbital: PO, IM, IV Pentobarbital: IM, IV	Bradycardia, hypotension, syncope, profound CNS depression, respiratory depression, Stevens-Johnson syndrome, nausea, vomiting.	These patients typically require airway management while receiving IV barbiturates.
Opioid analgesic medications				
Pain control or prevention in patients with discomfort from illness, injury, or invasive procedures, or as an adjunct to sedation in mechanically ventilated patients	Bind with opioid receptors in the CNS, preventing painful impulse transmission	Fentanyl (Sublimaze): Transdermal, IM, IV Hydromorphone (Dilaudid): PO, SC, IM, IV Meperidine (Demerol): PO, SC, IM, IV Morphine sulfate (Roxinol): PO, SC, IM, IV Nalbuthine (Nubain): SC, IM, IV Sufentanil (Sufenta): IV	Respiratory depression, apnea, hypotension, bradycardia, palpitations, flushing, nausea, vomiting, noncardiogenic pulmonary edema	Titrate medication doses and intervals to each particular patient and situation. Opioid overdose may be reversed with an opioid antagonist medication.
Opioid antagonist medications				
Reversal of opioid intoxication following accidental, intentional, or therapeutic overdose	Displace opioids and bind with opioid receptor sites in the CNS	Naloxone (Narcan): Endotracheal tube, SC, IM, IV, intranasally	May precipitate withdrawal symptoms in patients addicted to opioids	Carefully titrate naloxone intervals and dosing to reverse opioid-induced respiratory depression and sedation without precipitating withdrawal symptoms. Many opioids have a longer duration of action than naloxone, risking undetected return of toxic symptoms.
NSAIDs				
As adjunctive pain relief in patients who have already received or cannot receive opioid medications; various NSAIDs have antipyretic properties as well; decrease inflammation	Inhibit prostaglandin synthesis by impairing the function of cyclooxygenase	Ibuprofen (Advil, Motrin): PO Ketorolac (Toradol): PO, IM, IV	Abdominal discomfort, gastritis, hematologic abnormalities, gastrointestinal hemorrhage, Stevens-Johnson syndrome, renal insufficiency	Provide adequate hydration. Administer oral preparations with food.

Abbreviations: CNS, central nervous system; ECG, electrocardiographic; ICH, intracranial hemorrhage; IM, intramuscular; NSAID, nonsteroidal anti-inflammatory drug; PO, oral; SC, subcutaneous; TBI, traumatic brain injury.

Histamine-2 Blocker Medications

Histamine-2 (H_2) blocker medications are used clinically to minimize the effects of gastric acids on the stomach and digestive tract. Acids and enzymes are produced in the stomach by cells in the stomach lining, including the gastric parietal cells. Stimulation of these cells can occur by stimulating the H_2 receptor on the cells. The medications used to reduce acid production do so by antagonizing the H_2 receptors. These medications are particularly useful because they are very selective for the H_2 receptors,

have no effect on histamine-1 (H_1) receptors, and have no anticholinergic effects. Despite this, H_2 blockers potentiate the effects of H_1 (common antihistamine) medications, which are used to treat allergic reactions and related symptoms. This additive effect is beneficial when treating anaphylaxis and other significant allergic reactions.

Ranitidine (Zantac) is one such H_2-blocking medication used to treat gastroesophageal reflux disease. There is no proven benefit of IV ranitidine compared with oral doses of 150 mg. Particular caution needs to be used in patients with renal failure, and adverse reactions include diarrhea, constipation, dizziness, dry mouth, and dry skin.

Cimetidine (Tagamet) works the same as ranitidine, but the dose is higher at 400 mg. Cimetidine may increase the serum levels of some cardiac medications and tricyclic anti-depressants. Elderly patients may experience confusion, and young males can experience impotence when taking cimetidine. Serious adverse reactions include neutropenia, anemia, depression, psychosis, and hallucinations.

Famotidine (Pepcid) is similar to both cimetidine and ranitidine. It selectively blocks the H_2 receptor to reduce the release of acid in the stomach. The dose is 20 mg and has no significant contraindications. Famotidine can cause cardiac arrhythmias, but most other serious side effects are extremely rare.

Phenothiazine Antiemetic Medications and Metoclopramide

The general classification of antiemetic medications, those intended to treat nausea and vomiting, is comprised of more specific classifications. Nausea and vomiting are typically triggered in the medulla and can also be triggered by the vestibular system. The vestibular system has a high concentration of both histamine and acetylcholine. By using certain antihistamine medications, the activity of the histamine in the vestibular system can be inhibited, thereby suppressing the stimulation to the medulla. The same suppression can be accomplished by blocking the acetylcholine receptors as well. Meclizine and dimenhydrinate are two examples of antihistamines used as antiemetics. Scopolamine is another anticholinergic used to treat nausea and vomiting. Both of these groups have similar adverse reactions, with sedation, visual acuity changes, and, most notably, the worsening of narrow-angle glaucoma.

The vomiting center of the medulla can be triggered by the neurochemical transmitter dopamine when it activates the D_2 receptor. Medications that antagonize the D_2 receptors are effective in reducing nausea and vomiting. Promethazine (Phenergan) and prochlorperazine (Compazine) are phenothiazine-type antiemetics that are in this category. Promethazine is typically administered at a dose of 12.5 to 25 mg IV or IM, which is cut in half for elderly patients. Significant drawbacks exist, however, because these medications have been found to have major side effects. They can cause considerable sedation, orthostatic hypotension, and extrapyramidal effects. Promethazine should always be diluted with normal saline when injected intravenously.

Prochlorperazine (Compazine) is very similar to promethazine in that it blocks dopamine at the D_2 receptor in the medulla. The dose is 2.5 to 10 mg every 3 to 4 hours when given IV. It is contraindicated in patients who have bone marrow disease and severe liver or cardiovascular disease. This medication frequently causes Parkinson-like syndromes and can produce extrapyramidal effects. It is imperative that prochlorperazine is administered slowly or by infusion. Rapid injection frequently causes orthostatic hypotension. Both prochlorperazine and promethazine have the potential for seizures and may increase the likelihood of seizures in patients already predisposed to them. Use caution with these medications in elderly and other at-risk patients.

Metoclopramide, or Reglan, has similar action on the D_2 receptors but also has the added benefit of increasing GI motility. This is accomplished by enhancing ACh effects on receptors in the upper GI tract. Metoclopramide can cause drowsiness, dizziness, akathisia, and dystonic reactions, similar to other phenothiazine antiemetics. CCTPs should administer 5 to 10 mg IV or IM to most routine patients who

require an antiemetic. When nausea and vomiting control is essential in situations such as chemotherapy and oral antidote administration, metoclopramide can be administered in large doses up to 1 to 2 mg/kg. Many providers administer diphenhydramine (Benadryl) in these situations as prophylaxis against dystonic reactions. Rapid IV infusion can cause a profound dysphoria. IM and IV infusions are strongly preferred. The action of metoclopramide begins within 1 to 3 minutes and persists for 1 to 2 hours.

5-HT_3 Receptor Antagonist Antiemetics

The serotonin antagonists are believed to cause their effect by selectively blocking serotonin receptors in the medulla to suppress the vomiting centers. These medications have been gaining popularity as a result of the relatively low-level adverse reactions. The most common reported reaction is fatigue, which is followed by headache and diarrhea. Ondansetron is typically referred to by its trade name Zofran and is administered at 4 mg IV, IM, or PO. Granisetron (Kytril) and dolasetron (Anzemet) are other 5-HT_3 receptor antagonists that are gaining popularity. They each have a mechanism similar to ondansetron. Granisetron is usually administered IV during critical care transport, ranging from 0.1 to 2 mg/dose. Dolasetron is given at 0.35 mg/kg up to a maximum of 12.5 mg, although much higher doses are used for chemotherapy. Dolasetron, ondansetron, and granisetron work well in preventing emesis but have minimal to varied effectiveness in patients who are already vomiting. Clinician experience demonstrates more effectiveness in the treatment of active vomiting than the mechanism would suggest.

Antisecretory Agents: Somatostatin and Octreotide

Upper GI bleeding is a frequent, often fatal, medical condition. One hundred thousand hospital admissions occur each year for this condition, and patients with upper GI bleeding have an overall 10% mortality rate. Causes of upper GI bleeding include duodenal ulcers (approximately 35%), gastric ulcers (approximately 20%), hemorrhagic gastritis (18%), and esophageal varices (5% to 11%, depending on geographic region). Esophageal varices occur as a consequence of elevated portal venous pressure (portal hypertension), where portosystemic and gastroesophageal collateral blood pathways develop. Severe, potentially lethal, GI hemorrhage is the most significant risk associated with esophageal varices.

Somatostatin is a naturally occurring peptide chain that decreases intestinal fluid secretion, slows GI motility, and reduces portal blood flow with vascular smooth-muscle vasoconstriction. Somatostatin has been replicated pharmacologically for the management of bleeding from esophageal varices and other disorders, but it is extremely limited by its approximately 3-minute half-life.

Octreotide (Sandostatin) is a synthetic peptide with actions analogous to somatostatin with a longer, more clinically useful, duration of action. Octreotide is administered therapeutically for control of peptide-secreting tumors, certain acquired immunodeficiency syndrome–related diarrhea conditions, fistulas, and a variety of other GI conditions in addition to its primary use in critical care as a vasoconstrictor in patients with bleeding esophageal varices. Another novel and intuitively unrelated use of octreotide is for the treatment of hypoglycemia following an overdose of oral sulfonylurea (a hypoglycemic agent for control of type 2 diabetes).

Octreotide is given as a loading dose of 25 to 100 μg IV over at least 3 minutes, followed by an IV infusion of 25 to 50 μg/h. Common side effects include bradycardia, chest pain, fatigue, malaise, headache, diarrhea, and abdominal discomfort.

Total Parenteral Nutrition and Partial Parenteral Nutrition

Severe illness, major surgery, and GI tract dysfunction are widespread in critical care patients. Wound healing, hypermetabolic states, and physiologic stressors significantly increase nutritional requirements in these patients. When oral nutrition is inadequate or impossible, critical care providers use either partial parenteral nutrition (PPN) (administered other than through the digestive tract) or total parenteral nutrition (TPN). PPN is given to supplement enteral (into the digestive tract) feeding. TPN is administered as the

sole nutritional source. For purposes of this section, the terms TPN and PPN will be used interchangeably. Each type of nutrition is administered IV through a central venous catheter or a peripherally inserted central catheter, or PICC line. Parenteral nutrition can be administered concurrently with a lipid solution, although not in the same container.

Parenteral nutrition is customized for each patient based on estimated caloric and nutrition needs, adjusted for that patient's particular medical condition and any nutritional deficits. It is prepared in a hospital pharmacy and confirmed with the orders at the patient's bedside. H_2-blockers, electrolytes, insulin, glucose, minerals, and appropriate IV fluids are frequently present in TPN.

TPN is administered via an infusion pump at a precise rate. Unless line incompatibility problems or equipment limitations exist, parenteral nutrition should be maintained (continued) during interfacility critical care transport. No additional medications should be added to TPN or lipid solutions. No other medications should be administered into an IV line infusing TPN or lipids as well.

Any patient receiving insulin and/or dextrose should have frequent, scheduled determinations of blood glucose levels. This is important, even if the infusion has been discontinued during the transport. The effects of insulin will persist after the infusion has been stopped. CCTPs who use portable point-of-care testing devices such as the I-STAT should assess electrolyte and acid-base status during transport, especially if the transport period is extended. If this type of device is unavailable, it is important that CCTPs assess the most recent laboratory values at the sending facility and closely monitor the patient during transport for any signs of fluid or electrolyte abnormalities. In addition to glucose, fluid, or electrolyte abnormalities, parenteral nutrition may adversely impact the liver, gallbladder, and certain hematologic parameters.

Gastrointestinal medications used in critical care transport are summarized in **Table 7-7**.

Miscellaneous Medications Used in Critical Care Transport

The following section contains selected medications that do not easily fit into one of the broad categories previously described, or have widespread use for a variety of clinical situations. CCTPs should be familiar with these medications, including their indications, major side effects, and administration considerations.

Alprostadil

Alprostadil (prostaglandin E_1, [PGE]) is a vasodilator medication used to treat erectile dysfunction, but its major role in critical care transport is to maintain a patent ductus arteriosis (PDA) in newborn infants with certain congenital heart defects. The use of this medication in infants with ductal-dependent heart defects provides a life-sustaining bridge until major corrective surgery can be accomplished. Specialty consultation and training is required for CCTPs who carry this medication or who may be expected to administer or monitor this medication. Alprostadil is administered as an IV infusion at 0.05 to 0.1 µg/kg/min, which may be increased if results are unsatisfactory. Maintenance infusions can range from 0.01 to 0.4 µg/kg/min. The role of specialty consultation when giving this medication cannot be overstated. Neonatal medications should undergo additional scrutiny when being calculated or administered.

There is a greater than 10% chance of apnea when alprostadil is given intravenously. It is imperative that CCTPs consider early RSI or airway management in these patients rather than risk apnea occurring at a time when effective airway management is difficult or impossible, such as during severe aircraft turbulence. Flushing, fevers, bradycardia or tachycardia, hypotension, and hypertension are also frequent side effects of IV alprostadil.

TABLE 7-7 Gastrointestinal Medications for Critical Care Transport

Indications	Mechanism of Action	Commonly Used CCT Medications and Route of Administration	Side Effects Common to This Medication Class	Special Considerations
Histamine-2 blocker medications				
Gastric acid reduction in patients with ulcers, reflux, or excessive gastric secretions; adjunct to histamine-1 blockers in patients with allergic or anaphylactic reactions	Inhibition of histamine-2 receptors, in cells that release gastric acids	Famotidine (Pepcid): PO, IV Ranitidine (Zantac): PO, IM, IV Cimetidine (Tagamet): PO, IM, IV	Agitation, arrhythmias, confusion, vomiting, headache, dizziness, diarrhea, constipation	Modify the dose in patients with significant renal disease.
Phenothiazine antiemetics				
Nausea or vomiting; patients who would have catastrophic consequences from vomiting (ocular globe injury, patients on a backboard, various toxic exposures)	Block dopamine receptors in the cerebral medulla; have some antihistamine properties that also suppress nausea and vomiting	Promethazine (Phenergan): PO, PR, IV, IM Prochlorperazine (Compazine): PO, PR, IV, IM Metoclopramide (Reglan): PO, IM, IV	Hypotension, hypertension, bradycardia, tachycardia, sedation, akathisia, extra pyramidal symptoms, neuroleptic malignant syndrome, seizures, delirium, disorientation	Use slow infusion when prochlorperazine is administered IV. Monitor patients carefully for many possible side effects.
5-Hydroxytriptamine receptor antagonist antiemetics				
Nausea or vomiting; patients who would have catastrophic consequences from vomiting (ocular globe injury, patients on a backboard, various toxic exposures)	Selectively block serotonin receptors in the medulla to suppress vomiting	Dolasetron (Anzemet): PO, IV Granisetron (Kytril): PO, IV Ondansetron (Zofran): PO, IM, IV	Headache, drowsiness, fatigue, dizziness	Theoretically, these antiemetics work best before vomiting starts.
Antisecretory agents				
Bleeding esophageal varices	Decrease intestinal fluid secretion, decrease gastrointestinal motility, reduce portal blood flow	Octreotide (Sandostatin): SC, IM, IV	Exhaustive list of side effects with this medication	These agents may also be used for treatment of oral sulfonylurea overdose. Hypoglycemia or hyperglycemia may occur in diabetic patients.

Abbreviations: IM, intramuscular; PO, oral; PR, as required; SC, subcutaneous.

Drugs Used in Infectious Diseases

Critical care providers routinely transport patients with an active infectious disease or who are receiving treatment to prevent an opportunistic infection associated with their illness or injury. These patients require appropriate levels of personal protective equipment. Newer approaches to treatment such as early goal-directed sepsis management will only increase the role of antimicrobial medications in critical care transport. Early goal-directed sepsis management is a diagnostic and management strategy for patients with possible sepsis who receive prompt antimicrobial therapy and hemodynamic support when they meet specified criteria, designed to improve patient care and decrease mortality. In many instances, CCTPs will be expected to initiate appropriate antimicrobial therapies in high-risk patients at outlying community health care settings or during transport to a tertiary care center.

In most transport situations, antimicrobial therapy will have already been initiated before the CCTP arrives. It is essential that CCTPs determine whether any antimicrobial agents need to be administered during each transport. Depending on the pharmacodynamics and pharmacokinetics of a particular medication, a missed dose may alter the medication's plasma level and effectiveness for hours or even days. In severe cases, such as with gas-forming bacteria or profound sepsis, delays in initiating antibiotic therapy may have lethal consequences.

Antibiotics

Antibiotics, a subclassification of antimicrobial medications, are classified into several categories based on their composition and the types of bacteria they target. Not all antibiotics affect all types of infections. Antibiotics generally work by killing bacteria, or by preventing multiplication of bacteria, and thereby allowing the body's immune system to overcome the infectious invaders. Many patients are allergic to certain antibiotics. These patients may be allergic to multiple antibiotics or multiple groups of antibiotics. It is essential that CCTPs assess for the presence of medication allergy and consider the possibility of cross-reactivity of other antibiotics. In addition to allergic cross-reactivity, antibiotics and other antimicrobials can potentiate, inactivate, or otherwise alter the performance of other antimicrobials or medications. It is essential that each patient's medication profile be considered individually for medication cross-reactivity. Medication line incompatibility is a significant concern when multiple medications, especially antibiotics, are administered simultaneously. There are simply too many antibiotics and other antimicrobials that a CCTP may encounter to discuss individual indications and characteristics of each individual medication. CCTPs should develop the practice of evaluating each patient care situation to ensure proper administration and monitoring of antibiotics and other medications through the use of reliable, current reference materials.

Antifungal Medications

Fungal infections have evolved into a significant factor in critical care medicine. Immunocompromised patients, immunosuppressant medications, malignancy, and an increased prevalence of invasive procedures have promoted fungal infections to this dubious status. Five IV medications and numerous oral and topical antifungal medications are currently in widespread use in the United States. Each IV preparation has a long list of side effects and adverse reactions, including several with CNS and cardiovascular side effects occurring with a greater than 10% frequency. The CCTP should evaluate each medication when transporting patients receiving antifungal therapy.

Calcium Preparations

Calcium is an essential medication for CCTPs. Calcium chloride and calcium gluconate are the two IV preparations that are available. A 10-mL dose of calcium chloride provides approximately three times as much elemental calcium as 10 mL of calcium gluconate, although when identical elemental calcium doses are administered, the clinical effects appear identical. Each is typically supplied in a 10-mL vial or Bristojet. The IV dose is often tailored to a particular situation, to either replace a calcium deficiency or mitigate the toxic effects of another substance.

IV calcium is indicated in numerous clinical situations. Hypocalcemia is the most obvious indication. Hypocalcemia is identified either by hospital laboratory testing or on many of the portable point-of-care diagnostic devices being used in critical care transport. Normal adult serum calcium levels are between 8.2 and 10.2 mg/dL, or between 4.60 and 5.08 mg/dL for ionized calcium, which is the more clinically active of the two values. Calcium levels must be adjusted when patients have hypoalbuminemia, hemolysis, and certain blood transfusions. Hypocalcemia is observed with numerous cardiac arrhythmias, hypotension, prolonged QT intervals, or T-wave inversions on ECG. Noncardiac manifestations include muscle cramps, tetany, seizures, tremors, and ataxia.

Another indication for IV calcium is the prevention of cardiac arrhythmias associated with hyperkalemia. Severe hyperkalemia presents with characteristic ECG changes that are an indication for calcium as a myocardial cell membrane stabilizer until the excess potassium can be sequestered or eliminated.

Calcium is also given intravenously to treat hypotension and bradycardia associated with calcium channel–blocker overdoses. Verapamil (Calan) is often pretreated with IV calcium to prevent unwanted

hypotension. Additionally, IV calcium can improve blood pressure, but not pulse rate, in patients experiencing beta-blocker toxicity.

Calcium is the antidote for magnesium toxicity. When magnesium sulfate infusions are being administered to obstetric patients as a tocolytic or for pregnancy-induced hypertension, either calcium gluconate or calcium chloride should be readily available.

Hydrofluoric acid toxicity (discussed in detail in Chapter 20) is treated with aggressive calcium replacement. IV, oral, and/or topical calcium is administered in large quantities to these patients.

Use extreme caution when administering IV calcium. Extravasation may lead to significant tissue necrosis, especially from calcium chloride. When only peripheral access is available, calcium gluconate is the preferred agent for calcium replacement. Use a secure IV line, placed into a large vein, and monitor the infusion and site frequently for any signs of early infiltration. Hypotension, vasodilation, arrhythmias, and syncope are all possible side effects from IV calcium administration. Calcium can cause lethal arrhythmias in patients with cardiac glycoside toxicity (discussed in detail in Chapter 20).

Diphenhydramine

Diphenhydramine (Benadryl) is another medication carried by CCTPs with a myriad of therapeutic uses. It is an H_1 antihistamine, capable of anticholinergic effects, with a variety of beneficial clinical effects. Diphenhydramine is administered by itself or with a combination of additional medications for the treatment of allergic and anaphylactic reactions. Diphenhydramine is used as a mild sedative and sleep aid as an over-the-counter medication and can be used intravenously for this same purpose with often more profound results. This medication has mild antitussive (cough suppressant) and mild antiemetic properties in the setting of motion sickness. Diphenhydramine is extremely useful in the management of a dystonic reaction or in patients with extrapyramidal symptoms from various other medications.

Most CCTPs carry the injectable form of diphenhydramine (50 mg/mL). Adults receive 25 to 50 mg for most situations, but may receive up to 0.5 to 1 mg/kg for severe dystonic reactions. The adverse effects of diphenhydramine include tachycardia, palpitations, and chest pain, in addition to drowsiness, dizziness, and ataxia. Many other side effects are characteristic of anticholinergic medications, such as dry mouth, constipation, restlessness, agitation, and seizure activity. Despite the numerous potential side effects, diphenhydramine is well tolerated in most patients.

Glucagon

Glucagon is an endogenous peptide produced in the pancreas that has been replicated commercially for use in medicine and critical care transport. Glucagon is carried by CCTPs for use as either a rescue agent for acute hypoglycemia in patients without IV access or an antidote in select overdose or toxicity situations.

One milligram of glucagon is administered to larger children and adults who are hypoglycemic and do not have IV access. Ideally, IV dextrose would be administered to these patients, but without proper IV access, parenteral dextrose cannot be administered. Glucagon is given IM as a bridge until IV access can be established or the patient is able to receive oral sugars. Glucagon causes the increased production of cAMP, which in turn promotes hepatic glycogenolysis and gluconeogenesis, ultimately raising blood glucose levels. Onset begins in 30 minutes, and elevations in blood glucose levels can be observed up to 90 minutes following glucagon administration.

Glucagon receives widespread, but unlabeled, use as an antidote for both beta-adrenergic blocker and calcium channel blocker overdoses or toxicity. In these situations, glucagon also increases cAMP, which causes a potent increase in heart rate (chronotropy) and an increase in myocardial contractility (ino-tropy). In this setting, glucagon is administered 5 to10 mg IV followed by an infusion of 1 to 10 mg/h. These situations often require more glucagon than is readily available to most CCTPs.

Glucagon is usually packaged in powder form with phenol included for reconstitution. At high doses used for beta-blocker and calcium channel–blocker toxicity, sterile water, rather than phenol, should be used for reconstitution to avoid the risk or effects of phenol toxicity from the large amount required.

Magnesium Sulfate

Magnesium sulfate is another versatile IV medication frequently carried and encountered by CCTPs. Similar to calcium, the most obvious indication for magnesium sulfate is documented or presumptive hypomagnesemia, or low serum magnesium levels. Extracellular fluid contains approximately 1/20th the magnesium concentration of intracellular fluid. Only 1% of total body magnesium is present in extracellular fluids, making serum magnesium levels a poor indicator of actual body magnesium content. Despite this, the widespread use of serum magnesium monitoring continues. Clinical signs of hypomagnesemia include cardiac arrhythmias (atrial and ventricular), CNS hyperexcitability (psychosis, seizures, or disorientation), and neuromuscular symptoms (muscle cramps or hyperactive deep tendon reflexes). Causes of hypomagnesemia include impaired GI absorption, nutritional deficiencies, excessive GI secretions, dramatic fluid volume expansion, and uncontrolled renal excretion from pathologic or chemical toxicity.

Magnesium sulfate is used aggressively to treat ventricular cardiac arrhythmias, specifically torsade de pointes, ventricular tachycardia, and ventricular fibrillation. In these situations, 1 to 2 g of magnesium sulfate is infused over 5 minutes, which is a much faster treatment than most other situations.

The use of magnesium sulfate in high-risk obstetric patients is becoming controversial. Magnesium remains the first-line anticonvulsant in patients with preeclampsia and eclampsia. Patients with eclampsia who receive magnesium as an anticonvulsant have a lower recurrence of seizures than those treated with conventional anticonvulsants, such as benzodiazepines and phenytoin. The role of magnesium in pre-eclampsia and eclampsia is largely undisputed. Patients are typically administered a 4- to 6-g bolus over 15 to 20 minutes followed by an infusion at 2 g/h. It is essential that CCTPs closely monitor patient respiratory status, blood pressure, and deep tendon reflexes during magnesium sulfate infusions.

Magnesium sulfate as a uterine tocolytic agent is facing additional scrutiny. Its use continues to be widespread for this purpose in the management of preterm labor. Safety concerns and questionable efficacy have been cited in several exhaustive meta-analysis studies. Pulmonary edema, increased fetal mortality, and maternal respiratory arrest from magnesium toxicity are cited as reasons not to administer magnesium sulfate for this condition.

Finally, another indication for magnesium sulfate is asthma exacerbation.

Magnesium sulfate causes respiratory arrest or hypoventilation, particularly during IV infusions. Hypotension, vasodilation, cardiac conduction abnormalities, and a flushed feeling are also possible. IV calcium preparations (discussed previously) are the antidotes for magnesium toxicity. Hemodialysis is sometimes necessary for severe magnesium overdoses.

Potassium Chloride

Potassium is the major intracellular electrolyte, essential for nerve and muscle tissue function. Normal serum potassium values range from 3.5 to 5 mEq/L, reflecting only 2% to 3% of total body potassium stores. Large amounts (up to 500 mEq/d) are absorbed and eliminated each day. The kidneys are almost entirely responsible for potassium regulation in healthy persons. Many critical care patients have hypokalemia, or are at risk for hypokalemia, defined as a serum potassium level of less than 3.5 mEq/L. This serum value will not reflect actual body potassium levels in many situations such as acid/base alterations, hemolysis, and errors during common laboratory sampling techniques (pseudohyperkalemia).

Patients presenting with hypokalemia often have vague signs and symptoms. Abdominal pain, nausea, vomiting, paresthesias, and constipation are common symptoms. ECG changes, arrhythmias (especially

premature ventricular contractions and ventricular arrhythmias), hypotension, respiratory failure, and mental status changes are more severe manifestations. It is now possible to diagnose hypokalemia using portable point-of-care testing devices during critical care transport.

When potassium stores are depleted from impaired absorption, kidney dysfunction, or unintended elimination, potassium replacement is essential. Potassium chloride is available as oral and IV preparations. ECG monitoring is highly recommended for any IV infusions totaling greater than 10 mEq/h. Peripheral IV infusions should not be administered at a rate greater than 10 mEq/h. Central venous catheter infusions can be administered up to 40 mEq/h at concentrations no greater than 40 mEq/100 mL. Peripheral IV administration is likely to cause local discomfort. Hyperkalemia is the main adverse side effect of IV administration, demonstrated by ECG changes (especially peaked T waves), paralysis, palpitations, hypotension, and bradycardia. Avoid or use extreme caution when administering potassium chloride to patients with renal disease or impairment, patients with acid/base disorders, and patients receiving cardiac glycosides. If potassium levels fail to increase during repletion, it is important to assess magnesium levels. The kidneys depend on magnesium for renal potassium reabsorption.

Sodium Bicarbonate

Sodium bicarbonate is an electrolyte solution with powerful alkalinization effects. It is used as a pharmacologic therapy for certain (but not all) metabolic acidosis conditions. Sodium bicarbonate enhances sodium channel membrane functioning to stabilize myocardial functioning following tricyclic antidepressant and other medication overdoses. Salicylate removal is increased when sodium bicarbonate is used to alkalinize urine following an aspirin overdose. Other medications, particularly acidic formulations, have enhanced elimination when a patient's urine is alkalinized with sodium bicarbonate. Sodium bicarbonate promotes intercellular potassium shifts in patients with documented or presumptive hyperkalemia and may be administered when these patients experience cardiac arrest. Additionally, sodium bicarbonate protects renal tubules from damage by deposited myoglobin in patients with rhabdomyolysis. This is a powerful, capable medication carried by CCTPs.

Sodium bicarbonate is typically administered at 0.5 to 1 mEq/kg per dose IV push, ideally into a central venous catheter. Salicylate and tricyclic overdose situations and rhabdomyolysis are indications for a sodium bicarbonate infusion. IV infusions may also be used when certain variants of metabolic acidosis are present. Sodium bicarbonate is not recommended for routine use in cardiac arrest except for situations of documented metabolic acidosis or hyperkalemia.

Numerous electrolyte abnormalities (hypokalemia, hypocalcemia, and hypernatremia) and alkalosis are side effects of sodium bicarbonate. Cerebral hemorrhage, pulmonary edema, and congestive heart failure exacerbations are possible as a result of electrolyte changes and fluid volume overload. Alterations of the oxygen-hemoglobin dissociation curve occur following sodium bicarbonate administration, increasing hemoglobin oxygen affinity.

Tocolytic Agents in Critical Care Transport

Pharmacologic tocolytics are used clinically to prolong fetal gestation in order to minimize adverse medical conditions associated with prematurity or to allow time for maternal-administered corticosteroids to enhance fetal lung maturity in the event of a premature delivery. CCTPs are often requested to transport patients in preterm labor. At the time of this text, there are no current FDA-approved chemical tocolytic agents to suppress uterine contractions. Ritodrine, a beta-adrenergic agonist, had been approved for this purpose, but it has since been discontinued in the United States. Any other medications used as tocolytic agents have not been approved for this purpose.

Terbutaline and magnesium sulfate have been previously discussed. Magnesium sulfate has considerable risks to a pregnant woman and fetus but continues to receive widespread use. Magnesium is

generally administered as an IV bolus followed by infusion, which requires close monitoring by CCTPs during transport.

Terbutaline is a beta-2 agonist that is approved as a bronchodilator medication and is used frequently as a tocolytic medication. Terbutaline administration is often associated with hypertension, tachycardia, restlessness, and tremors. Pulmonary edema from terbutaline has led to at least 25 maternal deaths. A low-dose subcutaneous continuous or intermittent infusion appears to be effective for tocolysis without many of the side effects or tachyphylaxis issues. The FDA appears to be accepting the role of terbutaline as a tocolytic, but no new approvals for this use have been granted as of this writing.

The calcium channel blockers, nifedipine (Procardia) and nicardepine (Cardene), have tocolytic properties and are frequently used for this purpose. In general, the side effects with these medications are minimal, especially when given orally. Serious side effects, including pulmonary edema, have been reported in a small number of patients. It is advisable to avoid these medications in hemodynamically unstable patients and those with preexisting cardiovascular disease.

CCTPs may additionally encounter patients who have received indomethacin (Indocin) and various COX 1 and 2 inhibitors for tocolysis. These medications are in various phases of use and evaluation, but may be given to patients as a tocolytic agent; these patients then require transport. The safety and efficacy of these medications are still being debated.

Miscellaneous medications used in critical care transport are summarized in **Table 7-8**.

Medication Infusion Technique

Medication infusion is indicated when the patient requires continuous medication administration and has restricted fluid requirements. When altitude increases, IV drip rates will increase; conversely, when altitude decreases, IV drip rates will decrease. Flow rates should not be affected at 1,500′ to 2,000′. Patients should always be placed on pumps to ensure precise medication delivery during critical care transport.

A two-tone alarm from the infusion system indicates that infusion is complete or the battery is low. Four quick beeps and a corresponding red light alarm on the screen indicate a more serious problem. Silence the alarm and press the *Alarm channel* key if needed to access alarm information, then press *Start/stop* to restart fluids.

TABLE 7-8 Miscellaneous Medications for Critical Care Transport

Indications	Mechanism of Action	Commonly Used CCT Medications and Route of Administration	Side Effects Common to This Medication Class	Special Considerations
Alprostadil (prostaglandin E)				
Maintains patent ductus arteriosis in neonates with certain ductal dependent congenital heart defects	Prostaglandin, which causes direct relaxation of ductus arteriosis and vascular smooth muscle	IV infusion	Apnea, flushing, fever, bradycardia, tachycardia, hypotension, hypertension, cardiac arrest	Anticipate more than a 10% chance of apnea. Consider early rapid sequence intubation or airway management. Consult an appropriate specialist when managing neonatal patients who require alprostadil.
Calcium chloride and calcium gluconate				
Documented or presumed hypocalcemia, hyperkalemia with ECG changes, magnesium toxicity, hydrofluoric acid exposure	Replacement of lost or sequestered body calcium; membrane stabilizer that promotes normal cell function	IV	Hypercalcemia, tissue necrosis following extravasation, arrhythmias, hypotension, bradycardia	Avoid IV calcium in patients with cardiac glycoside toxicity. Closely monitor peripheral IV sites for signs of infiltration.
Diphenhydramine (Benadryl)				
Allergic or anaphylactic reactions, mild sedation, treatment of dystonic reactions, mild cough suppressant, mild antiemetic, extrapyramidal symptoms	Histamine-1 blocker with anticholinergic effects	IV, IM, PO	Palpitations, tachycardia, hypotension, seizures, insomnia, sedation, dry mucous membranes, decreased GI motility, nausea, vomiting, paradoxical excitement	The drug is well tolerated in most patients despite the wide range of potential side effects.
Glucagon				
Hypoglycemic patients without IV access; unlabeled use for beta-blocker and calcium channel-blocker toxicity	Endogenous peptide that increases production of cAMP, causing gluconeogenesis and glycogenolysis	IM, IV	Hypotension, hypertension, tachycardia, nausea, vomiting	Large quantities may be potentially required for severe beta-blocker or calcium channel-blocker overdose. Reconstitute with sterile water when large quantities of glucagon are administered.
Magnesium sulfate				
Hypomagnesemia, ventricular arrhythmias, anticonvulsant in patients with preeclampsia and eclampsia, unlabeled use as a tocolytic	Stabilizes excitable cell membranes, slows SA node conduction, decreases acetylcholine in motor nerve terminals, electrolyte essential for ion movement across cell membranes	IV bolus infusion or maintenance infusion	Flushing, hypotension, respiratory depression/apnea, vasodilation, cardiac conduction abnormalities	Have IV calcium available when administering magnesium sulfate. Monitor respiratory status, blood pressure, and deep tendon reflexes in patients receiving a continuous magnesium infusion.
Potassium chloride				
Documented or presumed hypokalemia	Electrolyte required for nerve, muscle cell, and tissue functioning; helps maintain acid-base balance	IV infusion, PO	Hyperkalemia, ECG changes, muscle paralysis, palpitations, hypotension, bradycardia	Administer no more than 10 mEq/h through peripheral IV sites. Use cardiac monitoring for patients receiving infusions totaling more than 10 mEq/h. Use extreme caution in patients with renal disease, patients with acid-base alterations, and those receiving cardiac glycosides. Consider point-of-care testing during transport if available.
Sodium bicarbonate				
Certain types of metabolic acidosis, for enhanced elimination of certain toxic exposures, severe hyperkalemia, rhabdomyolysis	Powerful alkalinizing agent that stabilizes various cell membranes, increases serum and urinary pH, and promotes renal excretion of weak acids and myoglobin	IV bolus or infusion	Cerebral hemorrhage, edema, worsening of congestive heart failure, hypernatremia, metabolic alkalosis, hypocalcemia, hypokalemia, altered hemoglobin oxygen affinity	Drug is not indicated for routine administration during cardiac arrest unless hyperkalemia or metabolic acidosis is documented. Monitor serum potassium during and after administration.

Abbreviations: cAMP, cyclic adenosine monophosphate; ECG, electrocardiographic; GI, gastrointestinal; IM, intramuscular; PO, oral; SA, sinoatrial.

The sequence for medication infusion is presented in **Skill Drill 7-1** and described as follows:

1. To set up a medication infusion system, start by pressing the *On/Off* key for 1 second, and then prime the tubing system **Step 1**.
2. Pull the white slide clamp on the cassette to the out position and insert the cassette into the appropriate channel **Step 2**.
3. After placing the tubing collar into the recessed area, select the appropriate channel by pressing *ABC*

on the soft pad that corresponds to the pump **Step 3**.

4. Set the rate and volume on the system and press the *Accept* button **Step 4**.
5. Press *Select* to advance the volume infused; press *Clear* to zero the amount infused **Step 5**.
6. Press the *Standard Display* key and then press *Start/Stop* to initiate infusion **Step 6**.

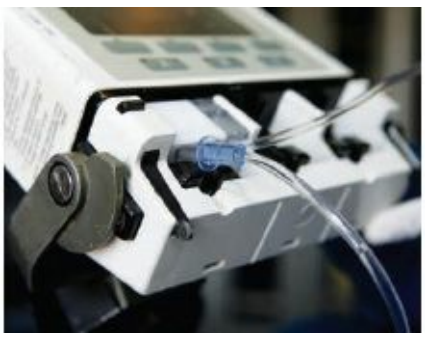
Fluids that are run using a dial-a-flow are not considered reliable and should be switched to IV infusion pumps.

Skill Drill 7-1

Administering Medication With an Infusion Pump

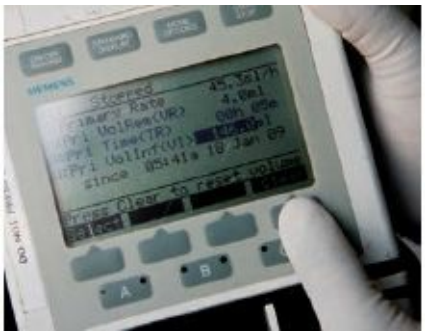
1 Press the *On/Off* key for 1 second and then prime the tubing system.

2 Pull the white slide clamp on the cassette to the out position. Insert the cassette into the appropriate channel.



3 Place the tubing collar into the recessed area. Select the appropriate channel by pressing *ABC* on the soft pad that corresponds to the pump.

4 Set the rate and press *Accept*. Adjust volume and press *Accept*.



5 Press *Select* to advance the volume infused. Press *Clear* to zero the amount infused.

6 Press the *Standard Display* key. Press *Start/Stop* to initiate infusion.

Summary

The variety of medications used in critical care medicine is significantly greater than medications used in standard prehospital medicine. It is necessary that the CCTP have an intimate understanding of the medications used and the effects they may have when administered. Continued review and research are necessary to truly effectively treat critical care patients.

Case Study

YOU ARE CALLED TO A REGIONAL HOSPITAL EMERGENCY department for a male patient who is experiencing an active ST-segment elevation myocardial infarction (STEMI) and requires cardiac intervention and emergent air transfer to a tertiary care facility. Transport time by air will be 20 minutes.

Upon arrival, the staff reports that the 55-year-old, 122-kg man presented to the emergency department with chest pain with a rating of 7/10 and mild shortness of breath. He has had chest pain on and off for the last few days and awoke this morning with symptoms. His evaluation revealed an active

STEMI.

The patient's medical history and report per the referring registered nurse includes hypertension, coronary artery disease, and hyperlipidemia. This patient's prescription medications include Lopressor, Plavix, and aspirin.

In the emergency department, he was placed on the monitor and given oxygen at 4 L/min via nasal cannula. An 18-gauge angiocath was placed in the left forearm, and a 20-gauge angiocath was placed in the right hand. Blood samples were obtained. Both IVs were 0.9% normal saline. He received one nitroglycerin tablet sublingually, and a drip of 10 μg/min was initiated with a 100 mg/250 mL concentration running at 3 mL/h. Acetylsalicylic acid, 325 mg, was given, and 2 mg of morphine was administered as well. Serial ECGs revealed ST elevation in V_3 and V_4, which is indicative of an anterior infarct. Positive cardiac markers confirmed the ECG findings. A heparin drip of 1,000 U/h was initiated using a 25,000 U/250 mL concentration running at 10 mL/h. A 30.6-mg bolus of Reopro was given, and a drip using 9 mg/250 mL was initiated at 15.25 μg/min, or 17 mL/h. The patient also received 5 mg of metoprolol via IV push. His pain is currently a 4/10. His temperature is reported as 98.6°F (37°C). The referring nurse has no further report.

Your assessment reveals he is alert and oriented and consents to transfer. He reports chest pain at 4/10, but his shortness of breath feels resolved. Current vital signs at this facility are a blood pressure of 126/86 mm Hg, a pulse rate of 84 beats/min and normal sinus rhythm on the ECG, respirations of 16 breaths/min and nonlabored, and an oxygen saturation as measured by pulse oximetry (SpO_2) of 97% with 4 L/min oxygen via nasal cannula. The patient feels afebrile to touch. An examination of the patient's head, ears, eyes, nose, and throat reveals equal reactive pupils at 5 mm, a midline trachea, no jugular vein distention, and no audible carotid bruits on auscultation. His chest is symmetric with equal rise and fall, and lung sounds are clear with auscultation. His S_1 and S_2 heart tones are normal on auscultation, and no rubs or gallops are noted. He has a moderately obese abdomen and no organomegaly or pulsatile masses. His extremities are within normal limits, with no trauma, deformity, or other abnormality noted. Pulse quality is 2^+ (normal) on palpation. All IVs are infusing well, and no local redness or swelling is noted. The nitroglycerin is infusing in the right IV, and the heparin and Reopro is infusing in the left IV.

You duplicate flow rates and transfer his IVs to your pumps. The ECG, blood pressure cuff, and SpO_2 sensors are transferred to your monitors. Oxygen is transferred to your portable cylinder. The patient is transferred to your cot and secured, and IVs are transferred to the cot. You discharge the patient from the emergency department, obtain all records, and move to your helicopter. He is placed in the ship, and all oxygen and power needs are transferred to onboard systems. You lift off and transport is begun.

En route no changes in the patient's hemodynamic status are noted, as vital signs remain within the previously described range. He continues to complain of chest pain at 4/10, but has no shortness of breath. He denies having any nausea. Medical control and standing protocols are initiated. You arrive within the 90-minute door-to-balloon time standard at the tertiary care facility, and your patient is moved directly to the cath lab and transferred to staff without incident. You give your report and all paperwork to the charge nurse and retreat to complete your paperwork and reassemble your ship for the next call.

1. Are the medication doses correct?
2. Are any compatibility issues identified?
3. What further adjustments can be made to current medications to benefit this patient?

Analysis

The case study represents some of the most common scenarios a CCTP will face. The medication dosing is *not* correct. Although all the concentrations are within standards, the dosing for nitroglycerin is not

correct. The patient is receiving 20 µg/min with this concentration.

The administration of heparin and Reopro is under scrutiny. Although Reopro is not reported as having incompatibility issues in the same IV line, the manufacturer recommends that it is run separately in an IV. This could be accomplished by placing the nitroglycerin and heparin into the same IV.

This patient's condition may be better treated by increasing his nitroglycerin dose incrementally and monitoring his responses. Further doses of morphine may be used as well. Any adverse reactions may require discontinuing one or more of these medications.

This patient has had, and is receiving, multiple anticoagulant medications. He must be monitored for any bleeding because he is a substantial anticoagulation risk from his history. If bleeding is suspected, the CCTP should stop the infusions and immediately consult with medical control or follow established protocols. No prescreening information for anticoagulation was readily offered. It is always good practice to ask for this information because it may uncover a contraindication to medication use. Speed is essential in time-sensitive patients, but moving too quickly without paying attention to details is just as detrimental to the patient as moving too slowly.

There is a standard treatment for STEMI, but treatments and medications vary from region to region because of local physician preferences, drug availability and cost, and referral patterns related to facilities. The CCTP must be familiar with the protocols of his or her region and common treatment modalities. It does appear that the referring facility and the transferring crew all share a common ground in treating the patient's STEMI, preventing further ischemia, and rapidly transferring for interventions.

The identification of a wrong medication dose is of paramount importance. Although all health care providers strive to provide accurate care, errors can and do occur. The CCTP must ensure that a mistake is not repeated. Some of the most common errors involve mistaken concentrations, which result in dosing errors. This risk is increased when IV drips are hand mixed by the practitioner. The CCTP must ensure that concentrations are correct and match the dosing required. All medications administered using IV drips should be checked for flow rate and dosing accuracy. The CCTP must be well versed in many pharmacologic interventions. It is always recommended that up-to-date pocket guides or charts be consulted as well for accuracy as a result of the large number of medications you may encounter.

Another issue the CCTP must be alert to is compatibility. Although many medications are compatible with each other, many are not. Again, double-checking all medications for compatibility is a responsibility of the CCTP. Adjustments may be required to obtain compatibility in medications administered.

An understanding of pharmacology is a very challenging part of CCTP practice. The responsibilities of the CCTP can be as simple as ensuring the highest flow rates are properly placed in the IV lines to avoid line back-up and alarms, to making complex mathematic calculations to ensure that proper medication doses are being administered. It is the responsibility of CCTPs to maintain their knowledge of current and emerging pharmacology and to maintain due diligence in practice.

Prep Kit

Ready for Review

- Pharmacology is defined as the study of the preparation, properties, uses, and actions of medications.
- Current and reliable medication information may be obtained from a variety of print and electronic reference sources, including the Internet.
- Medications work in one of four ways: (1) by binding with a receptor site on a particular cell to either promote or inhibit a specific activity of that cell; (2) by affecting the physical properties of a cell and,

thereby, its functioning; (3) by combining directly with other chemicals within the body to either alter or limit the effects of a chemical or allow it to be removed; and (4) by altering a metabolic pathway.

- In down-regulation, as the medication molecules bind to their corresponding receptor sites, the number of receptors decreases. In up-regulation, the medication increases the number of available receptor sites.
- The drug-response relationship correlates the amount of medication given with the response it causes.
- The onset of action is defined as how long it takes for the concentration of the medication at the target tissue to reach the minimum effective level.
- The duration of action is defined as how long the medication can be expected to remain above that minimum level to provide the intended action.
- The termination of action is the amount of time after the concentration level falls below the minimum level to the time it is eliminated from the body.
- The onset of action, duration of action, and termination of action combine to determine the therapeutic index for a medication, which gives an indication of the medication's margin of safety (defined as the ratio of a drug's lethal dose for 50% of the population to its effective dose for 50% of the population).
- Patients of different ages may have vastly different responses to the same drug, owing to age-related factors such as renal function, muscle mass, body water/fat content, and metabolic rate.
- Both pediatric and geriatric patients often have slower absorption and elimination times, necessitating modification of the doses of many drugs administered to these patients.
- To correct for differences in weight between patients, drugs are dosed in milligrams or micrograms per kilogram of the patient's body weight.
- Other factors that may affect the dose-response relationship include gender, environmental factors (eg, stress), time of the medication's administration, the patient's overall state of health, and genetic factors.
- In pregnant patients, many medications will pass from the mother's bloodstream into the placenta and ultimately affect the fetus. For this reason, many medications are either contraindicated or used only after careful consideration in pregnant patients.
- Every medication has some side effects—that is, reactions that can manifest as undesired signs or symptoms but that are nevertheless expected based on how the medication works.
- An iatrogenic response is an adverse condition inadvertently induced in a patient by the treatment given. Some of these responses are devastating and even potentially lethal.
- Medication errors related to selection, administration, or monitoring are responsible for thousands of deaths annually—and the chaos often associated with critical care transport conditions makes such errors more likely.
- The most common unpredictable response encountered in the prehospital setting is the allergic reaction.
- The effects of one medication may alter the response of another medication in sometimes unexpected ways, a phenomenon known as a drug interaction.
- The critical care transport environment continually exposes personnel and vehicles to temperature extremes; it is essential that medications remain within their required temperature range.
- The optimal medication for a particular situation may or may not be immediately available during patient transport. For example, specialized medications such as antidotes, thrombolytics, and antibiotics are not routinely carried by critical care transport organizations.

- The transport team must be adequately trained and equipped to recognize and effectively manage anticipated side effects or adverse reactions associated with a particular medication.
- The route of administration affects how quickly and how much of an administered dose is absorbed into the patient's body. CCTPs generally use IV, intramuscular, subcutaneous, oral, sublingual, transdermal, nasal, and sometimes rectal routes for medication administration.
- The route of medication administration affects bioavailability—the amount of an administered medication that reaches the patient's systemic circulation without any alteration.
- A medication or other foreign substance in the body undergoes elimination, biotransformation, or both. The kidneys and urinary system are the main routes of elimination.
- Biotransformation may have any of four outcomes: (1) an active drug may be changed into an inactive metabolite and eliminated; (2) an active drug can be changed into an active metabolite that causes continued or new clinical effects; (3) an active medication may be changed into a reactive metabolite that has a greater potential for action than its parent substance; and (4) an otherwise inactive substance may change into an active, potentially toxic substance.
- Definitive airway management in critical care transport combines techniques for airway device placement with medications designed to facilitate this placement.
- To create the best patient condition possible for invasive airway procedures, the following classes of drugs are used: ultra-short-acting nonbarbiturate hypnotic agents, sedative hypnotic agents, benzodiazepines, and paralytic medications (depolarizing or nondepolarizing agents). Typically, a sedative-hypnotic agent is used in conjunction with a chemical paralytic agent.
- Beta-agonist medications act on receptors in the lower airways to improve air flow into and out of the lungs.
- Medications such as catecholamines, beta-blocking agents, calcium channel–blocking agents, and anticholinergic agents may simultaneously affect both the heart and the blood vessels and are used to ensure effective functioning of the cardiovascular system.
- Other medications involved in cardiovascular management include anticoagulants and thrombolytics, phosphodiesterase inhibitors, and diuretics.
- Clonidine and phentolamine are alpha-blocking medications encountered periodically during critical care transport; other alpha-blocking oral medications that may be observed as a patient's personal medication include terazosin, doxazosin, and methyldopa.
- Phentolamine should be carried by any transport provider who administers any IV medication with alpha-adrenergic properties (eg, norepinephrine, epinephrine, dopamine).
- Angiotensin-converting enzyme inhibitors inhibit vasoconstriction and block the breakdown of the vasodilator bradykinin.
- The management of cardiac arrhythmias involves several classes of antiarrhythmic medications, many of which create additional risk for catastrophic and lethal rhythm disturbances.
- Class I antiarrhythmic medications work by blocking sodium channels; they include anticholinergic medications such as quinidine, procainamide, and disopyramide.
- Class II antiarrhythmic medications (beta-blockers) work by competitively binding to the beta receptor sites to inhibit their stimulation. They are used to treat arrhythmias, hypertension, acute myocardial infarctions, and congestive heart failure.
- Class III antiarrhythmic medications (potassium channel blockers) are particularly useful for treating reentry tachycardias and arrhythmias occurring because of cellular depolarization as a result of

excessive excitability. Their use may produce prolonged QT intervals on the patient's ECG.

- Class IV antiarrhythmic medications (calcium channel blockers) cause vasodilation, negative inotropy, negative chronotropy, and negative dromotropy. Because these medications decrease the conduction velocity through the atrioventricular node, they are useful for treating tachyarrhythmias originating in the atria.
- Adenosine is not effective in converting atrial fibrillation, but may be used as a diagnostic tool when differentiation between atrial fibrillation and supraventricular tachycardia cannot be made as a result of the rate.
- Anticholinergic medications include diphenhydramine, a potent antihistamine, and other histamine-blockers. Other anticholinergic medications are administered therapeutically to treat nausea and vomiting, excessive secretions from a variety of organs, abdominal cramps, and excess vagal tone leading to bradycardia or asystole.
- Many RSI protocols include atropine as a prophylactic medication to prevent bradycardia from succinylcholine administration and airway manipulation, especially in pediatric patients.
- Dopamine (a sympathomimetic agent) stimulates alpha-1 receptors when given at a higher dose, thereby producing peripheral vasoconstriction. Stimulation of the dopaminergic receptors may have a myriad of effects: increased myocardial contractility and cardiac output, increased renal output, decreased fluid volume, and increased blood pressure.
- Epinephrine (a sympathomimetic agent) is administered to support respiratory function by opening up larger airways; to increase blood pressure by increasing vascular tone; and to enhance myocardial perfusion during cardiac arrest resuscitation.
- Other sympathomimetic agents include norepinephrine, phenylephrine, and dobutamine; all these agents are administered to improve cardiac output.
- Hydralizine is used with apparent safety as an emergent antihypertensive in pregnant patients with preeclampsia. Additional uses include congestive heart failure, primary pulmonary hypertension, and malignant hypertension.
- Diuretics are widely used by CCTPs for situations such as fluid volume overload, cerebral edema, hyperkalemia, and rhabdomyolysis. The most commonly administered diuretic is furosemide, although both bumetanide and mannitol are used for these purposes as well.
- The traditional first-line medication for cardiac ischemia is nitroglycerin (a nitrate). Nitroglycerin also treats hypertension. Nitroprusside (another nitrate) is both an arterial and a venous dilator, which makes it more potent than nitroglycerin; at normal doses, nitroglycerin is only a venous dilating agent.
- CCTPs often encounter situations that require dissolution of blood clots with thrombolytics, prevention of blood clots with anticoagulants, and expansion of the circulating blood volume with crystalloid and colloid medications.
- Aspirin is considered to be the first-line anticoagulant medication and is technically considered an antiplatelet medication.
- Glycoprotein IIB-IIIA inhibitors are becoming increasingly popular as antiplatelet medications, but carry a high risk of excessive bleeding.
- When a patient is taking heparin, the CCTP should review the latest lab values and the partial thromboplastin time prior to transport and monitor the patient closely for bleeding problems.
- Enoxaparin is a low-molecular-weight heparin that is used as an adjunct to thrombolytic medications in patients experiencing myocardial infarctions and in patients experiencing unstable angina.

- CCTPs frequently encounter patients taking warfarin who have suffered devastating effects (eg, cerebral hemorrhage) from inadequate monitoring and dose adjustments. This situation should be approached cautiously, because the reversal of anticoagulation can be just as dangerous as over-anticoagulation in high-risk patients.
- Thrombolytic medications are administered to break down an existing clot.
- Prehospital blood products and blood substitute products are still in the investigational stage, so CCTPs must rely on other fluids to replace the missing blood volume—namely, crystalloid solutions and colloid solutions.
- Three types of crystalloid solutions are used in the field: isotonic, hypertonic, and hypotonic solutions.
- Isotonic solutions have the same tonicity as human blood. Normal saline and lactated Ringer's solution are the most commonly used isotonic fluids.
- Albumin (a blood product) is a colloid solution that is used to treat hypovolemia, burns, and certain surgical procedures.
- Hetastarch is a synthetic colloid solution that is designed to expand the plasma volume. When it is used, consideration must be given to the possibility of pulmonary edema, fluid overload, and congestive heart failure.
- Dextran—another volume expander—is used in situations when blood products are not immediately available or to prime the tubing of various external medical devices that sequester large amounts of blood.
- Analgesia, anxiolysis, sedation, and seizure control are the main purposes of neurologic medications administered by CCTPs.
- Benzodiazepines are versatile, treating anxiety, controlling seizures, and providing sedation in a vast array of clinical situations.
- The initial pharmacologic treatment of seizures in prehospital and critical care transport should be done with IV benzodiazepines.
- Mannitol, a powerful diuretic medication, is often utilized for cerebral edema and may be a last-ditch effort to save a patient from impending brain stem herniation.
- Magnesium sulfate is highly effective in controlling seizures in preeclamptic and eclamptic obstetric patients.
- The use of morphine and other opiate-based medications is an essential component of patient care during critical care transport. Other analgesic medications used may include ketamine, acetaminophen, and various NSAIDs.
- A variety of gastrointestinal medications are used in critical care transport to counteract nausea or vomiting, control gastrointestinal bleeding, or provide parenteral nutrition during or after a severe illness or injury.
- Histamine-2 blocker medications are used clinically to minimize the effects of gastric acids on the stomach and digestive tract.
- Nausea and vomiting are typically triggered in the medulla and can also be triggered by the vestibular system, which is characterized by a high concentration of both histamine and acetylcholine. Antihistamine medications, which inhibit the activity of the histamine in the vestibular system, and medications that block the acetylcholine receptors are often used to treat nausea and vomiting.
- Medications that antagonize the D_2 receptors—such as the phenothiazine-type antiemetics—are

effective in reducing nausea and vomiting.

- The serotonin antagonists are believed to exert an antiemetic effect by selectively blocking serotonin receptors in the medulla to suppress the vomiting centers.
- Somatostatin is a synthetic peptide (based on a naturally occurring peptide) that decreases intestinal fluid secretion, slows gastrointestinal motility, and reduces portal blood flow with vascular smooth muscle vasoconstriction.
- Octreotide is a synthetic peptide with actions analogous to somatostatin, but a longer, more clinically useful, duration of action.
- Unless line incompatibility problems or equipment limitations exist, parenteral nutrition should be maintained (continued) during interfacility critical care transport. No additional medications should be added to total parenteral nutrition or lipid solutions.
- Any patient receiving insulin and/or dextrose should have frequent, scheduled blood glucose levels checked during transport because the effects of insulin will persist for a period of time after the infusion has been stopped.
- Alprostadil (prostaglandin E_1; PGE) is a vasodilator medication that is used during critical care transport to maintain a patent ductus arteriosis in newborn infants with certain congenital heart defects.
- CCTPs will be expected to initiate appropriate antimicrobial therapies in high-risk patients at outlying community health care settings or during transport to a tertiary care center.
- When selecting antibiotics, CCTPs must assess for the presence of medication allergy and consider the possibility of cross-reactivity of other antibiotics. In addition, they must assess the patient's medication profile individually, recognizing that antibiotics and other antimicrobials can potentiate, inactivate, or otherwise alter the performance of other antimicrobials or medications.
- Increases in the numbers of immunocompromised patients, immunosuppressant medications, malignancies, and invasive procedures have increased the prevalence of fungal infections in recent years. Five IV and numerous oral and topical antifungal medications are currently in widespread use.
- IV calcium is indicated in numerous clinical situations encountered by the CCTP—to treat hypocalcemia, for the prevention of cardiac arrhythmias associated with hyperkalemia, to treat hypotension and bradycardia associated with calcium channel–blocker overdoses, as an antidote for magnesium toxicity, and to counteract hydrofluoric acid.
- Diphenhydramine is administered by itself or with a combination of additional medications for the treatment of allergic and anaphylactic reactions, for use as a mild sedative, for use as a mild antitussive and antiemetic agent in the setting of motion sickness, and for the management of a dystonic reaction. It is also used in patients with extrapyramidal symptoms from various other medications.
- Glucagon is carried by CCTPs for use as either a rescue agent for acute hypoglycemia in patients without IV access or an antidote in select overdose or toxicity situations.
- Magnesium sulfate is another versatile IV medication frequently carried and encountered by CCTPs. It is used to treat hypomagnesemia, ventricular cardiac arrhythmias, and convulsions in patients with preeclampsia and eclampsia; it is also used as a uterine tocolytic agent.
- Potassium chloride is available as oral and IV preparations to treat patients in whom potassium stores are depleted from impaired absorption, kidney dysfunction, or unintended elimination.
- Sodium bicarbonate is an electrolyte solution that is used as a pharmacologic therapy for certain metabolic acidosis conditions. It is administered to stabilize myocardial functioning following tricyclic antidepressant and other medication overdoses, and to facilitate salicylate removal following

an aspirin overdose.

- When altitudes increase, IV drip rates will increase; conversely, when altitudes decrease, IV drip rates will decrease.
- Patients should always be placed on pumps to ensure precise medication delivery during critical care transport.

Vital Vocabulary

acetylcholine (ACh) Chemical neurotransmitter of the parasympathetic nervous system.

bioavailability The amount or percentage of a medication that reaches systemic circulation without being altered following administration.

chronotropic Altering the rate of contraction of the heart.

cross-tolerance A form of drug tolerance in which patients who take a particular medication for an extended period can build up a tolerance to other medications in the same class.

cumulative effect An effect that occurs when several successive doses of a medication are administered or when absorption of a medication occurs faster than excretion or metabolism.

depolarizing paralytics Medications that cause neuromuscular blockade by binding and briefly activating receptor sites at the neuromuscular junction, preventing further activation of these sites and causing chemical paralysis.

dromotropic Influencing the conduction rate within the heart.

drug antagonism Medications that bind with a receptor site and prevent activation of these receptors by other medications, without causing receptor activation or related clinical effects.

drug interaction The alteration of the action of a particular medication when combined with another medication.

duration of action How long the medication concentration can be expected to remain above the minimum level needed to provide the intended action.

first-order elimination The plasma concentration of a medication or substance is proportional to its rate of elimination.

first-pass effect Medications absorbed from the intestine that are partially inactivated as they pass through the hepatic circulation into the liver before entering the systemic circulation; also called first-pass metabolism.

half-life (T1/2) The time period required to eliminate one half of the plasma concentration. During the second "half-life," an additional 25% of the original plasma concentration is eliminated. After three half-lives, one-eighth of the original plasma concentration remains.

iatrogenic response An adverse condition inadvertently induced in a patient by the treatment given.

idiosyncrasy An abnormal (and usually unexplained) reaction by a person to a medication to which most other people do not react.

inhibition The presence of one medication that decreases the effect of another medication.

inotropic Affecting the force with which muscle tissue contracts, especially cardiac muscle.

interference A direct biochemical interaction between two drugs.

mechanism of action The way in which a medication produces the intended response.

nicotinic receptors Cholinergic receptors that bind with the neurotransmitter acetylcholine.

nondepolarizing agents Medications designed to cause temporary paralysis by binding in a competitive but nonstimulatory manner to part of the ACh receptor; they do not cause fasciculations.

onset of action The time needed for the concentration of the medication at the target tissue to reach the minimum effective level.

pharmacodynamics The branch of pharmacology that studies reactions between medications and living structures, including the processes of body responses to pharmacologic, biochemical, physiologic, and therapeutic effects.

pharmacokinetics The study of the metabolism and action of medications with the particular emphasis on the time required for absorption, duration of action, distribution in the body, and method of excretion.

potentiation The effect of increasing the potency or effectiveness of a drug or other treatment; may occur by administering two medications concurrently, where one increases the effect of the other.

side effects Reactions that can manifest as signs or symptoms that are not desired but are expected based on how the medication works.

steady state A point in drug administration at which the rate of administration (frequency and dose) is equal to the rate of elimination, resulting in a constant plasma medication level.

summation effect The process whereby multiple medications can produce a response that the individual medications alone do not produce.

sympathomimetic Medication that mimics the body's sympathetic nervous system response (fight or flight response); includes epinephrine and norepinephrine.

synergism An interaction of two or more medications that results in an effect that is greater than the sum of their effects if taken independently.

tachyphylaxis A condition in which the patient rapidly becomes tolerant to a medication.

termination of action The amount of time after the medication's concentration falls below the minimum effective level until it is eliminated from the body.

therapeutic index The ratio of a drug's lethal dose for 50% (LD_{50}) of the population to its effective dose for 50% (ED_{50}) of the population; a medication's margin of safety.

tolerance Physiologic adaptation to the effects of a drug such that increasingly larger doses of the drug are required to achieve the same effect.

Vaughan-Williams classification scheme Classification system for antiarrhythmic medications.

zero-order elimination Medications or chemicals are eliminated from the body at a constant rate, regardless of plasma concentration.

Laboratory Analysis and Diagnostic Studies

Authors

Barbara L. Chorney, RN, CEN, CTRN, EMT-P

Chris Handley, BS, EMT-P

Objectives

1. Understand the overall principles of laboratory analysis (p 236).
2. Understand the difference between sensitivity and specificity (p 236).
3. Discuss the difference between specimen culture and sensitivity (p 237).
4. Understand relevant basic chemistry and physiology (p 237–238).
5. Recognize the most commonly ordered laboratory tests done in the emergency department and in the intensive care unit (p 239–247).
6. Understand the importance of abnormal laboratory results as they relate to patient condition (p 239–247, 250–252).
7. Discuss the causes of abnormal laboratory results (p 239–247, 250–252).
8. Recognize blood typing and blood groups (p 248).
9. Understand the proper procedure for collecting blood specimens (p 249).
10. Identify the proper test tubes used for collecting blood specimens (p 249–250).
11. Identify the common errors in specimen collection (p 252).
12. Understand the basics of diagnostic imaging, including the standard radiograph, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (p 252–253).

Introduction

CCTPs, when performing interfacility transports, are often responsible for patients who have undergone a battery of tests and have had examinations performed at the referring institution. These laboratory tests (sometimes called "labs") can be very useful in determining the seriousness of the patient's condition or aiding in anticipation of potential problems while en route. These tests will include laboratory examinations of the patient's blood, possibly urine, cerebrospinal fluid (CSF), or other body fluid.

Laboratory analysis serves many purposes in the critical care transport environment. A CCTP must be comfortable with not only the normal ranges for each lab value, but also the associated physiologic meaning of the test. Lab tests should not be used to satisfy one's curiosity, "complete the picture" for a particular panel of tests, or reassure concerned family or staff. Today's health care environment mandates a thoughtful and evidence-based approach to ordering tests, especially laboratory work.

Principles of Analysis

Laboratory analysis should run deeper than simply surmising whether the value is outside the normal range for that test. If the normal value range for creatinine is 0.6 to 1.2 mg/dL, for example, it will be clear that a patient whose creatinine value is 4.5 mg/dL is out of the normal range. The crucial thing to know is how this excess level affects the patient now and how it will affect the patient en route to the receiving facility. Certain principles that guide the analysis of all laboratory values must always be

present in a CCTP's mind.

An appreciation of a lab test's **precision** and **accuracy** is essential to the proper use of the particular lab test. If a particular lab test has a high precision, every time the test is performed, the value will be the same. For example, if a patient's serum sodium level was measured five times on the same sample, the values may range from 152 to 155 mEq/L. This test exhibits high precision (tightly packed values), but the results would be inaccurate if the patient's true serum sodium level is 140 mEq/L **Figure 8-1**. A test is considered accurate if the value (or average value) measured conforms to the standard or true value. Precision, on the other hand, is a measure of tolerance or variation within multiple measurements but does not reflect how well the measurements compare with the true value **Figure 8-2**. The scientists who design laboratory tests strive for tests that are precise and accurate.

As with their precision and accuracy, laboratory tests have differing levels of sensitivity and specificity. **Sensitivity** refers to the ability of a test to indicate whether a person does or does not have a certain condition. If a test is highly sensitive, most of the people with a particular condition would have a positive result. If a test has a low sensitivity, many people with the condition would have a negative result. Sensitivity is the proportion of people with the target disorder who have a positive test result. **Specificity**, on the other hand, is the proportion of people without the target disorder who have a negative test result. The **D-dimer test**, a test of hypercoagulability that detects a fragment, d-dimer, from the fibrinolysis process, is used to help diagnose and monitor diseases and conditions related to inappropriate clotting; for example, it can be used to test for deep venous thrombosis (DVT). This test provides a good illustration of sensitivity vs specificity. The presence or absence of DVT was determined by ultrasound (the "standard" in this example). The results are shown in **Table 8-1**.

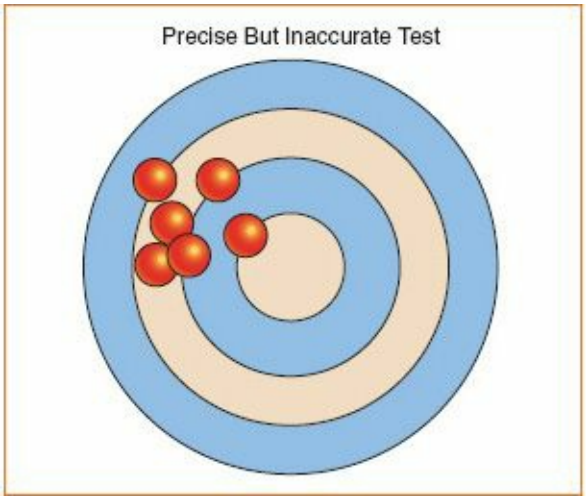

Figure 8-1 Precise (because results cluster together) but inaccurate (because results are out of the normal range [center circle]) lab test.

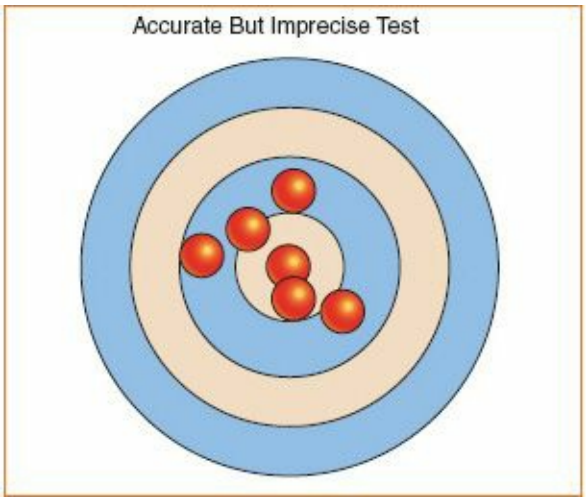

Figure 8-2 Imprecise (because results vary substantially) but accurate lab test.

TABLE 8-1 D-Dimer Test for DVT

D-dimer test result	Target disorder (DVT) present on ultrasound	Target disorder absent (no DVT) on ultrasound	Total
Positive	13	19	32
Negative	1	72	73
Total	14	91	105

Abbreviation: DVT, deep venous thrombosis.

The sensitivity of the d-dimer test for the presence of DVT is calculated by dividing the number of patients with a positive test result by the actual number of patients with the disorder:

$$13/14 = 0.928, \text{ or } 93\%$$

In other words, the d-dimer test will correctly identify a patient with a DVT 93% of the time.

On the other hand, the specificity of the d-dimer test for the presence of DVT is calculated by dividing the number of patients with a negative test result by the actual number of patients without the disorder:

$$72/91 = 0.791, \text{ or } 79\%$$

In other words, the d-dimer test will correctly identify a patient without DVT 79% of the time.

Certain tests lend themselves to certain levels of analysis. For example, often a serologic blood test examining for the presence or absence of the hepatitis B virus will show a result as positive or negative. This is a *qualitative* assessment because the result does not identify the specific level of hepatitis B virus within the blood. If the viral load of hepatitis B is desired, a *quantitative* test is performed to indicate the exact amount of the virus within the blood. Sometimes semiquantitative assessments are performed. For example, a urine test looking for blood in the urine may give the result as none, mild, moderate, or severe.

Novices in laboratory analysis can become overly concerned about the notion of normal vs abnormal lab values. One must remember that normal ranges were identified based on findings in healthy people—not the patients being transported by ambulance. By convention, a **normal range** is empirically derived and represents values that 95% of *healthy* people would have for the particular test. Thus, for every 100 healthy people tested, 5 will not have results that fall in the normal range, even though their particular level is "normal" for them.

When this idea of "normality" is transferred to dealings with patients who have acute diseases, one must be careful not to react too impulsively to spuriously high or low values. Not only is the normal range

for a particular lab test subjective in the emergency department (ED) or intensive care unit context, but an abnormal result may also be the desired effect of a particular treatment. Consider the intentional fluid depletion that is used with patients who have experienced a traumatic brain injury. Part of the therapy may be to decrease the intravascular volume, which will result in abnormally high serum sodium values. Trying to correct the "abnormal" serum sodium value would harm the patient. The message here is simple: Although abnormal lab values cannot be ignored, it is essential that they be put into context of the patient's entire clinical picture.

When dealing with an acute care patient, one must confirm abnormal findings by considering them part of the patient's entire clinical picture. If a particular lab test indicates a certain condition (eg, fluid depletion) but that finding is not confirmed by other tests or by other assessment methods (eg, increased heart rate or decreased blood pressure), the validity of the test or test result in that patient must be reexamined.

With all tests, it is important to keep in mind that errors in specimen collection, identification, labeling, and laboratory analysis can and do occur and may result in erroneous values being reported.

When evaluating laboratory results, it is critical to recognize that different laboratories have different normal ranges for the same tests. In fact, readers may find that many of the normal ranges listed in this text are different from the ranges they are accustomed to using in their local practice. It is likely that three different labs would have three different sets of normal ranges for each test they perform. It is essential to give careful attention to the normal values (indicated on report forms) when reviewing lab reports.

Specimen Cultures

Blood, urine, sputum, and other body fluid cultures provide information that is used to identify microorganisms and treat specific infections. For example, a sputum culture is obtained when a respiratory infection is suspected. It requires a conscious patient to be well hydrated and able to follow commands to produce sputum from a deep cough. An unconscious patient may be deep suctioned to obtain a sample. If a sample is not actual sputum, false results are likely, identified on the laboratory report as "mixed flora"; such results are not useful.

Sensitivity testing can be done as well (culture and sensitivity testing is sometimes called C and S). For bacterial infections, the sensitivity results indicate which antibiotic will most effectively treat the organism causing the infection. A specimen for culture should be obtained before antibiotic therapy is started so that the antibiotic does not influence the culture result and the proper antibiotic (one to which the microorganism is sensitive) can be selected. Usually, it takes 3 days for a laboratory to complete a culture and sensitivity report; an initial report is generated in about 24 hours, whereas a complete and final report will not be available for 72 hours.

Chemistry Review

Many consider the care of an acute patient to be akin to an advanced experiment in physiology. Physiology is built on the basics of chemistry and cellular biology, the principles of which should be part of the health care provider's educational background. Insightful test interpretation requires a firm grasp of these principles.

Ions

Ions are atoms that have gained or lost electrons. Recall that each electron has a single (–1) negative charge. If electrons are lost, the charge on the atom is "less negative," or the atom is now "more positive." The reverse is true if electrons are gained by the atom. A positively charged ion is referred to

as a **cation**, whereas a negatively charged ion is called an **anion**. If one electron is deleted from an atom, its charge is +1. If two electrons are deleted, its charge is +2. Conversely, if one electron is added to an atom, its charge is –1. If two electrons are added, its charge is –2. Often ions of opposite charge will join together with an **ionic bond**. Sodium chloride (NaCl—table salt) is an example of a molecule that is joined by an ionic bond. When molecules with ionic bonds interact with water (remember that plasma is 90% water), they often dissociate into the basic ionic forms **Figure 8-3**. This is why Na^+ and Cl^- exist as separate ions within plasma, rather than as the compound NaCl. The ionic components of plasma constitute the electrolytes, which include sodium (Na^+), potassium (K^+), chloride (Cl^-), calcium (Ca^{++}), and magnesium (Mg^{++}), among others.

Amounts of ions are expressed in moles or equivalents. A mole is a unit representing 6.02 × 1023 atoms, in much the same way that a "dozen" is used to specify 12 eggs. Equivalents (Eq) are used to measure amounts of charged particles (ie, ions). Essentially, 1 Eq is equal to 1 mole of ionic charges. Given that a single Na^+ atom has one charge, 1 mole of Na^+ atoms has 1 mole of charges (1 Eq). Similarly, calcium (Ca^{++}) has two charges, so 1 mole of Ca^{++} has 2 moles of charges (2 Eq). This concept applies only to charged particles; uncharged molecules, such as proteins, are electrically neutral overall.

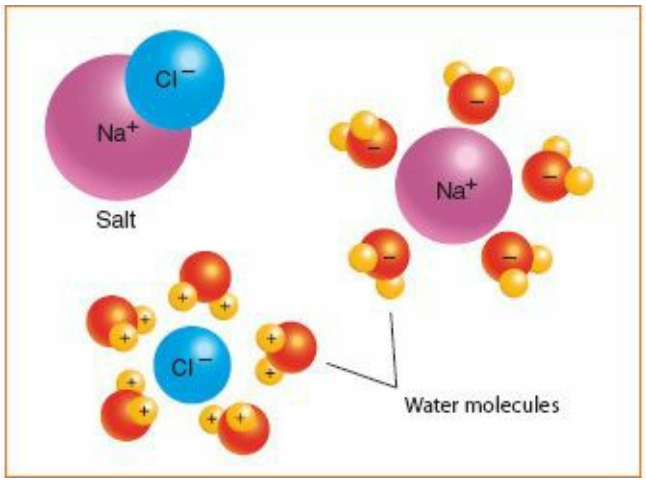

Figure 8-3 The ionic bonds of sodium chloride dissociate into their basic ionic forms when they interact with water.

Osmolarity

Laboratory testing often involves the analysis of certain fluid characteristics. One characteristic of interest to CCTPs is the **osmotic pressure** created by the blood, CSF, or urine sample. Because human cells are semipermeable membranes, **osmosis** (the diffusion of water across membranes) is a major mechanism of fluid movement between the body's different fluid compartments. The osmotic pressure is created in the space divided by the semipermeable membrane owing to differences in concentrations of solutes (dissolved substances) found in the solutions on either side of the membrane.

The osmotic pressure generated by the particles in the fluid is called the osmolarity or osmolality, depending on the method of measurement. Physiologic measurement of osmotic pressure in humans is measured as osmolality, often mislabeled as osmolarity. **Osmolarity** measures the amount of dissolved substance in 1 L of water, whereas **osmolality** measures the amount of dissolved substance in 1 kg of water. Because the volume (liter) of a fluid depends on the temperature of the fluid, osmolality is used because the weight (kilogram) of fluid is independent of temperature. The unit of measurement for osmolality is the osmole (Osm), which is the pressure created by 1 mole of particles in solution.

It is important to note a particular chemical property of osmosis: osmotic pressure depends only on the number of particles in the fluid, not on the size of the particles. A single protein or sugar molecule

induces the same osmotic pressure as a single ion of sodium (Na^+).

Ultimately, we want to know the amount of a particular ion or protein that is present in the sample. This amount is expressed as a **concentration**, which is the amount of the substance present in a given volume of fluid. For example, a patient's Na^+ concentration may be expressed as mmol/dL (millimoles of Na^+ per deciliter of blood). Because Na^+ has a single charge, the Na^+ concentration may also be expressed as mEq/L (milliequivalents of Na^+ per liter of blood). In the physiologic system, most concentrations are incredibly small. As a result, units of 1/1,000 (milli-) are often used to describe concentrations, including millimoles (mmol), milliequivalents (mEq), and milliosmoles (mOsm).

Laboratory values are reported in conventional units (such as milliequivalents per liter) or in Système International d'Unités (SI units; such as millimoles per liter). Many laboratories use SI values for some tests and conventional units for others, or they might use only conventional units. When reviewing results for a patient, CCTPs need to be sure that the reported units of measure are the same as the units of measure (that is, both conventional or both SI) given in the normal range.

CCTPs need to be aware that each laboratory has its own normal ranges that usually are printed on the laboratory report with the patient's values. In addition, normal ranges may differ from one instrument manufacturer to another. CCTPs should be familiar with the normal ranges for tests often used in the critical care transport setting, and they should be alert to normal ranges listed for all tests used for a specific patient, especially when comparing results from different facilities.

Biochemistry Review

Examining the basic ions and fluid properties provides only part of the story. To ascertain how well an organ (such as the liver) is functioning, it is necessary to look at various proteins and enzymes in a serum sample. Thousands of different kinds of proteins reside in the human body, and specific laboratory tests examine the amount of the various types of proteins present in a sample.

Enzymes are critically important proteins that act as catalysts for biochemical reactions. The formation of one biologic substance from another may proceed slowly when just the two substances are present; with the addition of the appropriate enzyme, however, the reaction rate may increase many times. Methods of measuring enzyme levels often rely on this basic catalytic principle. The beginning substrate (material) for the reaction is added to the sample, and the amount of product generated in a given time is measured. By knowing the beginning amount of substrate and the amount of product produced and by assuming normal enzyme function, one can then calculate how much enzyme is present. The function of enzymes is measured in units per liter (U/L), which is the amount of enzyme that catalyzes 1 micromole (μmol) of substrate per minute.

Lab Profiles

In laboratory testing, groups of related tests can be performed as a single unit, called a **panel** (or profile). The single unit comprising these related tests is often named for the tests' common link. For example, a liver panel consists of a set of tests that examine liver function, and a basic electrolyte and metabolite panel may be called a Chem-7. In a patient's hospital chart, these panels are written in the form of a matrix.

Lab Values in Blood Samples

Examination of the electrolytes and metabolites in the extracellular fluid constitutes one of the most basic and fundamental assessments done in the ED or intensive care unit. Often this is done as a standard panel

as mentioned earlier: the basic metabolic panel (or Chem-7) **Figure 8-4**.

Sodium

Sodium (Na^+) is the major extracellular ion; its serum concentration in a healthy person ranges from 136 to 142 mEq/L (mmol/L). This contrasts with intracellular concentrations of Na^+, for which the normal range is only 3 to 20 mEq/L. Dramatic changes in a patient's serum sodium level are possible and are primarily due to changes in extracellular water concentrations. As a patient becomes depleted of free (solute free) water, the serum sodium concentration increases (more sodium ions per liter of water). The introduction of excess extracellular water (without additional sodium) will, therefore, decrease serum sodium levels.

Serum sodium is a convenient marker for a patient's fluid status and is one of the key components of the serum osmolality calculation explained later in this chapter. Unlike with potassium derangements (discussed later), an abnormal sodium level will not manifest with electrocardiographic (ECG) changes. Most signs and symptoms revolve around neurologic sequelae owing to changes in osmolality.

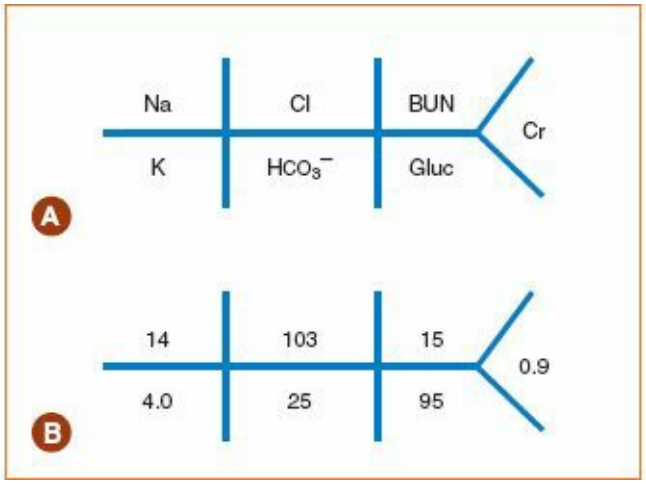

Figure 8-4 **A.** The items measured in a basic metabolic panel, shown in the format in which values are written. **B.** An example of how the values would be written, with each slot representing a particular lab value. These values are for a healthy person.

Elevated sodium levels are not uncommon in patients who are undergoing critical care transport. An elevated sodium level in a patient with a traumatic brain injury is likely a consequence of treatment at the referring hospital. Diuretics and restricted fluid intake are used in an effort to cause the excretion of more water than is taken in—essentially "drying out" the patient. This treatment is aimed at lowering intracerebral pressure. The serum sodium level in patients with traumatic brain injury can often exceed 170 mEq/L.

Hyponatremia (an abnormally low level of sodium in the blood) often results from an excess of free water or excessive sodium depletion. It can be found in patients with congestive heart failure, renal failure, or liver disease and in patients undergoing diuretic therapy. Although some debate exists about how fast a hyponatremic state should be corrected, slower (0.5 mEq/L per hour) is better to avoid causing subsequent neurologic problems.

Patients with a sodium imbalance (high or low) need to be monitored for intake and output, including oral and IV input. A sodium level of less than 125 mEq/L can result in behavioral changes, confusion, delirium, increased respiratory rate, muscle twitching, increased intracranial pressure, and cardiac abnormalities. Increased sodium levels can cause fluid retention and cardiac abnormalities.

Potassium

Whereas sodium is the major extracellular cation, potassium (K^+) is the major intracellular cation. The extracellular K^+ concentration (as typically measured in blood) is normally 3.5 to 5.0 mEq/L.

Of primary concern is the effect of an elevated K^+ level on cardiac cells, with cardiac arrhythmias occurring with **hyperkalemia** (an abnormally high level of potassium in the blood). A potassium level of 5.5 to 6.5 mEq/L can result in the classic peaked T waves, with flattened P waves occurring when the potassium level exceeds 7.0 mEq/L. Derangements in other electrolytes (for example, hypocalcemia, hypomagnesemia, and hyponatremia) can exacerbate hyperkalemia. Hyperkalemia in an acute care patient can occur as the result of excessive potassium supplementation, intracellular to extracellular fluid shifts with cellular lysis (seen with crush injuries and tissue necrosis), drug administration (angiotensin-converting enzyme inhibitors, for example), metabolic acidosis, and decreased excretion, as might occur in acute renal failure. CCTPs should be aware that many abnormally high potassium levels are actually reported in error—for example, cellular lysis (hemolysis) can cause an elevated potassium level, so if the sample is hemolyzed before analysis, an incorrect value may be reported.

Causes of **hypokalemia** (an abnormally low level of potassium in the blood) include cellular shifts (for example, as the result of insulin administration or hypothermia) or increased excretion of potassium (gastrointestinal [GI] tract or renal losses). Although younger patients may have a higher tolerance for decreased levels of potassium, older patients (especially patients taking a digitalis preparation) are more likely to have arrhythmias and ECG changes with low K^+ levels.

Low K^+ levels result in muscle pain, hyporeflexia, nausea, vomiting, and orthostatic hypotension. High K^+ levels can cause cardiac abnormalities, particularly atrioventricular and intraventricular blocks. Atrial arrest is likely when the K^+ level reaches 9 mEq/L.

For any patient with a cardiac history, altered renal function, liver disease, GI disturbances, or who is receiving insulin, a recent K^+ level should be available for review before transport.

Special Populations

Older patients with decreased potassium levels, especially those taking digitalis preparations, will have cardiac changes. Hyperkalemia can indicate digitalis toxicity.

Chloride

Chloride (Cl^-) is the major extracellular anion. Its single electrical charge is responsible for offsetting the positive charge of Na^+ and K^+, thereby maintaining electrical neutrality within the body. Serum concentrations range from 96 to 106 mEq/L in healthy people. Chloride is an important tool that the kidney uses to concentrate urine. Patients with **hypochloremia** (an abnormally low level of chloride in the blood) may have impending renal dysfunction. Care should be used with patients receiving diuretic therapy because they may also have abnormally low chloride levels. Strangely, patients with excess diuresis can also exhibit **hyperchloremia** (an abnormally high level of chloride in the blood).

In practice, chloride levels mimic sodium levels; when hypernatremia is present, hyperchloremia often is as well. Clinically, serum chloride levels help differentiate certain types of metabolic acidosis.

High chloride levels can result in circumoral numbness and tingling, muscle hypertonicity, decreased respiratory rate and depth, possible complaints of nervousness, and signs of central nervous system stimulation.

Carbon Dioxide

One of the most basic indications of the acid-base status of a patient is the *venous* bicarbonate level.

Confusing as it may seem, the carbon dioxide level (CO_2) is not a CO_2 level at all; rather, this test indicates the amount of bicarbonate (HCO_3^-) in the venous sample. Carbon dioxide and bicarbonate are in equilibrium according to the following equation:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

Thus, CO_2 and HCO_3^- are related, although they are actually very different substances. Carbon dioxide is a gas, so when it is measured, the value should be expressed as a partial pressure. Bicarbonate is an ion and, like the other ions mentioned earlier in this chapter, the value is expressed as a concentration. A level below the normal range could indicate metabolic acidosis or respiratory alkalosis, whereas an elevated level could indicate metabolic alkalosis or respiratory acidosis. The normal HCO_3^- value is 21 to 28 mEq/L, and the normal CO_2 value is 22 to 28 mEq/L.

Blood Urea Nitrogen

A product of protein catabolism, urea is related to the amount of protein intake, protein metabolism, and rate of excretion. Urea is considered a useful marker for adequate kidney function because its level in kidney filtrate is often the same as in serum. The normal range for **blood urea nitrogen (BUN)**, which is the test used to measure urea, is 8 to 23 mg/dL. The BUN level tends to increase with age as a consequence of gradually declining renal function; a slightly elevated BUN finding of 28 to 35 mg/dL in older patients should not necessarily be a cause for concern owing to the slowing of renal function. Concern for an elevated BUN level in an elderly patient may vary depending on the results of other lab tests and the findings of the patient assessment. Any value of more than 40 mg/dL should be monitored closely.

When patients have high renal output levels, BUN values are a less valid means of assessing kidney health because of the inverse relationship between urine formation and urea reabsorption. Elevated levels of urea occur not only with decreased renal function, but also with consumption of a high-protein diet and in the presence of a high-protein catabolism state (for example, burns and crush injuries).

Creatinine

A major storehouse of intramuscular high-energy phosphate, **creatine** is degraded to **creatinine (Cr)** (a chemical waste product that results from muscle metabolism) at a relatively steady rate by the muscles. Within one person, the rate of Cr production typically varies by only 10% at any particular time. Creatinine is filtered from the blood by the kidneys and, without reabsorption, is excreted in the urine. Because of its steady rate of production, this by-product of metabolism can be used to assess kidney function. If urine function decreases, serum Cr levels rise above normal (normal range, 0.6 to 1.2 mg/dL).

An abnormal serum Cr level does not indicate exactly what the disease or cause is, but it does indicate some level of decreased renal function. Under certain circumstances, a patient may have an increased Cr level with adequate renal function, such as when the patient has had a large amount of muscle damage (owing to protein release from trauma, called rhabdomyolysis). Care must be taken when a geriatric patient has a Cr level slightly more than the upper normal value (near 1.5 mg/dL): Owing to the proportionately smaller amount of muscle mass and consequent lower Cr production in older people, a small elevation in the Cr level may reflect greater kidney dysfunction than would the same level in a younger patient.

If the cause of the elevated Cr level is not identified and corrected, damage to the kidneys will be permanent, requiring lifetime dialysis or kidney transplantation.

Creatinine clearance is identified as the most accurate measure of the glomerular filtration rate. The results of a Cr clearance test can be used to determine long-term management of patients with chronic

disorders of renal function and to calculate appropriate fluid and electrolyte replacement therapy. Creatinine clearance is calculated by multiplying the concentration of measured urine Cr by the volume of urine during a set time and dividing the product by the serum concentration of Cr. One test result does not give a great deal of information. However, serial results can be very useful in determining a patient's course of therapy.

Special Populations

Beware of geriatric patients with creatinine levels approaching 1.5 mg/dL. They may have more kidney damage than might otherwise be suspected, owing to the relatively smaller amount of muscle mass present, such that less creatinine is produced.

Glucose

Glucose is the most important carbohydrate within the body and is the lab measurement with which CCTPs may be most familiar. Glucose is commonly assessed in the field with a point-of-care testing device, and prehospital care providers often measure the blood glucose level of unconscious or semiconscious patients. Concentrations of glucose are normally in the range of 70 to 110 mg/dL. Maintaining a normal glucose level is an extremely important activity for CCTPs because patients may be receiving insulin drips or may have acute renal failure, which will affect the blood glucose level. If a patient is receiving an insulin drip, adjustments to the drip may be required if the patient's glucose level is steadily dropping. If the glucose level rises in a patient with renal failure, hypovolemic shock may occur.

High glucose levels that are not identified and corrected can potentially result in coma and death. Low glucose levels are generally easier to recognize early because of symptoms such as blurred vision, dizziness, nausea, vomiting, and shakiness. If left untreated, the patient can become unconscious, possibly injuring himself, herself, or someone else.

Total Calcium

Calcium is one of the most essential electrolytes found in the body. It is responsible for functions from muscle contraction to intracellular signal transduction. Physiologically, calcium is found in three states: free, chelated, and bound. The largest portion of calcium (47%) is found as a free calcium ion dispersed in the body fluids. Another 43% of calcium in the body is bound to proteins, mostly albumin. Naturally, the amount of calcium bound to proteins depends on the ability of the protein to complex with the calcium ion (Ca^{++}). Protein binding is a function of the shape of the protein, which in turn is heavily dependent on the surrounding pH. In abnormal pH states, the amount of calcium bound to proteins decreases, and, therefore, the amount of free calcium increases. Calcium that is chelated (bound) to other molecules, such as citrate, bicarbonate, lactate, phosphate, and sulfate, represents only 10% of the calcium in the body.

The sum of all calcium in the body is expressed as the total calcium level (Ca^{++}_{TOT}). The normal range for Ca^{++}_{TOT} is 8.2 to 10.2 mg/dL. The Ca^{++}_{TOT} is increased in elevated parathyroid hormone states such as hyperparathyroidism and parathyroid-secreting tumors. Low levels of Ca^{++}_{TOT} are seen with renal insufficiency, hypomagnesemia, and hyperphosphatemia and in patients who have received a massive blood transfusion or have decreased parathyroid hormone states.

Ionized Calcium

Only the calcium that is not bound or chelated (ie, free calcium) is physiologically active. In states in

which there are altered fractions of bound or chelated calcium, free calcium assessment is warranted. Examples of physiologic states that warrant assessment of **ionized calcium** include renal failure or nephrotic syndrome (hypoalbuminemia), acid-base derangements (particularly acidosis), and decreases or elevations in chelating compounds (citrate, bicarbonate, lactate, phosphate, and sulfate). The normal range for ionized calcium is 4.60 to 5.08 mg/dL.

Low levels of ionized calcium can cause serious arrhythmias and are especially pronounced in prolonged cardiac arrest. Although calcium administration has not been shown to be of long-term benefit to patients who have had cardiac arrest, its use for treatment may be warranted in patients with hyperkalemia, hypocalcemia, or toxic levels of calcium-channel blockers. CCTPs may find that patients with one of the aforementioned conditions are transported with a magnesium sulfate drip to decrease the likelihood of further cardiac arrhythmias or cardiac arrest.

Magnesium

Magnesium (Mg) levels can be affected by several body systems, in particular the GI and endocrine systems. The normal serum magnesium level is 1.3 to 2.1 mEq/L. High Mg levels are rarely encountered. Generally, the causes are renal defects, severe dehydration, overadministration of Mg, untreated diabetic coma, and aspiration of sea water. Low Mg levels are more commonly seen, as in GI distress, vomiting and diarrhea, hepatic cirrhosis, and pancreatitis.

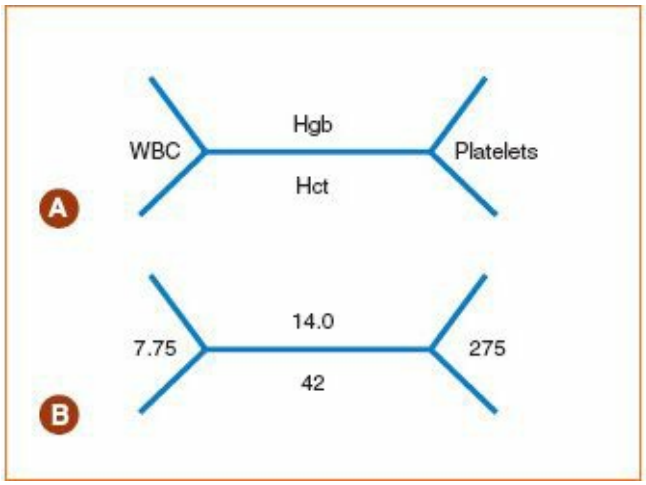

Figure 8-5 Complete blood count schematic (abbreviated notation). **A.** The format in which values are written. **B.** An example of values for a healthy person.

Blood Components

Figure 8-5 shows the schematic for abbreviated notation of a complete blood count (CBC) test. The schematic is intended to be used for quick reference of pertinent values. It is presumed that if one of these values is abnormal, the CCTP would go to the more complete medical record to ascertain other values.

Hematocrit

Hematocrit, sometimes abbreviated Hct, is one of the more general laboratory assessments. Its sensitivity for disease is very high, but its specificity is rather low. Thus, if a patient's hematocrit value is out of the normal range, disease may be indicated, but many different diseases or conditions could cause the abnormal value.

Hematocrit is the percentage of formed elements (that is, cells) in a venous blood sample. A hematocrit value of 45% indicates that 45% of the sample consists of cells or cellular debris, and the other 55% consists of plasma. The nature of this relationship leads to the lack of specificity for this test. For example, with an acutely ill patient, the health care provider is often concerned with a low hematocrit

value. A low level of formed elements, which are predominantly red blood cells, can indicate decreased capacity of the blood to deliver oxygen to the tissues. A patient who has an excess amount of plasma (such as from overzealous use of crystalloids) will also have a low hematocrit value. The normal range for hematocrit is 41% to 50%. For example, a patient with a hematocrit value of 22% could be exsanguinated or fluid overloaded **Figure 8-6**. Therefore, for a patient with an abnormal hematocrit level, further investigation must be done to identify the precise cause of the abnormality.

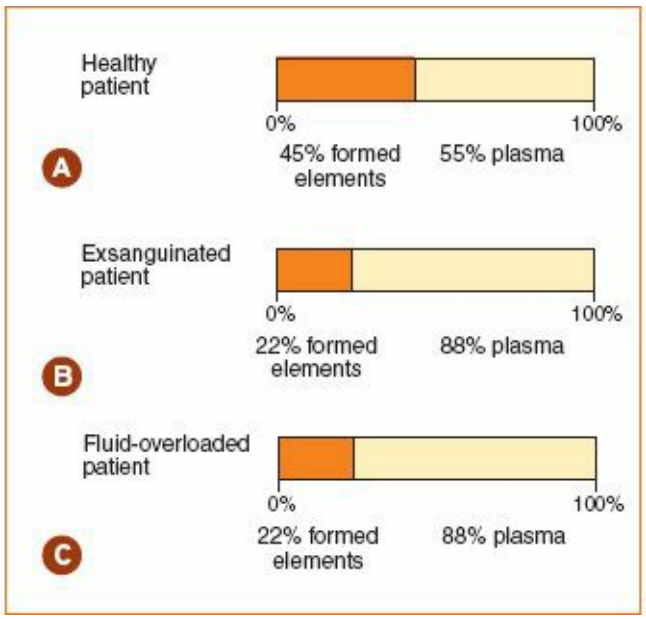

Figure 8-6 Examples of hematocrit levels and (B and C) potential causes. **A.** Healthy patient. **B.** Exsanguinated patient. **C.** Fluid-overloaded patient.

Hemoglobin

Hemoglobin (Hgb) is the protein responsible for carrying oxygen to the cells and, to a lesser extent, carbon dioxide back to the lungs. The abbreviations Hg and Hb are also used for hemoglobin. The level of hemoglobin varies by gender, with normal values falling in the range of 135 to 175 g/L (14.0 to 17.5 g/dL) for males and 120 to 160 g/L (12.0 to 16.0 g/dL) for females. Elevated levels are seen in people with **hemoconcentration** (decreased fluid in the blood, which means that concentrations of other blood components increase), which can result from dehydration, burns, or excessive vomiting. Of greater concern are low Hgb levels, which are typical of most types of anemia (microcytic, normocytic, and macrocytic).

Carboxyhemoglobin

Because carbon monoxide binds with hemoglobin irreversibly, the body's ability to transport oxygen can become extremely compromised when too much CO is present in the body. Although some **carboxyhemoglobin (COHb)**, a hemoglobin derivative, is always present in the vasculature, normal levels are thought not to exceed 0.02 (2%). The percentage is based on the amount of total hemoglobin. Assessment of COHb levels is useful in confirming a diagnosis of carbon monoxide poisoning, and it may be used to guide therapy as well. Caution should be used in assessing COHb levels in smokers, as their baseline COHb levels are normally higher than non-smokers. COHb levels must be requested specifically from the lab because the specimen is processed in a particular manner.

Red Blood Cell Count

The number of erythrocytes, or red blood cells (RBCs), per microliter of blood constitutes the RBC count. The normal range for **red blood cell (RBC) count** is 3.9 to 5.5 × 106/μL. Although an abnormal

number of RBCs does not necessarily mean the presence of disease, the RBC level can be elevated with hemoconcentration. Patients with elevated white blood cell counts may have an erroneously high RBC level owing to analysis errors. As expected, low levels are also seen in all types of anemia.

Leukocyte Count

The **white blood cell (WBC) count** is a measure of the total number of leukocytes (WBCs) in the blood. Because an "ordinary" WBC count does not differentiate among the various types of leukocytes in the sample, only so much clinical information can be inferred from this test. The normal range for WBC counts is between 4,500/µL and 11,000/µL. Low levels of WBCs are seen in patients with certain anemias (such as aplastic anemia), vitamin deficiencies, or sepsis. Although it might seem counterintuitive, low levels are also seen in sepsis: WBCs are mobilized to fight the infection and are ultimately destroyed at a rate that exceeds their production. **Leukocytosis** (elevated WBC count) is seen not only with inflammation or infection, but also in certain malignancies (leukemia and lymphoma) and vascular conditions (such as pulmonary embolism, acute myocardial infarction [AMI], and DVT), with steroid administration, and with the stress of trauma.

Platelet Count

Given that platelets fulfill essential roles in clot formation, the **platelet (Plt) count** is useful in assessing a patient's coagulation status. The normal range for a whole blood sample is 150 to 350 × 103/µL. Elevated levels of platelets are seen in patients with certain myeloproliferative disorders (a group of diseases in which the bone marrow produces too many RBCs, WBCs, or platelets; examples include polycythemia and chronic myelogenous leukemia), most notably after severe bleeding or following splenectomy. Decreased levels may occur when disease causes decreased production in the bone marrow. Often **thrombocytopenia**—an abnormally low level of platelets—is due to splenomegaly, disseminated intravascular coagulation (DIC), or high circulating levels of platelet antibodies (such as after massive transfusions).

Proteins

Total Protein

One of the most basic protein tests, **total protein**, examines the total quantity of protein in a blood sample. This quantity consists of mostly albumin and immunoglobulins. The normal range for a serum sample of total protein is 6.0 to 8.0 g/dL, and variations are almost always due to fluctuations in serum albumin levels. As a consequence, most clinicians focus on albumin levels.

Albumin

By far the most common protein in the body is **albumin**. Albumin serves many functions: It acts as a transport protein (for free fatty acids, bilirubin, hormones, and drugs), it is a free-radical scavenger, and it serves as the main source (70%) of protein-generated oncotic pressure. This is the osmotic pressure that allows for colloids to move from one side of the cell membrane to the other as needed. The normal range for albumin is 3.5 to 5.0 g/dL.

A low level of albumin may be due to increased catabolism of the protein (as seen in malnutrition), decreased production, or edema in the spaces between the cells in the tissue. Decreased production is seen in patients who have liver damage or other liver disease. **Hypoalbuminemia** (an abnormally low level of albumin) from increased interstitial sequestration can occur in high-vascular-permeability states and leads to diseases such as acute respiratory distress syndrome. High levels of albumin generally indicate only dehydration and are not pathologic.

C-reactive Protein

C-reactive protein (CRP) is an acute phase protein synthesized in the liver. It is an indicator of inflammation that begins to rise four to six hours after tissue injury. The normal range is 0.08 to 3.1 mg/L. A CRP level above 10 mg/L indicates significant inflammatory disease.

Myoglobin

Myoglobin is an oxygen-carrying heme protein present in high concentrations in the cytoplasm of cardiac and skeletal muscles. In cardiac patients, you may see an increase within two hours after the onset of chest pain. A positive myoglobin result after chest pain warrants further investigation; however, a negative myoglobin result can be used in ruling out a myocardial infarction. The normal range is 19 to 92 μg/L.

Lactate Dehydrogenase

In the absence of a functioning citric acid cycle (discussed in Chapter 9), pyruvate (the end product of glycolysis) is metabolized to lactate. The enzyme catalyzing this reaction is **lactate dehydrogenase (LDH)**. Found in almost all tissues of the body, the total form—LDH—is not sensitive or specific for any disease. The normal range of LDH is 100 to 200 U/L. Its usefulness in the clinical setting comes from analysis of its isoenzyme forms (LD_1 to LD_5). Various organs, tissues, and cells differ in terms of the amount of each isoenzyme they possess. For example, LD_1 is found largely in the heart, kidneys, and RBCs. Other tissues, such as skeletal muscle and the liver, contain relatively high amounts of LD_5.

Determination of the amount of each isoenzyme present may be used to aid in the diagnosis of cellular damage. In cases of liver disease, congestive heart failure, or skeletal muscle damage, the LD_5 level may be increased. The primary point of analysis of the LDH isoenzymes is to calculate the LDH_1/LDH_2 ratio. The normal range for LD_1 is 17% to 27%; and for LD_2, 27% to 37%. A ratio of more than 85% indicates possible AMI. This finding is useful if the AMI occurred more than 24 hours earlier or if the results of testing for the creatine kinase MB fraction are inconclusive. The LD_1/LD_2 ratio will often rise to levels exceeding 85% within 24 to 48 hours after myocardial injury. The LDH value was once considered useful to aid in the diagnosis of AMI but has been replaced in routine use by troponin analysis (discussed later in this chapter). Lactate dehydrogenase can also be helpful in assisting with the diagnosis of *Pneumocystis carinii* pneumonia and determining the severity of pancreatitis.

Creatine Kinase

Creatine kinase (CK) is found in muscle, liver, lung, GI, brain, kidney, and spleen tissues. If any of these tissue cells become damaged, CK is released into the vascular space. Elevated levels are indicative of muscle damage, which may or may not be specific to AMI; concomitant muscular tissue damage also leads to elevated CK levels. With myocardial damage, CK levels rise within 4 to 8 hours, peak within 12 to 24 hours, and return to normal within 2 to 4 days. The normal range for the total CK level is 40 to 150 U/L.

The MB fraction of CK, or CK-MB, refers primarily to CK in the heart muscle. The normal range for the CK-MB level is 0 to 7 ng/mL. With a level of less than 10 ng/mL, a myocardial event is unlikely. Results ranging between 10 and 12 ng/mL are not conclusive, and additional workup and serial lab tests are required. Results of more than 12 ng/mL are indicative of a myocardial event.

Troponin I

Troponin is a key protein involved in muscle contraction. This protein has three subunits: T, C, and I. The I subunit has three separate isoforms, one of which is found only in cardiac muscle. Troponin is expressed in the serum *only after* cellular necrosis releases the respective cellular contents. Thus, measurement of the troponin levels offers some advantage over measurement of the CK and LDH levels because CK and

LDH are normally present in the serum. The normal range for cardiac troponin I (often abbreviated cTnI) is 0 to 0.04 ng/mL, but elevations following myocardial injury are detectable in a serum sample after 4 hours; tests for cTnI are 97% sensitive and 95% specific at 6 hours after an AMI. Peak levels are expressed 8 to 12 hours postinjury, but the protein may be still be detected 5 to 7 days later. Not only is the cTnI level useful in detecting AMI, but it has also been shown to be predictive of adverse outcomes in patients with severe unstable angina. Normal values for the various troponins depend on the method used to do the test, but, in general, the normal range is 0 to 0.4 ng/mL for troponin I and 0 to 0.1 ng/mL for troponin T.

B-type Natriuretic Peptide

The **B-type natriuretic peptide (BNP)** level can be indicative of abnormal ventricular function and congestive heart failure if it is more than the normal range. The normal value for BNP is less than 167 μg/mL.

Aspartate Aminotransferase

Although not truly tests of liver function, elevated **liver function test (LFT)** results are indicative of liver damage. These tests measure enzymes that normally appear, to some extent, in liver cells. When the liver is damaged, these enzymes often spill out into the vasculature. These tests include aspartate aminotransferase, alanine aminotransferase, total bilirubin, direct bilirubin, and alkaline phosphatase.

Found in large amounts in the liver, the intracellular enzyme **aspartate aminotransferase (AST)**, previously called SGOT, is also found in skeletal muscle, the brain, RBCs, and the heart. Damage to cells of any of these organs causes them to release their contents, which can then be detected in a blood sample. Low levels of AST are not of serious consequence, considering that the normal range for this enzyme is 10 to 30 U/L. Elevated levels are seen in liver damage, especially with acute conditions such as acute hepatitis or biliary tract obstruction. Chronic liver damage (due to alcoholic cirrhosis, hepatitis, and liver cancer) also produces elevation of the AST level, although not as much as that of the **alanine aminotransferase (ALT)** level (described in the next section). Elevations in AST may occur in a setting of right heart failure, hypoxia (global or endorgan), or extensive trauma.

Alanine Aminotransferase

Like its counterpart AST, ALT, previously called SGPT, is found in large amounts in the liver, kidney, skeletal muscle, and heart. Similar to the findings with AST, the normal range for ALT is 10 to 40 U/L, with low levels considered to be of no consequence. The causes of an elevated ALT level mirror the causes of an elevated AST level, with the exception that the ALT level is higher than the AST level in acute processes and lower than the AST level in chronic processes. The ALT test is considered slightly more specific than the AST test for hepatic injury because fewer organs have ALT than have AST. The ratio of AST to ALT is an important diagnostic tool and is explained further in the calculation section in this chapter.

Although AST and ALT are found in the heart, neither is valid for diagnosing myocardial infarction. Elevated levels of ALT may be prolonged because this enzyme has a long half-life (between 36 and 60 hours). As a consequence, levels may appear elevated even after resolution of the hepatic dysfunction.

Total Bilirubin

All RBCs are metabolized eventually, with bilirubin being one of the by-products of their breakdown. This by-product is unconjugated and, therefore, not water soluble (**indirect bilirubin**). When bilirubin is conjugated in the liver, it becomes **direct bilirubin**, which is ultimately excreted in the bile. The normal range for the total bilirubin level is 0.3 to 1.2 mg/dL. A measure of liver health, the total bilirubin level (direct + indirect) is often elevated in patients with liver disease. Other causes of elevated levels of total

bilirubin include biliary tract obstruction and RBC hemolysis.

Direct Bilirubin

In the medical laboratory, bilirubin may be fractionated to indicate the respective levels of unconjugated (indirect) and conjugated (direct) bilirubin. Although such tests are unreliable at times, the cause of elevated total bilirubin levels may be derived from the fractionated levels. The indirect bilirubin fraction is often elevated in conditions when massive **hemolysis** (as in massive blood transfusions or blood transfusion reactions) has occurred. If only the direct or indirect bilirubin level is reported, the other value may be obtained by subtracting the reported level from the total bilirubin level. The normal values for direct and indirect bilirubin are 0.1 to 0.3 mg/dL and 0.2 to 0.9 mg/dL, respectively.

Alkaline Phosphatase

Alkaline phosphatase is found in almost all body tissues and is manufactured by the bone, liver, intestine, and placenta. It is essential for proper digestion and absorption through the mucous membrane of the GI tract. It is clinically useful for testing liver function and, in particular, for diagnosing a common bile duct obstruction. The normal range is 30 to 120 U/L.

Amylase

A key enzyme used by the body to metabolize carbohydrates, **amylase** is produced by the salivary glands and the pancreas. Tissues such as the ovaries, small and large bowels, and skeletal muscle also produce small amounts of amylase. The normal range for amylase is 27 to 131 U/L. Tests for amylase are used to assess for pancreatic insufficiency or damage: Levels of this enzyme are elevated not only with pancreatic disease (such as pancreatitis, pancreatic cancer, and diabetic ketoacidosis), but also with bile duct obstructions and head trauma. A sign of pancreatic insufficiency, low amylase levels are seen in people with cystic fibrosis.

Lipase

The pancreatic enzyme **lipase** metabolizes lipids. Generally considered more specific than amylase for identifying pancreatic disease, lipase is also produced by the liver, intestine, and stomach. The normal range for lipase is 31 to 186 U/L. In acute pancreatitis, the levels of lipase and amylase are elevated, but the lipase level stays elevated longer. Although measurements of lipase levels have poor sensitivity in terms of identifying chronic pancreatitis and pancreatic cancer, elevated levels are often seen with both diseases. Like amylase, lipase is prone to elevation in the case of bile duct obstruction or biliary disease.

Coagulation

Assessment of the coagulation system involves looking at the intrinsic and extrinsic pathways of the coagulation cascade, shown in Chapter 9. The intrinsic pathway (initiated within the body, such as by platelet damage) begins with the activation of factor XII and then factors XI and IX, ultimately resulting in the activation of factor X and initiating the common pathway of coagulation. The extrinsic pathway (initiated outside the body) following tissue injury begins with tissue factor and factor VII, and leads to activation of factor X, initiating the common pathway of coagulation. Fibrin is eventually produced, resulting in a clot. The coagulation cascade is discussed in greater detail in Chapter 9.

The enzymes involved in coagulation are synthesized in the liver. Some clinicians consider assessments of these enzymes to be the true “liver function tests” because they are products of the liver, rather than merely being markers of liver cell damage. Many coagulation assessments are functions of time and, therefore, are reported in units of seconds.

Prothrombin Time

One of the steps in coagulation involves the creation of thrombin from prothrombin by prothrombin activator, which is a collection of activated substances. The **prothrombin time (PT)** is the rate of conversion of prothrombin to thrombin in a blood sample, and it represents the function of the extrinsic pathway. The normal range is 10 to 13 seconds. The PT may be increased in liver disease or with warfarin therapy, and decreased with low levels of vitamin K, in DIC, and after massive transfusions.

Activated Partial Thromboplastin Time

The **activated partial thromboplastin time (aPTT)** indicates the health of the intrinsic and common pathways of the coagulation system. Genetic diseases, such as hemophilia A, hemophilia B, and von Willebrand disease, may cause elevated aPTT levels. The aPTT is often used to assess for DIC, in which the level is often grossly elevated from the normal range of 25 to 40 seconds. Patients involved in interfacility transport may be receiving heparin therapy or anticoagulant prophylaxis. The aPTT is used to assess for the correct therapeutic effect of heparin.

International Normalized Ratio

Owing to lack of standardization of measuring the PT within different laboratories (especially internationally), a normalizing index has been created by using the international sensitivity index. The normal range for the **international normalized ratio (INR)** is 0.9 to 1.3. Increased ratios are seen in the same diseases in which PT is increased and in persons receiving anticoagulants. The INR is often used to target anticoagulant therapy, with ranges varying by the reason and type of anticoagulant used. The typical anticoagulation target for the INR often ranges from 2.0 to 3.0.

Lactate

Adequate indicators of a patient's tissue and end-organ perfusion and oxygenation are a long-sought "gold standard" for laboratory tests. Growing in popularity as an indicator of a patient's tissue and end-organ perfusion and oxygenation is the venous **lactate** level. Once tissue perfusion and oxygen become inadequate, cells switch to anaerobic metabolism. This mechanism allows the cells to use glucose, but less efficiently than if there was adequate perfusion and oxygen. The result of this inefficient metabolism is production of lactic acid, which is measured as lactate. Perfusion and oxygenation of cells, tissues, and end organs is considered inadequate if the serum lactate level in the blood is more than normal (normal range, 5.0 to 15 mg/dL). Lactate levels are only a global indicator of perfusion and oxygenation and do not indicate which tissues are inadequately perfused or oxygenated. Apart from being nonspecific, the lactate level is slow to respond to adequate resuscitation with fluid and oxygen. Once tissue perfusion and oxygenation return to normal, anaerobic metabolism ceases and lactate is no longer produced. The remaining lactate is converted into nontoxic metabolic by-products in the liver and kidney and, eventually, to carbon dioxide and water.

Osmolality

The serum of the blood contains numerous components that contribute to its tendency to give or extract free water when blood is placed near a semipermeable membrane. As noted in the chemistry review section, this tendency is commonly called osmolarity, although it is measured as osmolality in clinical medicine. Physiologically, the normal range for osmolality is 275 to 295 mOsm/kg. If a patient has a low level of free water in his or her system (commonly referred to as the patient being "dry"), the osmolality will be high because there will be more particulate matter for a given volume of serum. If a patient is "wet," possibly owing to excess fluid retention, the osmolality will be low. This scenario is similar to the interpretation of the serum hematocrit value. The measured osmolality is often compared with the calculated osmolality to help determine the definitive diagnosis; this will be described in more detail

later.

Ethanol

Laboratory analysis may not only have patient care implications, but also legal ramifications. For example, ethanol (also called ethyl alcohol or EtOH) is not a normal physiologic product in the body; therefore, the value if the person has consumed no alcohol is 0 mg/dL (the normal level in medical literature is < 20 mg/dL). The consumption of alcohol, especially in excess, has neurologic implications and also raises serum osmolarity.

Most states define legal intoxication as an ethanol level of more than 80 mg/dL. Owing to the legal implications of ethanol measurements, precise protocols often govern the technique for drawing the blood specimen and its storage and analysis. Before obtaining a sample for measurement of the ethanol level, CCTPs need to refer to their protocols and guidelines.

Calculated Values

Sometimes in clinical medicine, the result of an individual lab test is also used in a formula for further analysis. For example, a particular lab result may be used only in relation to another test as part of a ratio or it may be part of a complex formula used to summarize many findings in one coherent manner. From a mathematical standpoint, it is extremely important to not change the order of the ratio variables. For example, a BUN:Cr ratio is not equal to a Cr:BUN ratio. If the ratios are not calculated correctly, deviations from normal cannot be properly interpreted.

AST:ALT

The **AST:ALT** is an easily calculated index that is useful for determining the cause of liver dysfunction. For example, this ratio may be used to distinguish between acute (viral) and cirrhotic liver disease. Although not 100% accurate, if the AST:ALT ratio is greater than 1 (especially 3:1 or greater), the etiology often involves alcoholic liver disease. If the AST:ALT ratio is less than 1, acute injury—often from a viral infection—is typically to blame.

BUN:Creatinine

An index to determine the cause of increased levels of two metabolites that indicate renal pathology—BUN and Cr—is the **BUN:Cr** ratio. A normal ratio is 13:1 to 19:1. If the ratio is increased, dehydration, GI bleeding, or increased catabolism may be at fault. A decreased ratio may be present in patients with acute tubular necrosis or a low protein intake, or following hemodialysis. However, many variables affect this ratio, and it is not generally useful in the transport environment.

Anion Gap

Disturbances in the overall electrical or acid-base balance of the body result from disease and can result in further deterioration in a patient's condition. The primary pathology is usually related to respiratory or kidney problems. The major contributors to the overall electrical charge are Na^+, Cl^-, and HCO_3^-. Their relationship is called the **anion gap (AG)** and is portrayed in the following equation:

$$\text{Anion gap} = Na^+ - (Cl^- + Hco_3^-)$$

The normal range for the AG is 8 to 16 mEq/L. An increased AG indicates that unmeasured anions (such as in lactic acid) are present.

Blood Gases

A typical **arterial blood gas (ABG)** panel assesses a patient's acid-base status (pH) based on CO_2 tension ($PaCO_2$), bicarbonate level (HCO_3^-), and base excess (BE). Measures of the patient's oxygen status, oxygen tension (PaO_2), and oxygen saturation (SaO_2) are also given as part of the ABG panel. There are many indications for assessing a patient's blood gas parameters, and any patient in the intensive care unit is likely to meet at least one of these criteria. For example, a patient's blood gas levels are typically analyzed when questions arise about the capacity of a patient to exchange oxygen and carbon dioxide, especially if the patient has an underlying cardiopulmonary disease or is in such unstable condition that the clinician needs to quickly assess if the patient is near death.

Acid-Base Status

The acid-base balance reflects how well the body's respiratory and metabolic systems are functioning. If they are working properly together, then there is a balance. When they are not, acidosis or alkalosis can occur.

Hydrogen Ion Concentration

A direct measure of the acid-base status of the patient, hydrogen ion (H^+) concentration, more commonly referred to as pH, quantifies the amount of unbuffered H^+ present. Physiologic pH is related to the amount of CO_2 and the amount of HCO_3^-. An increase in the PCO_2 will result in a smaller fraction component, which translates to a lower pH (acidic). Conversely, an increase in the HCO_3^- will cause a larger fraction and, therefore, will result in a pH increase (alkaline). The inverse of each of these disturbances will result in the respective opposite result on the pH. In other words, decreased PCO_2 will increase pH and decreased HCO_3^- will decrease pH. Based on the other components of the blood gas panel, the pH derangement (acidosis or alkalosis) can be classified as metabolic or respiratory, respectively.

The normal range for the arterial pH is 7.35 to 7.45; on the venous side, the normal range is slightly lower, 7.31 to 7.41. The body can handle minor variations in pH relatively well. By contrast, once deviations in pH become extreme—for example, 7.2 or less or 7.6 or more (arterial)—normal physiologic reactions may be drastically affected. With large derangements in serum pH, many proteins and enzymes cease to carry out their normal functions, and vasopressors are inactivated. For example, in severe acidosis, epinephrine is rendered physiologically inactive.

Partial Pressure of Carbon Dioxide

The natural by-product of cellular respiration, carbon dioxide, is transported back to the lungs by a number of mechanisms. Carbon dioxide exists in the blood as a soluble gas, which is measured as a partial pressure—called partial pressure of carbon dioxide ($PaCO_2$). Because alterations in respiratory function substantially affect the $PaCO_2$, this parameter is considered the "respiratory" component of the blood gas analysis. If the $PaCO_2$ is above or below the normal range of 35 to 45 mm Hg, a respiratory derangement is present. This derangement may be primary (that is, respiratory acidosis or alkalosis) or secondary (that is, compensated metabolic acidosis or alkalosis). The elevation above sea level indirectly affects the $PaCO_2$. At elevations above sea level, increases in respiratory rate as a result of lower partial pressure of oxygen (PO_2) will result in a lower-than-normal $PaCO_2$ in the blood.

Bicarbonate

In the blood gas panel, $PaCO_2$ represents the respiratory component, and **bicarbonate (HCO_3^-)** represents the metabolic component. If there is a metabolic aspect to an acidosis- or alkalosis-related condition, a

corresponding derangement in HCO_3^- will be seen—its level will be decreased in acidosis and increased in alkalosis.

The normal HCO_3^- is 21 to 28 mEq/L. The administration of intravenous bicarbonate to treat metabolic acidosis is controversial and not generally indicated unless the underlying cause of acidosis cannot be corrected or the pH is less than 7.20.

Base Excess

Base excess (BE), is a measurement of metabolic derangement that is included as part of the ABG panel. Base excess is also known as base deficit (BD) because the value can be either a positive number (excess) or a negative value (deficit). Healthy people do not have an appreciable BE. The BE is measured in units of mEq/L and has a normal range of –2 to +3. If there is an excess amount of acid or lack of base, the BE is negative. Conversely, if there is a deficient amount of acid or an excess amount of base, the BE is positive. Positive values beyond the normal range indicate an excess of bicarbonate (base) and negative values less than the normal range indicate a deficit of bicarbonate. The more extreme the metabolic derangement, the larger the BE value.

Some clinicians use base excess to assess for proper fluid resuscitation. If there is inadequate fluid present to support metabolic activities (as in hypovolemic shock), the patient will experience ineffective energy production with a concomitant increase in lactic acid. The BE value in such a case may be mild (–2 to –6), moderate (–6 to –15), or severe (–15 or less). If a patient has normal vital signs with a continued large BE, a source of continued shock should be sought.

Oxygenation Status

Partial Pressure of Oxygen

The **partial pressure of oxygen (Po_2)** measures the amount of oxygen dissolved in the blood. A healthy person has an arterial Po_2 in the range of 80 to 100 mm Hg. Other than in unique cases (such as carbon monoxide poisoning), patients do not benefit from having a Po_2 greater than 100 mm Hg; the most important consideration is simply that the Po_2 remain within the normal range. As the Po_2 falls below 80 mm Hg, the affinity of hemoglobin for oxygen decreases and oxygen is released more readily from the hemoglobin molecule, which results in hypoxia. Once again, the elevation above sea level affects the arterial partial pressure of oxygen, or Pao_2. At elevations above sea level, the environmental Po_2 is lower, resulting in a lower Pao_2 in the blood.

Oxygen Saturation

The Sao_2 measures the percentage of potential oxygen-binding sites on hemoglobin that are occupied by oxygen molecules. The oxygen saturation measured transcutaneously (Spo_2), using a saturation monitor and probe, differs from the oxygen saturation calculated from an arterial or venous blood sample (Sao_2) that is reported on a blood gas report. The Sao_2 is calculated based on other parts of the blood gas panel. The normal value for measured Sao_2 for a healthy person is greater than 93%. The calculated saturation from the blood gas values can give a falsely elevated saturation when abnormal hemoglobin variants, such as carboxyhemoglobin and methemoglobin, are present in the sample. This is particularly important because although the Sao_2 value may appear normal, the patient actually has a poor oxygen content because the abnormal hemoglobin variants cannot carry oxygen.

Obtaining an Arterial Blood Sample

Finally, this section explains how to obtain an arterial blood sample used for the measurements previously discussed.

Skill Drill 8-1 shows the procedure for obtaining an arterial blood sample, discussed below:

1. Appropriately identify the patient. Explain the procedure. Determine the appropriate arm from which to take the specimen **Step 1**.
2. Perform an Allen test. Have the patient raise the hand above the level of the heart. Then have the patient make a fist while you simultaneously compress the radial and ulnar arteries **Step 2**.
3. When the patient's hand turns white or pale, release compression of the ulnar artery and assess circulation. The color should return to normal in approximately 5 to 7 seconds **Step 3**.
4. Repeat while releasing the radial artery. Sluggish return of color may indicate occlusion in one or both of the arteries. Arterial puncture should not be performed on this extremity.
5. Ensure universal precautions.
6. If possible, position the patient's arm with a small towel roll beneath the wrist to slightly extend the wrist (do not overextend) **Step 4**.
7. Prepare the site per protocol.
8. Palpate the radial artery with your index and middle fingers (do not use your thumb) **Step 5**.
9. Locate the radial artery and puncture the skin with the bevel of the needle at a 45° angle. The syringe should rapidly fill with bright red blood **Step 6**. Do not dig or probe with the needle! If you have difficulty, slightly reposition the needle. If you continue to have difficulty, stop and restart the procedure.
10. Once the appropriate amount of blood has filled the syringe, rapidly remove the needle and hold pressure for approximately 2 to 5 minutes **Step 7**.
11. Safely remove the needle and expel any air contained within the syringe **Step 8**.
12. Place a rubber stopper on the syringe.
13. Label the syringe with appropriate patient identification **Step 9**.
14. Immediately perform the test or place the specimen on ice.
15. Reassess neurovascular status **Step 10**.

Blood Group Testing

Blood typing is done to determine the blood group according to the ABO system and other classification systems. The ABO system is based on the antigen groups that cause the largest humoral response. There are four that result from two primary antigens, A and B, giving the blood types of A, B, AB, and O. Type A carries the A antigen, type B carries the B antigen, type AB carries both antigens, and type O carries neither antigen. People with type AB are known as universal recipients. They may receive blood of any type. People with type O are universal donors; their blood can be given to people with any type, but they can receive only type O blood. Nevertheless, caution is warranted because people with any blood type can develop an immune response if they receive large amounts of unmatched blood.

It is also important to know about the Rh antigens found in all blood types. The Rh antigen D, which is called the Rh factor, is important in immune responses. Rh positive means the person has the Rh

antigen; people who are Rh negative do not have the antigen. The majority of the population is Rh positive, but caution is needed if a patient is Rh negative. An Rh-negative patient who receives an Rh positive blood transfusion may have an immune response reaction, anaphylaxis, that could develop into anaphylactic shock. For an Rh-negative woman who receives Rh-positive blood, even in the absence of an immediate reaction, she will develop antigens that can cause significant problems with future pregnancies. Most patients needing blood products are given type O–negative blood until typing and crossmatching (which determines the compatibility between donor blood and recipient blood) can be done. Blood groups are discussed in more depth in Chapter 9.

Skill Drill 8-1

Obtaining an Arterial Blood Sample

1 Determine the appropriate arm from which to take the specimen.

2 Have the patient make a fist. Compress the radial and ulnar arteries.

3 When the patient's hand turns white or pale, release compression of the ulnar artery and assess circulation. Repeat for radial artery. Ensure universal precautions.

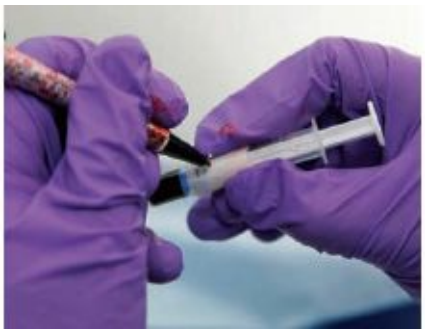
4 Position the patient's arm with a small towel roll beneath the wrist to slightly extend the wrist.

5 Palpate the radial artery with your index and middle fingers.

6 Locate the radial artery and puncture the skin with the bevel of the needle at a 45° angle.

7 Rapidly remove the needle and hold pressure for approximately 2 to 5 minutes.

8 Safely remove the needle and expel any air contained within the syringe.



9 Label the syringe with appropriate patient identification.

10 Reassess neurovascular status.

Obtaining a Venous Blood Sample

Obtaining venous blood samples should initially be completed before administering any IV fluids or medications, such as during the baseline evaluation of the patient. For many medications, ongoing lab results are required to determine the continued course of therapy. Some antibiotics require that a peak and trough be monitored at certain times. Samples for serial levels of CK-MB and troponins and for PT and aPTT testing need to be drawn at specific times. Therefore, blood samples may need to be obtained during transport of the patient.

If the patient has an IV line and is receiving fluids or medications, if at all possible, the other extremity should be used. If the patient has IV lines in both extremities, the one without IV medication or without the medication that is being tested should be used. The flow of fluid or medication needs to be paused or stopped immediately prior to obtaining the blood sample or the sample may be contaminated with infusate.

Blood Tube Uses

Blood tubes are selected primarily for the preservatives or lack of preservatives that they contain. Most laboratories have specific requests regarding tube selection and the number of tubes needed. The desired tube selection is usually communicated by the laboratory **Table 8-2 Figure 8-7**.

TABLE 8-2 Blood Tube Uses

Blood Tube Color	Use
Lavender	Complete blood count
Red	Blood banking
Marbled	Serum chemistry tests
Blue	Coagulation studies
Green	Plasma studies
Yellow	Human leukocyte antigen typing
Navy	Trace metals
Gray	Lactate

Figure 8-7 The colors of blood tube tops relate to their intended use.

Urine Lab Values

Urinalysis (UA) involves performing various laboratory tests (some of the same performed on blood samples) on a patient's urine. Roughly one quarter of the heart's cardiac output enters the kidneys for filtration, and the resulting urine provides a way of investigating the patient's physiologic status. The tests performed on urine may range from simple (such as color) to complex (such as specific gravity). Many drugs can be detected in the urine for hours, days, or weeks after use of the drug. **Table 8-3** lists drugs of abuse that can be tested in urine, including how long the drug can be detected in the urine after the drug's use. **Table 8-4** lists toxic levels of selected substances.

Color

Color may be the most simplistic laboratory analysis performed. This assessment simply notes the urine color, which is often classified as yellow, pale, clear, and so forth. Urine's color is a function of concentration, with more concentrated urine being darker yellow. Various other particulates in the urine can affect the color as well. If the person's glomeruli or renal tubular system is damaged and blood is spilling into the urine, the urine may be reddish. Brown or tea-colored urine often reflects the presence of

large amounts of protein in the urine and is a hallmark sign of rhabdomyolysis.

TABLE 8-3 Drugs of Abuse That Can Be Tested in Urine

Drug	Length of Time Detected in Urine
Alcohol	7–12 h
Amphetamine	48 h
Barbiturate	24 h (short acting); 3 wk (long acting)
Benzodiazepines	3 d
Cocaine	6–8 h (metabolites, 2–4 d)
Heroin	36–72 h
Marijuana	3 d to 4 wk (depending on dose)
Methadone	3 d
Methaqualone	7 d
Morphine	48–72 h
Phencyclidine	8 d
Propoxyphene	6–48 h

TABLE 8-4 Toxic Levels of Selected Substances

Drug Serum Screen	Toxic Blood Level
Acetaminophen	> 250 µg/mL
Alcohol	
Intoxicated	0.1%–0.4%
Stuporous	0.4%–0.5%
Comatose	> 0.5%
Aspirin	> 300 µg/mL
Barbitals	
Sedatives	> 10 µg/mL
Antiepileptics	> 40 µg/mL
Carboxyhemoglobin	> 20%
Phenytoin (Dilantin)	> 20 mg/L
Lead (adult)	> 40 µg/dL
Lithium	> 2.0 mEq/L

Appearance

Similar to color, urine appearance is a rather coarse assessment. Appearance is categorized as clear

(similar to color) or **turbid**. Turbidity can be indicative of a bladder infection and should be examined further.

Specific Gravity

Specific gravity is the chemical property of a fluid that relates its density to the density of water. Distilled water is arbitrarily given a specific gravity of 1, so fluid that is denser than water has a specific gravity greater than 1. The more concentrated a urine sample, the denser the sample and the higher its specific gravity. Conversely, a low specific gravity indicates a more dilute urine sample. At the most simple level, athletes measure specific gravity to assess their hydration status. Higher-than-normal specific gravity would reflect volume depletion in an otherwise healthy athlete.

Numerous factors can affect the kidney's ability to concentrate the urine. For example, if a low level of antidiuretic hormone is secreted from the pituitary gland, diabetes insipidus may result. This metabolic disorder impairs the ability of the kidney to concentrate the urine (that is, the body reabsorbs free water), so the specific gravity of urine will be very low (there would be copious amounts of dilute urine). Other disorders, such as glomerulonephritis and pyelonephritis, may also impair the kidney's ability to concentrate urine. The normal range for urine specific gravity is 1.003 to 1.035; in the setting of impaired ability to concentrate urine, the specific gravity may approach 1.001.

pH

The H^+ concentration in the urine can be a useful marker for metabolic acidosis. Unlike serum pH, urine pH has a relatively wide normal range, 4.5 to 8. Patients with acidic urine often have large amounts of unbuffered acid (such as lactic acid or keto acid). Salt wasting may also occur as the body excretes a positive ion (such as Na^+) to counteract the negatively charged acid salt of lactate or keto acetate.

Certain renal abnormalities may induce the inability to excrete H^+ in the urine, even in the presence of overwhelming metabolic acidosis. This abnormality is called **renal tubule acidosis (RTA)**. Four types of RTA are distinguished, although the specifics of each type are not included here. Nevertheless, CCTPs should be able to identify the presence of RTA, defined as an arterial pH of less than 7.35 and a urine pH of greater than 6. Generally, the biggest concern is that the kidneys are not able to concentrate urine, which will cause wasting of potassium and magnesium.

Glucose

The presence of glucose in the urine (**glycosuria**) is almost always indicative of elevated serum glucose levels. In healthy people, the urine is free of glucose, so the normal value is 0. If glucose is present, its amount is graded on a scale of mild to severe, expressed as + 1, + 2, + 3, or + 4. The presence of glycosuria may not always signal ineffective insulin production or use (as in diabetes mellitus); however, it may result from the administration of a carbohydrate-containing intravenous fluid such as 5% dextrose in water. The context of the patient will dictate when a value outside the normal range is pathologic.

Ketone Bodies

If the body does not completely break down fat to carbon dioxide and water, ketone bodies are produced. Fat catabolism occurs when the need for glucose is not satisfied by the available supply. The term **ketone bodies** describes a number (typically three) of organic products: acetoacidic acid, acetone, and betahydroxybutyric acid. Acetoacidic acid and beta-hydroxybutyric acid are the keto acids that result from poorly controlled diabetes mellitus when inadequate insulin is present and cells are unable to use glucose as a source of energy. Although ketone bodies are not normally present in the urine, the presence

of ketone bodies can help identify inadequately controlled diabetes mellitus. Other causes of **ketonuria** (ketone bodies in the urine) include alcoholic ketoacidosis and starvation ketosis. Grading of the level of ketonuria uses the same system as grading of the amount of glucose in urine—that is, +1, +2, +3, or +4.

Protein

Although the body excretes 40 to 80 mg of protein (one third of which is albumin) in the urine daily, this amount is below the detectable threshold; thus, the normal reference value in a qualitative test for protein would be negative (or not detectable). Urinary protein is one of the most important assessments for kidney diseases. Detectable levels of urinary protein can result from renal causes (such as glomerulonephritis, polycystic kidneys, diabetic nephropathy, toxic nephropathy, nephrosclerosis, and nephritic syndrome) or extrarenal causes (such as preeclampsia, multiple myeloma, urinary tract disease, amyloid disease, systemic lupus erythematosus, congestive heart failure, and constrictive pericarditis).

Blood and Hemoglobin

The presence of blood in the urine is highly suggestive of kidney or urinary tract damage. Recall that blood is not able to cross the glomerular membrane and enter the filtrate. Thus, the presence of hemoglobin in the urine (**hemoglobinuria**) most often indicates traumatic passage of RBCs through the collecting ducts, urinary bladder, or urinary tract. Urinary hemoglobin may also result from filtering of serum hemoglobin during hemolytic transfusion reactions or certain blood disorders such as hemolytic anemia.

The presence of RBCs in the urine (**hematuria**) may indicate the presence of glomerular membrane or urinary tract disease. The cause may be infectious processes (commonly from urinary tract infections), neoplasms, ureterolithiasis, or trauma. Note that RBCs detected in a urinalysis performed soon after placement of an indwelling urinary catheter may merely reflect trauma from insertion of the catheter.

Finally, the presence of hemoglobin in the urine without the presence of RBCs can indicate rhabdomyolysis.

To get a better handle on how the body is eliminating certain electrolytes, a quantitative analysis is performed on the urine. Similar to a basic metabolic panel, this panel analyzes numerous components of the urine. Although their discussion is beyond the scope of this text, urine electrolytes can be useful in clinical management as well.

Cerebrospinal Fluid

Cerebrospinal fluid is obtained for testing by inserting a needle into the lumbar section of the back, between the vertebrae, a procedure that is called a lumbar puncture. Fluid collection and testing are done to identify many conditions, such as increased intracranial pressure, diabetic coma, diabetes, multiple sclerosis, Guillain-Barré syndrome, and meningitis (bacterial or fungal).

Normal results are as follows:

- Pressure: 50 to 180 mm H_2O
- Appearance: clear, colorless
- Total protein: 10 to 45 mg/100 mL
- Glucose: 50 to 80/100 mL
- Cell count: 0 to 5 WBCs, no RBCs
- Chloride: 110 to 125 mEq/L

Common Errors in Specimen Collection

Incorrect patient identification and the mislabeling of samples are the most common specimen collection errors. Two of the most common problems associated with any specimen collection in the field are improper technique or handling and improper labeling. CCTPs generally care for only one patient at a time.

Improper labeling can be resolved by placing the minimal required information on the label for the sample. This required information includes the patient's name and date of birth, date and time the specimen was collected, and the CCTP's name or initials should there be any questions. Ideally, a patient identification number or the last four digits of the patient's Social Security number will be included as well.

Improper technique or handling can be difficult to address, especially in the field setting. CCTPs may encounter extreme temperatures, which can affect optimal processing and results. Trauma to blood specimens may create a hemolyzed sample. Fluids or medication the patient is receiving may interfere with obtaining a "clean" sample. Particular laboratories may require samples to be supplied in specific tubes or containers.

Additional factors that lead to errors in lab results include hemolyzed samples, incorrect collection techniques, and insufficient quantities for accurate testing.

Diagnostic Imaging

Diagnostic imaging is typically performed by a technologist and is often interpreted by a physician on site or possibly sent off site for interpretation. Typically, copies are included with the patient's charts upon transfer.

The CCTP should be familiar with these studies and be able to perform basic interpretation for obvious abnormalities, such as long-bone fractures, masses, and catheter placements. It is important to have a system and use that system every time. Think of it like the steps of a primary exam. This will prevent the CCTP from overlooking findings. Extensive interpretation requires significant training and is beyond the scope of this book.

Standard Radiographs

One of the oldest and still frequently used diagnostic imaging modalities is the standard or plain radiograph. It can be rapidly obtained and used for quick diagnostics in patient care.

A radiograph or roentgenogram is radiation projected through the tissue and onto a photographic plate. Different densities of the body cause gradation changes in black and white onto the film. Dense objects such as bone or blood appear white, whereas less dense objects such as air appear black. Objects with a medium density such as tissues will appear as shades of gray.

Typically obtained in a lateral or AP (anteroposterior) view, a radiograph can provide confirmation of endotracheal tube placement, cervical fractures, chest interpretations, and most major bone fractures.

Computed Tomography

Computed tomography (CT), also called CAT scanning, is an imaging method in which cross-sectional images of the structures in the body plane are reconstructed by a computer program. Focused beams examine an area of interest and are reconstructed by computer to give a high-resolution view. The patient is typically on a table that feeds into the scanner device.

CT scans are commonly used when it is necessary to evaluate different characteristics of tissues, bones, and organs. Unlike conventional x-ray images, CT allows differences to be quantified, which

allows differentiation of tumors from soft tissue, old from new fractures, air from fluid, and blood clots from normal blood. The views or "slices" can pick up abnormalities not seen with traditional plain radiography. Interpreting a CT scan can reveal conditions such as aortic dissection, lung injuries, abdominal organ injuries, fractures, pulmonary emboli, pleural effusions, and acute respiratory distress syndrome.

The CT scan has seen major improvements with multiple slices (64 slices) and higher-speed capabilities. It is now a standard for diagnostics in multiple disciplines. It can be limited by morbidly obese patients who simply do not fit into the scanner or exceed the table operating limits. When transporting a critically ill patient who has had a recent CT scan, the CCTP should attempt to obtain a printed or electronic copy of the scan from the transferring facility to expedite care on arrival at the receiving center.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is primarily a diagnostic imaging technique most commonly used to visualize the internal structure and function of the body. MRI provides a much greater contrast of the different soft tissues of the body than a CT scan does. This makes it especially useful in brain, spinal cord, musculoskeletal, cardiovascular, and oncologic imaging. Another benefit is that the patient is not exposed to radiation.

MRI uses a large circular magnet and radio waves to align the water molecules and generate signals from atoms in the body. An image is obtained from this alignment and the speed at which molecules alter or release. The strength of the magnetic field precludes many types of patient monitoring and requires special ventilators for intubated patients. As such, MRIs are not often used to aid in the diagnosis of critically ill patients. When done, they are usually used to provide exquisitely detailed images of the brain, spine, skeletal system, heart, abdomen, or pelvis.

MRI may be limited by patient size and/or the patient's ability to tolerate an enclosed "tunnel" environment. Any preexisting metal in the patient's body may contraindicate a scan as well. Many advances have been made in the size and "openness" of the MRI, which allows for a more tolerable environment.

It is important to mention safety, because the powerful magnet will cause certain metal objects to become "missiles." Keeping your equipment and any other metals you may be wearing away from the control area is essential.

Ultrasonography

As with MRI, the ultrasound does not expose the patient to any radiation. It also has the advantage of being very portable.

Ultrasound uses sound, which is transmitted through an area of the body; the denser material reflects waves back to a transducer, which produces an image. This image may appear to be somewhat of a blur to the untrained eye, but an experienced technician can identify the area in question.

Ultrasound is typically used for obstetrics and gynecology as well as abdominal diagnostics. It has gained great momentum in blood-flow studies and cardiac diagnostics.

Summary

One of the core goals of CCTPs is to form as complete a clinical picture of the patient as possible. Each patient is unique in terms of his or her hemodynamic and ventilatory status, with various degrees of end-organ dysfunction. Laboratory analysis allows clinicians to assess or confirm the system or organ status.

The key lesson in laboratory interpretation is that no lab result must be analyzed in isolation. Not only are trends important, but also, derangements must be confirmed by other means. If that principle is retained throughout the patient's care, clinicians can be confident that their consideration of lab values is of the highest caliber.

Table 8-5 summarizes normal and abnormal lab values.

TABLE 8-5 Normal and Abnormal Lab Values for Adults*

Name	Abbreviation	Normal	Critically Low	Critically High
Electrolytes and Other Chemicals				
Sodium (mEq/L)	Na^+	136–142	< 125	> 145
Potassium (mEq/L)	K^+	3.5–5.0	< 3.0	> 5.0
Chloride (mEq/L)	Cl^-	96–106	Varies	Varies
Calcium, total (mg/dL)	Ca^{++}	8.2–10.2	< 6.5	> 13.5
Calcium, ionized (mmol/L)	Ca^{++}_i	1.15–1.27	Varies	Varies
Total co_2 (mEq/L)	co_2	22–28	< 15	> 40
Phosphate (mEq/L)	PO_4	2.3–4.7	< 1.2	> 9
Metabolites				
Blood urea nitrogen (mg/dL)	BUN	8–23	< 2	> 80
Creatinine (mg/dL)	Cr	0.6–1.2	< 0.4	> 2.8
Lactate/lactic acid (mmol/L)	N/A	Venous: 0.4–2.0 Arterial: 0.5–1.6	Varies	> 4.99
Proteins				
Protein, total (g/dL)	N/A	6.0–8.0	Varies	Varies
Albumin (g/dL)	N/A	3.5–5.0	Varies	Varies
Myoglobin (µg/L)	N/A	19–92	Varies	Varies
Troponin I (ng/mL)	cTnI	0–0.4 (negative)	Varies	Varies
Enzymes				
Lactate dehydrogenase (U/L)	LDH	100–200	Varies	Varies
Alanine aminotransferase (U/L)	ALT	10–40	N/A	Varies
Aspartate aminotransferase (U/L)	AST	10–30	N/A	Varies
Alkaline phosphatase (U/L)	Alk Phos	30–120	Varies	Varies
Amylase (U/L)	N/A	27–131	Varies	Varies
Lipase (U/L)	N/A	31–186	Varies	Varies
Creatine kinase (U/L)	CK	40–150	Varies	Varies
Coagulation				
Prothrombin time (s)	PT	10–13	N/A	Varies
Activated partial thromboplastin time (s)	aPTT	25–40	N/A	> 60
International normalized ratio	INR	2.0–3.0 (target for therapeutic anticoagulation therapy) Normal range for a patient who is not anticoagulated: 0.8–1.2	Varies	Varies
Serum				
Osmolality (mOsm/kg)	N/A	275–295	< 240	> 320
Blood Count	CBC			
Hematocrit (%)	Hct	41–50	< 20	> 60
Hemoglobin (g/dL)	Hgb	14.0–17.5	< 7	> 20
Erythrocytes ($\times 10^6$/µL)	RBC	3.9–5.5	Varies	Varies
Leukocytes (/µL)	WBC	4,500–11,000	< 2,000	> 30,000
Arterial Blood Gases				
Percentage of hydrogen ions	pH	7.35–7.45	< 7.2	> 7.6
Partial pressure of oxygen (mm Hg)	Pao_2	80–100	< 40	N/A
Partial pressure of carbon dioxide (mm Hg)	$Paco_2$	35–45	< 20	> 77
Bicarbonate (mEq/L)	Hco_3^-	21–28	< 10	> 40
Base excess (mEq/L)	BE	−2 to +3	< −5	> +5

*It is important to know the normal range for the laboratory where the specimen is tested.

Case Study

YOU HAVE BEEN DISPATCHED TO TRANSPORT , via helicopter, a 37-year-old man whose pretransport diagnosis is acute renal failure after renal transplantation.

You arrive at a rural hospital at the base of a mountainous region. The physician gives you the following history: The patient and his friend took a day hiking trip into the mountains and got lost. A search-and-rescue team was dispatched after 24 hours. The patient and friend were found 48 hours later. They were found severely dehydrated and confused. They only had "a little" water to sustain themselves. The patient underwent kidney transplantation approximately 1 year ago. Before today, he has not had any difficulties with the transplant. The patient has missed 2 days of his transplant antirejection drugs. The search-and-rescue team had inserted a large-bore IV needle and had provided fluid resuscitation to the patient with 2,000 mL of normal saline before getting him to the local hospital.

The staff gives you the following report: The patient is now alert and oriented with generalized weakness. He has had a total intake of 2,500 mL of normal saline. He has an indwelling urinary catheter in place with 100 mL of urine output since the catheter was placed. His current vital signs are as follows: temperature, 96.0°F (35.6°C); heart rate, 88 beats/min; respirations, 20 breaths/min; and oxygen saturation, 98% with 4 L/min of oxygen per nasal cannula. His blood pressure measures 150/90 mm Hg. He has two large-bore IV needles in place. His current ECG shows a normal sinus rhythm, with a rate of 88 beats/min. He has tall, peaked T waves in the precordial leads V_1 through V_6. His QRS is prolonged, measures 130 milliseconds, and shows an incomplete right bundle block pattern.

Lab analysis reveals the following results: sodium, 135 mEq/L; potassium, 7.3 mEq/L; chloride, 100 mEq/L; and total calcium, 8.8 mg/dL. His BUN is 70 mg/dL; and creatinine, 3.0 mg/dL. The physician says that the CBC and glucose levels were normal. He also says that the CK and myoglobin levels were elevated. He "does not remember the numbers" but will send hard copies along on the transport. The physician tells you he is transporting to tertiary care (45 minutes by air) for emergency dialysis and management of the patient's renal failure.

You give 1 g of calcium gluconate IV. You reassess the ECG and notice that the QRS is narrower at 90 milliseconds (within normal limits) and the T wave is less peaked. You elect to load and go with this patient, realizing that he still needs emergency treatment, but the rest of the medications can be given en route. En route, you administer 50 mL of 50% glucose in water solution ($D_{50}W$) IV followed by 10 U of regular insulin IV; sodium bicarbonate, 50 mEq IV; and 5 mg of albuterol in 3 mL of normal saline via nebulizer.

1. What are your priorities in care before transport?
2. What are your priorities in care during transport?
3. What reassessment parameters are important during transport?

Analysis

In evaluating the situation, you realize that this patient is in acute renal failure with hyperkalemia. You also realize the renal failure could be a result of his severe dehydration, transplant rejection, and/or rhabdomyolysis; however, your transport priority is the hyperkalemia. The markers for emergency treatment of hyperkalemia are profound muscle weakness and/or marked ECG changes. This particular patient has generalized weakness and an intraventricular conduction delay along with peaked T waves,

and he requires immediate treatment. The most important emergency intervention is the administration of calcium, which directly antagonizes the membrane actions of hyperkalemia. Calcium chloride or calcium gluconate may be administered. Calcium chloride contains three times the elemental calcium that calcium gluconate does and should be given via a central line placed at the hospital. You elected to give 1 g of calcium gluconate IV. You reassess the ECG and notice that the QRS is narrower at 90 milliseconds (within normal limits) and the T wave is less peaked. The effects of calcium are usually seen in 3 to 5 minutes and last approximately 30 to 60 minutes.

While en route, you also want to drive the potassium back into the cells by increasing the availability of insulin; therefore, you administer 10 U of regular insulin IV followed by 50 mL of $D_{50}W$ IV (the $D_{50}W$ prevents hypoglycemia). These effects are seen within 15 minutes, usually peak in 60 minutes, and can last for several hours.

Another medication that promotes the shift of potassium into the cells is sodium bicarbonate. Raising the systemic pH will also release hydrogen ions from the cells; potassium is then shifted back into the cell to maintain a neutral state. You gave sodium bicarbonate, 50 mEq IV. These effects are usually seen within 30 minutes and last a few hours.

Last, beta-2 adrenergic agonists (like insulin) drive potassium back into the cell by increasing the Na^+/K^+ ATPase activity needed for the sodium pump. To accomplish this effect, you elected to give 5 mg of albuterol in 3 mL of normal saline via nebulizer. The onset of action is about 30 minutes, and the effects last 2 to 3 hours.

During transport, it is imperative to continuously assess the ABCs. This patient's airway has remained patent, his respiratory rate has been 16 to 20 breaths/min, and oxygen saturation has been 98% with 4 L/min of oxygen. Continuous cardiac monitoring has shown a normal sinus rhythm with a heart rate in the 80s, a normal-appearing T wave, and a normal QRS at 90 milliseconds.

You have point-of-care laboratory testing available during transport. You check his blood glucose level and it is 130 mg/dL. You are also able to test basic electrolytes en route, and the results are as follows: sodium, 140 mEq/L; potassium, 4.4 mEq/L; chloride, 103 mEq/L; and total CO_2, 23 mEq/L. His extracellular potassium level is now within normal limits.

Last, you assess the patient's strength because he was previously weak. He has much stronger upper grip strength, which is equal, and has equal and strong dorsiflexion of his feet. His urine output en route is approximately 200 mL. The patient reports that he generally feels much better.

The patient was admitted directly to the intensive care unit, where you gave a report to the nursing and physician staff. The plan was to restart his antirejection medication and monitor serial lab values to see if the hyperkalemia and kidney function improved. If not, emergency dialysis would be performed.

Prep Kit

Ready for Review

- Laboratory tests—including laboratory examinations of the patient's blood, possibly urine, cerebrospinal fluid, or other body fluid—can be very useful in determining the seriousness of a patient's condition or aiding in anticipation of potential problems en route to the hospital.
- A CCTP must be comfortable with not only the normal ranges for each lab value, but also the test's associated physiologic meaning.
- The value of laboratory analysis is determined by the test's accuracy (a marker of whether the value measured by a test conforms to the true value), precision (a marker of tolerance or variation within

multiple measurements), sensitivity (the ability of a certain test to indicate whether a person does or does not have a certain condition), and specificity (the proportion of people without the target disorder who have a negative test result).

- A normal range for a test indicates the values that 95% of healthy individuals would have for the particular test. It may or may not be reflective of the patients who are being transported by ambulance.
- Although abnormal lab values cannot be ignored, it is essential that they be put into the context of the patient's complex clinical picture.
- Errors in specimen collection, identification, and labeling or errors in laboratory analysis procedures may result in erroneous values being reported.
- Different laboratories have different normal ranges for the same tests.
- A culture and sensitivity (C and S) report can be determined for any type of specimen. The culture results will reveal what is causing an infection; in bacterial infections, the sensitivity results will indicate which antibiotic will most effectively treat the organism causing the infection.
- The ionic components of plasma that are analyzed in the laboratory constitute the electrolytes, which include sodium (Na^+), potassium (K^+), chloride (Cl^-), calcium (Ca^{++}), and magnesium (Mg^{++}).
- Fluid characteristics assessed in the laboratory include osmotic pressure, which arises in a space divided by a semipermeable membrane owing to differences in concentrations of solutes (dissolved substances) found in the solutions on either side of the membrane. Osmotic pressure depends only on the number of particles in the fluid, not on the size of the particles.
- Concentration is the amount of a substance present in a given volume of fluid. In the physiologic system, most concentrations are incredibly small, leading to use of units such as millimoles (mmol), milliequivalents (mEq), and milliosmoles (mOsm) to quantify them.
- Thousands of different kinds of proteins are found in the human body, and specific laboratory tests examine the amount of the various types of protein present in a sample. For example, tests may assess levels of enzymes, which act as catalysts for biochemical reactions.
- In laboratory testing, groups of related tests can be performed as a single unit, called a panel (or profile).
- The basic metabolic panel examines the electrolytes and metabolites in the extracellular fluid and is one of the most basic and fundamental assessments done in the emergency department or intensive care unit.
- Serum sodium is a convenient marker for a patient's fluid status and is one of the key components of the serum osmolality calculation. An abnormal sodium level will not manifest with ECG changes.
- Elevated sodium levels are treated with diuretics and restricted fluid intake; the net effect of this treatment is aimed at lowering intracerebral pressure. Hyponatremia (an abnormally low level of sodium in the blood) is often encountered in patients with congestive heart failure, renal failure, or liver disease and in patients taking diuretics. Hyperkalemia (an abnormally high level of potassium in the blood) can lead to cardiac arrhythmias. Potassium levels of 5.5 to 6.5 mEq/L can result in the classic peaked T waves on an ECG, with flattened P waves occurring when the potassium level exceeds 7.0 mEq/L.
- Older patients (especially patients taking digitalis) are more likely to have arrhythmias and ECG changes with hypokalemia (an abnormally low level of potassium in the blood).
- For any patient with a cardiac history, altered renal function, liver disease, or GI disturbances, or a patient receiving insulin, a recent potassium level should be available for review before transport.

- Patients with hypochloremia (an abnormally low level of chloride in the blood) may have impending renal dysfunction. Care should be used with patients taking diuretics, because they may also have abnormally low chloride levels.
- Venous bicarbonate levels below the normal range could indicate metabolic acidosis or respiratory alkalosis, whereas elevated levels could indicate metabolic alkalosis or respiratory acidosis.
- Urea, which is considered a useful marker for adequate kidney function, is measured via the BUN test. The BUN level tends to increase with age as a consequence of gradually declining renal function.
- Creatinine levels can be used to assess kidney function, although some patients may have an increased creatinine level with adequate renal function. Geriatric patients with increased creatinine levels may have more kidney damage than might be suspected by testing the creatinine level.
- The glucose level is commonly assessed in the field with a point-of-care testing device, and prehospital care providers often measure the blood glucose level of unconscious or semiconscious patients.
- Total calcium is increased in elevated parathyroid hormone states such as hyperparathyroidism and parathyroid-secreting tumors. It is decreased in renal insufficiency, hypomagnesemia, and hyperphosphatemia and in patients who have undergone a massive blood transfusion or who have a decreased parathyroid hormone state.
- Low levels of ionized calcium can cause serious arrhythmias and are especially pronounced in prolonged cardiac arrest. Calcium administration may be warranted in patients with hyperkalemia, hypocalcemia, or toxic levels of calcium-channel blockers.
- A CBC includes measurements of hematocrit (the percentage of cells in a venous blood sample), hemoglobin (the protein responsible for carrying oxygen to the body's cells and, to a lesser extent, carbon dioxide back to the lungs), red blood cells (erythrocytes), white blood cells (leukocytes), and platelets (useful for assessing coagulation status).
- Protein-based tests include those for total protein and albumin. With albumin, abnormally low levels indicate liver disease, whereas abnormally high levels lead to acute respiratory distress syndrome.
- Elevated liver function test results may indicate the presence of liver damage. They measure enzymes that normally appear in liver cells (such as aspartate aminotransferase [AST], alanine aminotransferase [ALT], and bilirubin).
- Tests of pancreatic function include measurements of amylase (an enzyme used by the body to metabolize carbohydrates) and lipase (more specific than amylase for identifying pancreatic disease).
- Cardiovascular lab tests include those for lactate dehydrogenase (useful in diagnosing cellular damage), creatine kinase (elevated levels indicate muscle damage), and troponin (useful in detecting myocardial infarction and predictive of adverse outcomes in patients with severe unstable angina).
- Lab tests assessing the coagulation system focus on the prothrombin time (the time from creation of thrombin from prothrombin by the enzyme prothrombin activator), activated partial thromboplastin time (used to assess for various diseases), and the international normalized ratio.
- Lactate levels are a global indicator of perfusion and oxygenation; they do not indicate which tissues are inadequately perfused or oxygenated.
- Levels of ethanol (ethyl alcohol) can be quite high when patients consume alcohol. Owing to the legal implications of ethanol measurements, precise protocols often govern the technique for obtaining the blood sample and storing and analyzing it.
- The AST:ALT ratio is useful for determining the cause of liver dysfunction—for example,

distinguishing between acute (viral) and cirrhotic liver disease.

- An increased BUN:creatinine ratio may indicate dehydration, GI bleeding, or increased catabolism. A decreased ratio may be present in patients with acute tubular necrosis, in those with a low protein intake, or following hemodialysis.
- An excessively large osmolality gap (the difference between measured osmolality and calculated osmolality) often indicates the presence of a low-molecular-weight toxin, usually ethanol.
- Disturbances in the overall electrical balance of the serum can indicate disease; the anion gap is a measure of this balance.
- Urinalysis involves performing laboratory tests—ranging from the simple (such as color or appearance) to the complex (such as specific gravity)—on a patient's urine. Many drugs of abuse can be detected in the urine for a considerable amount of time after the drug's use.
- Other tests performed on urine include pH, glucose, ketone bodies (presence can help identify inadequately controlled diabetes mellitus), protein (one of the most important assessments for kidney diseases), and blood and hemoglobin (which are not normally found in urine).
- A typical arterial blood gas (ABG) panel assesses a patient's acid-base status and oxygen status.
- The acid-base balance (pH)—which is assessed based on carbon dioxide tension ($PaCO_2$), bicarbonate level (HCO_3^-), and base excess (BE)—indicates how well the body's respiratory and metabolic systems are functioning. Abnormalities result in acidosis or alkalosis.
- Oxygenation status is measured by assessing the partial pressure of oxygen, arterial (PaO_2) and oxygen saturation (SaO_2) levels.
- Blood groups are identified by using the ABO classification system, which is based on the antigen groups that cause the largest humoral response. The two primary antigens, A and B, yield the four blood types: A, B, AB, and O.
- Rh antigens are found in all blood types. The Rh antigen D (Rh factor) is important in immune responses.
- The majority of the population is Rh positive—so CCTPs need to be extremely aware and alert if they have an Rh-negative patient. A patient who is Rh negative and receives an Rh-positive blood transfusion may develop anaphylaxis, which could develop into anaphylactic shock.
- When possible, initial blood samples should be obtained before administering IV fluids or medications.
- If the patient has an IV line and is receiving fluids or medications, the other extremity should be used for taking a blood sample, if possible. If the patient has lines in both extremities, the one without IV medication or without the medication that is being tested should be used.
- Two of the most common problems associated with any specimen collection in the field are improper technique for handling the specimen and improper labeling of the specimen.
- The CCTP should be familiar with diagnostic imaging studies and be able to perform basic interpretation for obvious abnormalities, such as long-bone fractures, masses, and catheter placements.
- Radiographic studies can provide confirmation of endotracheal tube placements, cervical fractures, chest interpretations, and most major bone fractures.
- Computed tomography is an imaging method in which cross-sectional images of a body plane are reconstructed by a computer. A CT scan can pick up abnormalities not seen with traditional plain radiography. The CCTP should obtain a copy of the scan from the transferring facility to expedite care

on arrival at the receiving center.

- Magnetic resonance imaging provides a much greater contrast of the different soft tissues of the body than a CT scan does, which makes it especially useful in brain, spinal cord, musculoskeletal, cardiovascular, and oncologic imaging.
- Ultrasonography does not expose the patient to any radiation and has the advantage of being a very portable imaging technology.

Vital Vocabulary

accuracy A measure of the likelihood that an average of a set of test values will be the same as individual values in the set.

activated partial thromboplastin time (aPTT) A value that represents the intrinsic coagulation pathway's clotting ability; also known as partial thromboplastin time (PTT).

alanine aminotransferase (ALT) An intracellular enzyme that is found in large amounts in the liver and in the kidney, skeletal muscle, and heart; formerly known as SGPT.

albumin The most common protein in the body. It acts as a transport protein, is a free radical scavenger, and serves as the main source of protein-generated oncotic pressure.

alkaline phosphatase An enzyme that is essential for proper digestion and absorption through the mucous membrane in the gastrointestinal tract; clinically useful for testing liver function and for diagnosing a common bile duct obstruction.

amylase A key enzyme used by the body to metabolize carbohydrates; it is produced primarily by the salivary glands and the pancreas.

anion A negatively charged ion.

anion gap (AG) A summary of the relationship among the three major contributors to the overall electrical charge (Na^+, Cl^-, and HCO_3^-); abnormal AG values may signal disturbances in the overall electrical and acid-base balance of the serum and presence of disease.

arterial blood gas (ABG) Analysis of the following characteristics of blood: pH, partial pressure of carbon dioxide (in arterial blood), partial pressure of oxygen (in arterial blood), concentration of bicarbonate ion, base excess (indicating whether the patient is acidotic or alkalotic), and oxygen saturation of the hemoglobin molecule.

aspartate aminotransferase (AST) An intracellular enzyme that is found in large amounts in the liver and in skeletal muscles, the brain, red blood cells, and the heart; formerly known as SGOT.

AST:ALT A calculated index that is useful for determining the cause of liver dysfunction.

base excess (BE) A measure of metabolic derangement that is part of the arterial blood gas panel; also known as base deficit (BD) as the value can be either positive (excess) or negative (deficit).

bicarbonate (HCO_3^-) An ion (HCO_3^-) that is present in the blood; measurement represents the metabolic component of the arterial blood gas panel.

blood urea nitrogen (BUN) A test used to measure urea, which is a biomarker for adequate kidney function.

B-type natriuretic peptide (BNP) A polypeptide whose value that is indicative of abnormal ventricular function and congestive heart failure.

BUN:Cr A calculated index that is used to determine the cause of increased levels of blood urea nitrogen and creatinine.

carboxyhemoglobin (COHb) A measure of the amount of hemoglobin–carbon monoxide complexes in the blood.

cation A positively charged ion.

computed tomography (CT) An imaging study in which focused beams examine an area that is then reconstructed by computer to give a high-resolution view; multiple "slices" or views are created; also called CAT scanning.

concentration The amount of a substance present in a given volume of fluid.

C-reactive protein (CRP) An acute phase protein synthesized in the liver; an indicator of inflammation.

creatine A major storehouse of intramuscular high-energy phosphate.

creatine kinase (CK) An enzyme that cleaves the high-energy phosphate from creatine in muscle tissues and transfers it to adenosine diphosphate to yield adenosine triphosphate; measurement is used in the assessment for a myocardial infarction.

creatinine (Cr) A breakdown product of creatine that results from muscle metabolism.

D-dimer test A test of hypercoagulability that detects a fragment from the fibrinolysis process; the test can be used to help diagnose and monitor diseases and conditions related to inappropriate clotting; for example, it can be used to test for deep venous thrombosis.

direct bilirubin Conjugated bilirubin; the result of bilirubin's conjugation in the liver, which is ultimately excreted in the bile.

enzymes Proteins that act as catalysts for biochemical reactions within the body.

glycosuria The presence of glucose in the urine.

hematocrit The percentage of formed elements (that is, cells) in a venous blood sample.

hematuria The presence of red blood cells in the urine.

hemoconcentration Decreased fluid in the blood, which means that concentrations of other blood components increase.

hemoglobin (Hgb) The protein responsible for carrying oxygen to the body's cells and, to a lesser extent, carbon dioxide back to the lungs.

hemoglobinuria The presence of hemoglobin in the urine.

hemolysis Destruction of red blood cells, sometimes following massive blood transfusions or blood transfusion reactions.

hyperchloremia An abnormally high level of chloride in the blood.

hyperkalemia An abnormally high level of potassium in the blood.

hypoalbuminemia An abnormally low level of albumin in the blood.

hypochloremia An abnormally low level of chloride in the blood.

hypokalemia An abnormally low level of potassium in the blood.

hyponatremia An abnormally low level of sodium in the blood.

indirect bilirubin A by-product of the metabolism of red blood cells that is unconjugated and, therefore, not water soluble.

international normalized ratio (INR) A comparative rating of a patient's prothrombin time to help standardize the prothrombin time when planning treatment.

ionic bond A type of chemical bond formed between oppositely charged ions.

ionized calcium Calcium that is not bound or chelated (also called free calcium); its value is useful in assessing for renal failure, nephrotic syndrome, acid-base derangements, and decreases or elevations in chelating compounds.

ketone bodies Organic products of fat catabolism—specifically, acetoacidic acid, acetone, and beta-hydroxybutyric acid.

ketonuria The presence of ketone bodies in the urine.

lactate The form of lactic acid that is physiologically present in the body.

lactate dehydrogenase (LDH) An enzyme that catalyzes the metabolism of pyruvate (the end product of glycolysis) to lactate in the absence of a functioning citric acid cycle.

leukocytosis An abnormally high number of white blood cells.

lipase A pancreatic hormone that metabolizes lipids.

liver function test (LFT) A test for liver damage that measures enzymes that normally appear in liver cells but may spill out into the vasculature with parenchymal damage.

magnetic resonance imaging (MRI) A diagnostic imaging technique used to visualize the internal structure and function of the body, which works by using a powerful magnet to align water molecules present in body compartments; an image is obtained from this alignment and the speed at which molecules alter or release.

myoglobin An oxygen-carrying heme protein present in high concentrations in the cytoplasm of cardiac and skeletal muscles.

normal range A range of values encompassing the results that 95% of healthy people would have for the particular test.

osmolality The amount of dissolved substance in 1 kg of water.

osmolarity The amount of dissolved substance in 1 L of water.

osmosis The diffusion of water across membranes.

osmotic pressure The pressure created in a space divided by a semipermeable membrane owing to differences in concentrations of solutes found in the solutions on either side of the membrane.

panel Groups of related tests that are performed as a single unit; also called profile.

partial pressure of oxygen (Po_2) A measurement of the amount of oxygen dissolved in the blood.

platelet (Plt) count A measurement of the number of platelets in the blood, which is useful for assessing a patient's coagulation status.

precision A measure of how a value is likely to be the same every time a test is performed.

prothrombin time (PT) A value that represents the extrinsic coagulation pathway's clotting ability by taking into account various clotting factors, fibrinogen, the prothrombin ratio, and the international normalized ratio.

red blood cell (RBC) count A measure of the total number of erythrocytes in the blood.

renal tubule acidosis (RTA) An inability to excrete H^+ in the urine, even in the presence of

overwhelming metabolic acidosis.

sensitivity The ability of a certain test to indicate whether a person has a certain disease.

specific gravity The chemical property of a fluid that relates its density to the density of water.

specificity The ability of a certain test to indicate whether a person does not have a certain disease.

thrombocytopenia An abnormally low level of platelets.

total protein The total quantity of protein in a blood sample.

troponin A key protein involved in muscle contraction that is present in the serum only after cellular necrosis releases the cellular contents of cardiac muscle (such as after myocardial infarction).

turbid Cloudy or opaque.

ultrasound An imaging technique that uses sound, which is transmitted through an area of the body, then denser material reflects waves back to a transducer that produces an image; typically used for obstetrics, gynecology, and abdominal diagnostics.

urinalysis (UA) Laboratory tests performed on a patient's urine.

white blood cell (WBC) count A measure of the total number of leukocytes in the blood.

Shock, Sepsis, and Multiple Organ Dysfunction Syndrome

Authors

Jan Beyer, RN, BSN, CCRN, EMT-B

Deborah Harrington, RN, AAS, NREMT-P/CC, CCEMT-P

Holly Herron, RN, MS, CNS, CCRN, CEN, EMT-P

Timothy J. Whitaker, NREMT-P, EMSI, FP-C, CMTE

Objectives

1. Discuss oxygen transport and utilization of oxygen by the cell (p 265–267).
2. Discuss cellular respiration (p 264–265).
3. Discuss the pathophysiology of shock and its stages: initial, compensatory, progressive, and refractory (p 268–271).
4. Describe the clinical manifestations associated with the various shock states (p 268–271).
5. Discuss the classification of shock: hypovolemic, cardiogenic, distributive (neurogenic), anaphylactic, and septic (p 272–280).
6. Identify from a patient presentation what type and stage of shock the patient is experiencing (p 268–271).
7. Define the following terms: infection, sepsis, sepsis syndrome, systemic inflammatory response syndrome (SIRS), severe sepsis, septic shock, and multiple organ dysfunction syndrome (MODS) (p 271, 272, 280).
8. Describe the etiology and pathophysiology of shock, sepsis, SIRS, and MODS (p 280–282).
9. Describe the history and incidence of sepsis relative to mortality (p 280).
10. Describe the risk factors considered important in the development of sepsis (p 281).
11. Describe the new theory in the development of SIRS, including the four response stages (p 280).
12. Explain the pathophysiology of SIRS (p 282).
13. Describe the mediators involved in the development of sepsis (p 280).
14. Recognize the individual organ manifestations related to the development of SIRS (p 280).
15. Identify the signs and symptoms that describe the patient in shock, sepsis, SIRS, or MODS (p 273–276, 279, 281, 286).
16. Discuss lab values of the septic or MODS patient (p 281).
17. Discuss assessment and management of the shock/MODS patient (p 284–289).
18. List the parameters necessary to monitor during the transport of a critical patient experiencing shock, sepsis, SIRS, or MODS (p 274, 275, 278, 279, 286).
19. Select from a list those interventions necessary during transport of the critically ill patient experiencing shock, sepsis, SIRS, or MODS (286–294).
20. Discuss pharmacologic agents used in the treatment of the shock/MODS patient (p 288).
21. Discuss blood administration, including the ABO blood system, various blood products, and the

procedure for administering blood (p 289–294).

Introduction

Shock, sepsis, and multiorgan dysfunction syndrome (MODS) are complex disorders that affect the body in multifaceted dimensions. As unique as each of these are, they share a common denominator—a breakdown in oxygen supply and demand. When oxygen delivery to the cells is compromised, cells are damaged. A cascade of unfortunate events begins with localized tissue damage and may eventually progress to organ failure and death. Before jumping into the pathophysiology of shock, sepsis, and MODS, it is imperative to grasp the basic physiology of how the cell and the microcirculation function. After all, the cell and the microcirculation are the first to experience the insult of inadequate oxygen supply.

Cellular Respiration

All cells require a continuous supply of oxygen, glucose, and other nutrients for normal metabolic function and homeostasis. However, there is another essential piece: energy. Energy is required to maintain cellular metabolic processes, much like electricity is needed to power manufacturing plants. It is the responsibility of the mitochondria to take the nutrients supplied and manufacture them into energy in the form of adenosine triphosphate (ATP), the primary energy-carrying molecule in the body.

ATP is manufactured through a complex process known as cellular respiration. Essentially, cellular respiration involves three parts: glycolysis **Figure 9-1**, the citric acid cycle **Figure 9-2**, and the electron transport chain, otherwise referred to as oxidative phosphorylation. These three components work together in an aerobic environment to produce large amounts of ATP.

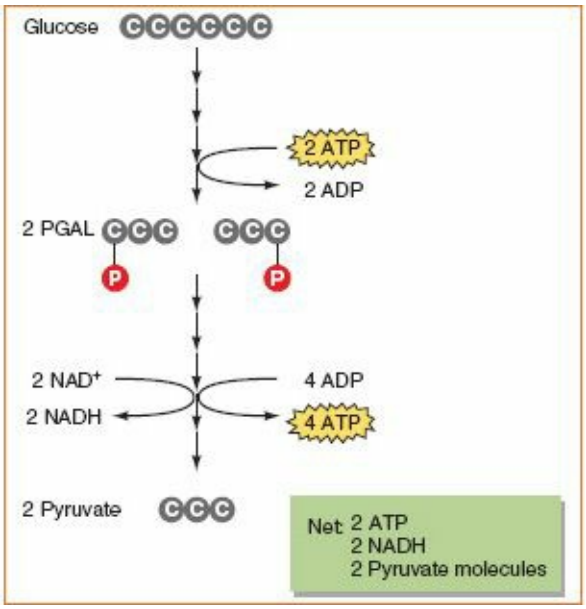

Figure 9-1 During glycolysis, glucose is broken down into two molecules of glyceraldehyde-3-phosphate (PGAL), which are converted to pyruvate. The cell nets two ATP and two NADH (reduced form of nicotinamide adenine dinucleotide) molecules.

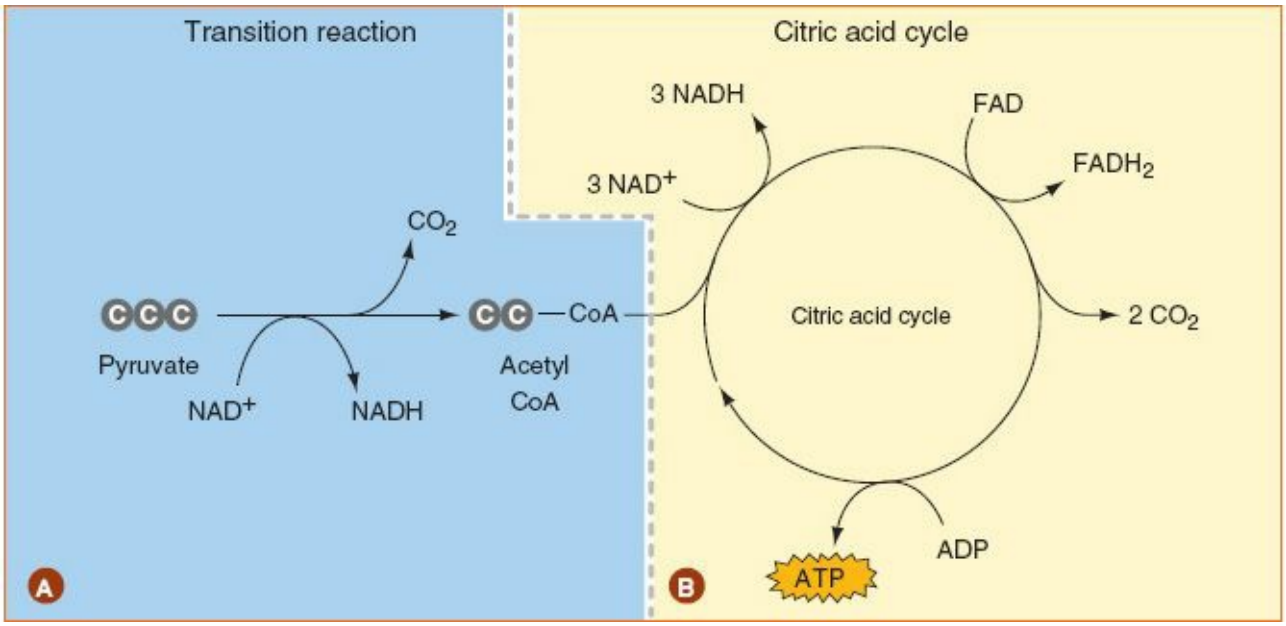

Figure 9-2 The citric acid cycle. **A.** Coenzyme A is created. **B.** In the mitochondrion, the citric acid cycle liberates two carbon dioxide molecules and produces one ATP molecule per pyruvate molecule. Its main products, however, are NADH (reduced form of nicotinamide adenine dinucleotide) and $FADH_2$ (a reduced form of flavine adenine dinucleotide), bearing high-energy electrons that are transferred to the electron transport system.

The citric acid cycle and the electron transport chain can only work in the presence of oxygen to break down glucose. However, glycolysis, the breakdown of glucose for energy, can occur in an aerobic or anaerobic environment. When there is not enough oxygen for aerobic metabolism of glucose, glycolysis must stand alone to produce ATP. This solo attempt to support cellular respiration causes a reduction in ATP and an increased production of lactic acid. As a result, cells are damaged and tissue function is impaired, leading to a cascade of injurious effects.

In the ATP molecule, the critical component for energy production is triphosphate. These phosphorus groups are connected to each other by oxygen molecules. Under normal conditions, the oxygen molecules have a negative charge and, thus, repel each other. It is this property that produces the potential energy of ATP. Removing just one of the phosphate groups results in conversion to adenosine diphosphate (ADP) and a release of energy. This conversion from ATP to ADP is crucial for supplying the energy required for biologic functions.

In **aerobic metabolism**, the ultimate acceptor of electrons is oxygen. The mitochondria utilize glucose, amino acids, and fatty acids combined with oxygen and ADP to produce ATP, carbon dioxide, water, and heat. The energy is stored as ATP, and the resultant carbon dioxide is eliminated by way of the respiratory tract.

In **anaerobic metabolism**, an alternative pathway converts glucose to pyruvic acid with the simultaneous production of ATP; however, significantly less ATP results from this process. This process also results in the production of lactate, which is released into the extracellular fluid and decreases the pH of body fluids. This process is less efficient than aerobic metabolism.

The Microcirculation and the Cell

Understanding the imbalance between oxygen supply and demand is critical to understanding the pathophysiology of shock, sepsis, and MODS. To a large extent, the pathophysiology can be compared with mechanisms of injury in trauma. When EMTs and paramedics respond to a vehicular trauma scene,

injuries can be identified and correlated to the impact the patient endured. This is all part of a good scene size up. This same principle is carried over to understanding the cell and the **microcirculation**—the nexus between the arterioles and venules consisting of the capillaries that course between cells of the various organs. The size of the conduits is large enough to allow passage of a single red blood cell. In cases of shock, sepsis, and MODS, the crash site is hidden deep within the body, at the cellular level.

Oxygen Transport and Utilization

For cells to function properly, oxygen is required. Oxygen is a key nutrient in maintaining homeostatic balance within the body. Put another way, homeostasis can only be maintained when the supply of oxygen is sufficient to meet the cellular demands of the body. Several requirements are necessary to achieve this balance. First, each of the body's systems must be intact and functioning normally. Next, the respiratory system must allow oxygen and carbon dioxide exchange across the alveolar-capillary membrane.

Once this transfer occurs, arterial blood transports oxygen to the tissues. Oxygen is dissolved in plasma (3%) or bound to hemoglobin (97%). Since the majority of oxygen is bound to hemoglobin, it is important to have an ample supply of hemoglobin. Simple formulas exist to determine the oxygen-carrying capacity of hemoglobin. As a standard, 1 g of hemoglobin carries approximately 1.39 mL of oxygen. (Note: Some texts say that 1 g of hemoglobin carries only 1.34 to 1.36 mL of oxygen, based on the theory that a certain percentage will be bound to methemoglobin and not hemoglobin.) Oxygen-carrying capacity is determined by using the following formula:

$$\text{Hemoglobin (Hgb)} \times 1.39 = \text{Oxygen-Carrying Capacity}$$

If the hemoglobin level is low, blood should be administered to optimize oxygen-carrying capacity. It may also be necessary to determine the total amount of oxygen in the arterial blood. The **arterial oxygen content (CaO_2)** formula is used to calculate this value. The normal arterial oxygen content is 17 to 20 mL/100 mL. The formula for determining arterial oxygen content is as follows:

$$Cao_2 = (Hgb \times 1.39 \times Sao_2) + (0.0031 \times Pao_2)$$

Use of the arterial oxygen content formula helps verify the importance of hemoglobin, oxygen saturation (SaO_2), and partial pressure of oxygen, arterial (PaO_2). However, hemoglobin and oxygen saturation have a greater impact on arterial oxygen content than does PaO_2. For this reason, some clinicians use an abbreviated formula for measuring arterial oxygen content:

$$Cao_2 = Hgb \times 1.39 \times Sao_2$$

Table 9-1 explains the components of the arterial oxygen content formula.

The cardiovascular system has the responsibility of delivering oxygen-rich blood to the tissues. There are various factors that can affect transport, including blood volume, viscosity, and arterial elasticity. However, the primary determinants of transport are blood pressure and cardiac output. Systolic blood pressure depends primarily on **cardiac output (CO)**, the force and volume of blood ejected from the ventricles during systole. Cardiac output is dependent on heart rate and the components of stroke volume—preload, afterload, and contractility. Diastolic blood pressure depends on peripheral resistance, which is determined by arteriolar vasoconstriction. Blood pressure is necessary in calculating the **mean arterial pressure (MAP)**. The MAP can provide information on how well organs are being perfused. Overall, an adequate cardiac output and a stable blood pressure are essential for proper perfusion and general performance of the body. The amount of oxygen delivered to the tissues each minute is reflected in

oxygen delivery (Do_2). Oxygen delivery is a calculated formula that combines arterial oxygen content with cardiac output. **Table 9-2** discusses the components of the formula shown here (CO represents cardiac output, and CaO_2 represents arterial oxygen content):

TABLE 9-1 Components of the Arterial Oxygen Content Formula		
Arterial Oxygen Content Formula: $Cao_2 = (Hgb \times 1.39 \times Sao_2) + (0.0031 \times Pao_2)$		
Hgb	97% of oxygen bound with Hgb	Hgb × 1.39 = Oxygen-Carrying Capacity
1.34 to 1.39 (varies in literature)	Each gram of Hgb capable of carrying 1.39 mL of oxygen	
Sao_2	The amount of oxygen carried on Hgb	Oxygen-Carrying Capacity × Sao_2
0.0031	0.0031 mL O_2/100 mL plasma/mm Hg Also known as the solubility coefficient for oxygen	0.0031 × Pao_2 = Amount of Oxygen Dissolved in Plasma
Pao_2	Partial pressure of oxygen dissolved in plasma (normal is 0.8-1.0 mm Hg)	

TABLE 9-2 Oxygen Transport and Utilization: Formula Description		
Step	**Formula Component**	**Normal Values**
Arterial oxygen content (Cao_2):		
1. Transfer of oxygen across the alveolar-capillary membrane 2. Adequate Hgb to carry the oxygen	$(Hgb \times 1.39 \times Sao_2) + (0.0031 \times Pao_2)$	17-20 mL/100 mL arterial blood
Oxygen delivery (Do_2):		
3. Adequate cardiac output to deliver the oxygen-rich blood to the tissues	$CO \times Cao_2$	640-1,400 mL/min
Oxygen consumption ($\dot{V}o_2$):		
4. Appropriate release of oxygen from Hgb	$CO \times Hgb \times 13.9 \times (Sao_2 - Svo_2)$	180-280 mL/min
5. Adequate utilization of oxygen by cells	Oxygen extraction ratio (ERO_2) $\frac{\dot{V}o_2}{Do_2}$	25%

$$Do_2 = CO \times Cao_2$$

If the arterial oxygen content is normal and oxygen delivery is down, measures are taken to enhance CO. These measures include fluid challenges and administration of an inotropic agent. Once all measures for CO enhancement have been attempted, pressor support is used.

When the oxygen-bound hemoglobin reaches the capillaries, oxygen is released from the hemoglobin to the cells in exchange for cellular waste. The amount of oxygen used by the cells and tissues is reflected in **oxygen consumption ($\dot{V}O_2$)**. The formula for $\dot{V}O_2$ is as follows:

$$\dot{V}O_2 = CO \times Hgb \times 13.9 \times (Sao_2 - Svo_2)$$

This formula is unique because it subtracts the percentage of oxygen saturation in the venous bed ($S_{\dot{V}}O_2$) from the oxygen saturation in the arterial bed (SaO_2). Mixed venous oxygen saturation (SvO_2) is measured much like an arterial blood gas (ABG), except that in measuring the venous saturation, blood is drawn from the distal port of the pulmonary artery (PA) catheter. This value reflects how well the body's tissues are able to extract and utilize the oxygen attached to hemoglobin. A sample from the distal port of the PA catheter reflects only a global perspective of how well the tissues are utilizing oxygen. The problem with this test is that different tissues extract more or less oxygen than others. For example, pulmonary and cardiac tissues extract approximately 40% of the oxygen from hemoglobin. As a result, the SvO_2 of venous blood drawn directly from the cardiovascular or pulmonary circulation will normally be about 60%. In contrast, the skin typically only extracts about 5% of the oxygen from hemoglobin. Measurement of the SvO_2 by using the tip of the PA catheter provides an average of the oxygen that was extracted from hemoglobin throughout the body. The normal SvO_2 level measured in the pulmonary artery is approximately 60% to 80%. When this value is abnormal, there is no way to specify which tissue bed or organ is responsible for the dysfunction. There are some specialty catheters that allow direct SvO_2 measurements.

Under certain circumstances, oxygen will more readily be extracted from hemoglobin or bound to hemoglobin, sometimes referred to as hemoglobin's affinity for oxygen. This affinity for oxygen is dependent on the PaO_2, the pH of the blood, the level of carbon dioxide in the blood, the ambient temperature, and the effects of BPG (2,3-biphosphoglycerate—a chemical that binds to deoxygenated hemoglobin, which helps red blood cells release oxygen). The effects of PaO_2 on the oxyhemoglobin saturation of red blood cells are reflected in the oxyhemoglobin dissociation curve (shown in Chapter 6). As the PaO_2 decreases, the amount of oxygen bound to hemoglobin in the arterial blood decreases, and less oxygen will be available for utilization by the tissues. A rightward shift of the dissociation curve causes decreased affinity for oxygen by hemoglobin. Conditions that cause a rightward shift are increased carbon dioxide level, BPG level, and temperature and a decreased pH. A leftward shift of the dissociation curve causes an increased affinity for oxygen by hemoglobin. In other words, oxygen is more readily bound to hemoglobin, and the body can maintain oxygen saturation with a lower PaO_2. However, release of the bound oxygen to tissues becomes more difficult. Conditions that cause a leftward shift are the opposite of those that cause a rightward shift. They are decreased carbon dioxide level, BPG level, and temperature and increased pH.

Finally, it is the responsibility of the cells to utilize the oxygen. The $\dot{V}O_2$ is dependent on the DO_2. The relationship between these two components is reflected in the **oxygen extraction ratio** (ERO_2), which is as follows:

$$ERO_2 = \frac{\dot{V}O_2}{DO_2}$$

Under normal conditions, only 25% of the oxygen delivered to the tissues is actually extracted. Therefore, the normal SvO_2 when measured in the pulmonary artery is approximately 75%. This allows the body a buffer zone for periods of low oxygen delivery when the cells must extract more oxygen. For

example, if the DO_2 drops to 600 mL/min, for $\dot{V}O_2$ to remain within normal limits (180 to 280 mL/min), the ERO_2 will need to increase 33%. If the $\dot{V}O_2$ drops, cells are forced to work under anaerobic conditions. Mortality rates increase as $\dot{V}O_2$ is compromised. Therefore, treatment is geared toward maximizing $\dot{V}O_2$, which is done partially by maintaining adequate oxygen supply, providing hemoglobin through administration of blood products, and optimizing cardiac output. If there is a breakdown in one or more of these components, homeostasis is lost.

Figure 9-3 summarizes the cycle of oxygen transport and utilization.

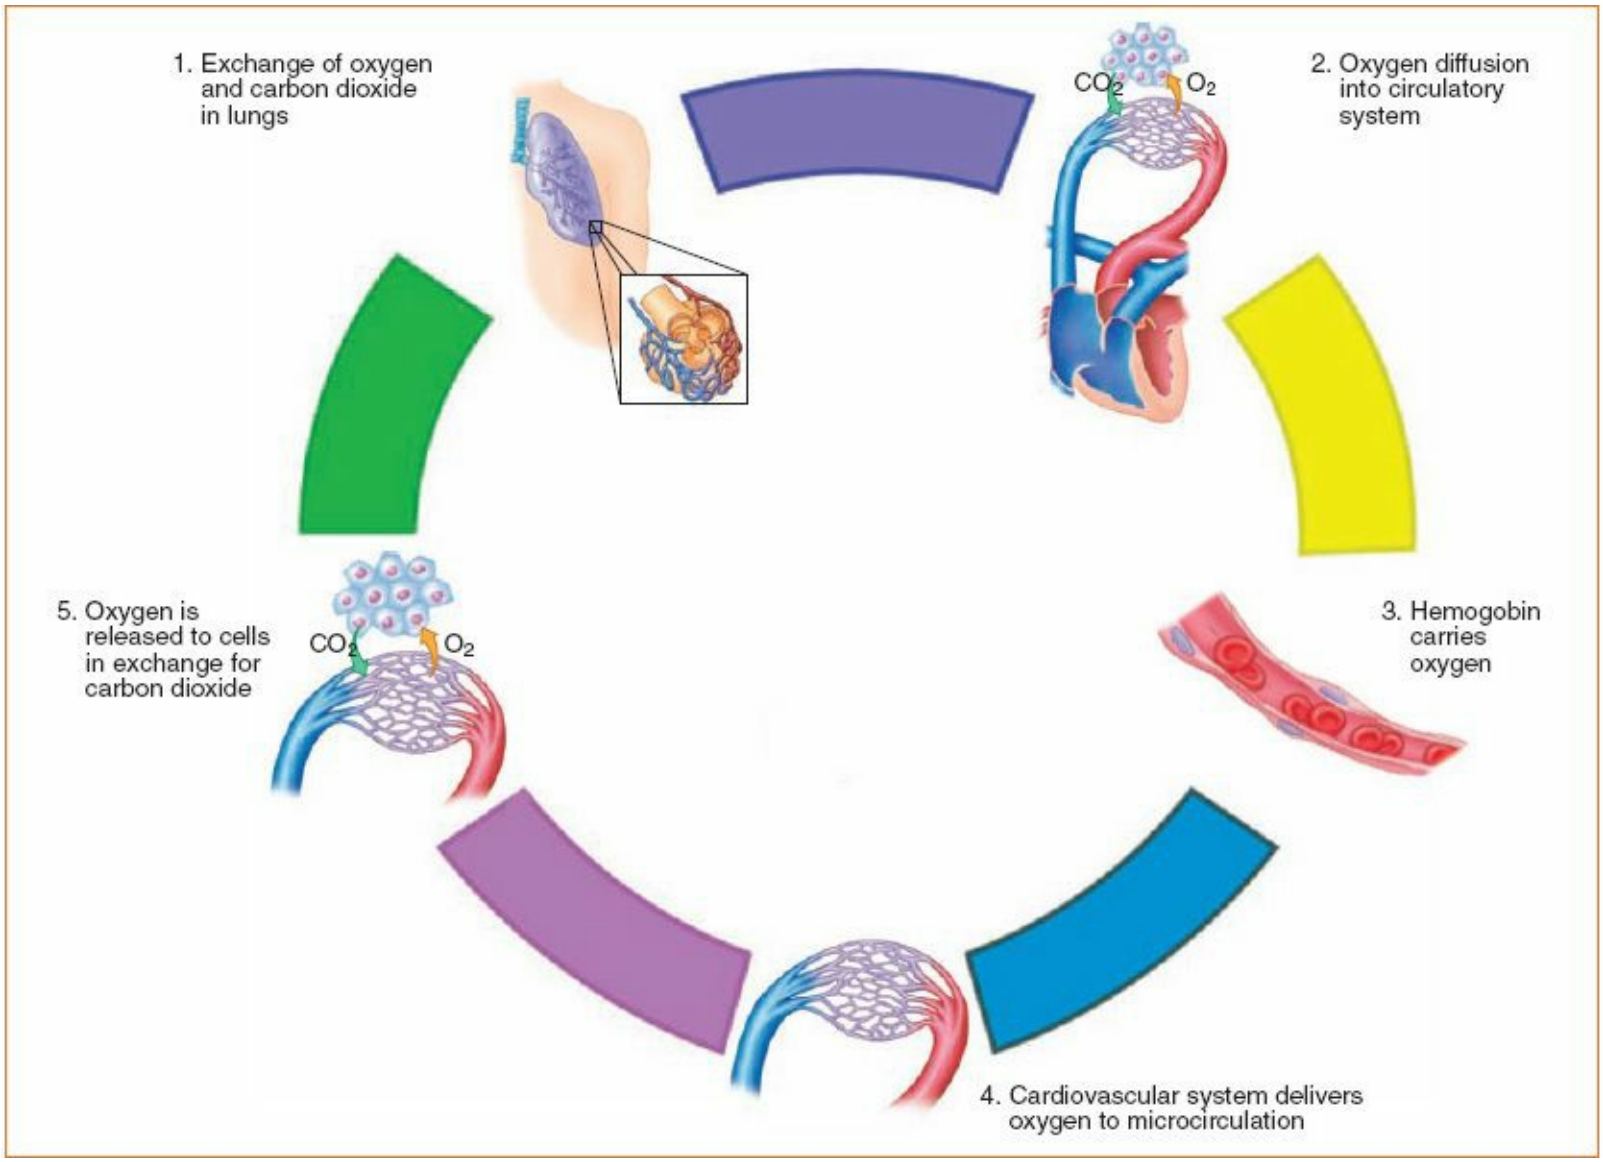

Figure 9-3 Oxygen transport and utilization.

Shock

Shock is a whole-body response to an inadequate supply of oxygen within cells, tissues, and organs from one or multiple causes. The beginning stages of shock occur at the cellular level. When oxygen is unable to be supplied to the microcirculation, cells are forced to function in an anaerobic environment, leading to widespread cellular hypoxia. Shock is a progressive condition that is commonly classified in four stages: initial, also referred to as early shock; compensatory; decompensatory or progressive shock; and, finally, irreversible or refractory shock.

Initial Stage

As a compensatory mechanism to maintain blood flow to the heart, brain, and adrenal glands, the microcirculatory blood flow to other tissue beds is severely restricted. The initial stage of shock begins as blood flow into the microcirculatory beds decreases to a point that oxygen delivery to the cells falls below levels required to maintain normal aerobic cellular function. Initially, the tissues respond to the restricted oxygen delivery by consuming as much available oxygen as possible, thereby increasing oxygen consumption. Eventually, oxygen oversupply is used up and cells are unable to extract enough oxygen. The mitochondria cannot function aerobically to produce ATP, and hypoxia develops. This anaerobic environment leads to increased lactate and carbon dioxide levels. As lactic acid levels rise, ATP production is severely reduced and cells are unable to maintain homeostasis, and, more specifically, microcirculatory flow to the heart, brain, and adrenal glands: failure of these organs will result in rapid death. In the early stages of shock, there are only very subtle clinical signs and symptoms of hypoperfusion or no signs at all. Vital signs may change temporarily. For example, heart rate and respiratory rate may increase, and the MAP may fall somewhat, but compensatory mechanisms are able to return these values to baseline. Research in this area has demonstrated that lactic acidosis begins to increase in the initial stage of shock. When clinical signs are normal, the serum lactate level is already on the rise.

Compensatory Stage

The compensatory stage of shock begins as the body uses its own physiologic mechanisms in an attempt to maintain cellular homeostasis. Compensatory mechanisms can be divided into neural, hormonal, and chemical mechanisms. The sympathetic nervous system controls these three mechanisms. The neural mechanism is typically thought of first because it can be reflected in the vital signs and physical assessment as increased heart rate, increased contractility, and vasoconstriction, which help shunt blood to vital organs. In reality, these compensatory mechanisms occur simultaneously to restore circulating volume and tissue oxygenation. Common signs and symptoms of compensatory shock are as subtle as mild tachypnea and tachycardia. The MAP may decrease 10 to 15 mm Hg from baseline. Cardiac output may also drop slightly. In compensatory shock, the body is still doing a great job of using its neural, hormonal, and chemical mechanisms in attempt to correct the problem, making it sometimes difficult to recognize the patient in shock **Figure 9-4**, **Figure 9-5**, and **Figure 9-6**.

In compensatory shock, oxygen delivery to the tissues is already severely reduced. To compensate for this imbalance, cells try to increase oxygen consumption by pulling more oxygen from the capillary bed. However, the cells are already working in an oxygen-deprived environment. Trying to work harder in this anaerobic environment produces more lactic acid and carbon dioxide. Chemoreceptors, strategically located in the carotid arteries and aortic arch, recognize an increase in carbon dioxide levels and relay this information to the brain, which, in turn, stimulates an increase in the respiratory rate. A patient in compensatory shock becomes tachypneic in an attempt to take in more oxygen while concurrently exhaling excess carbon dioxide. Blowing off carbon dioxide is a compensatory mechanism to raise the acidic pH caused by lactic acidosis and hypercarbia.

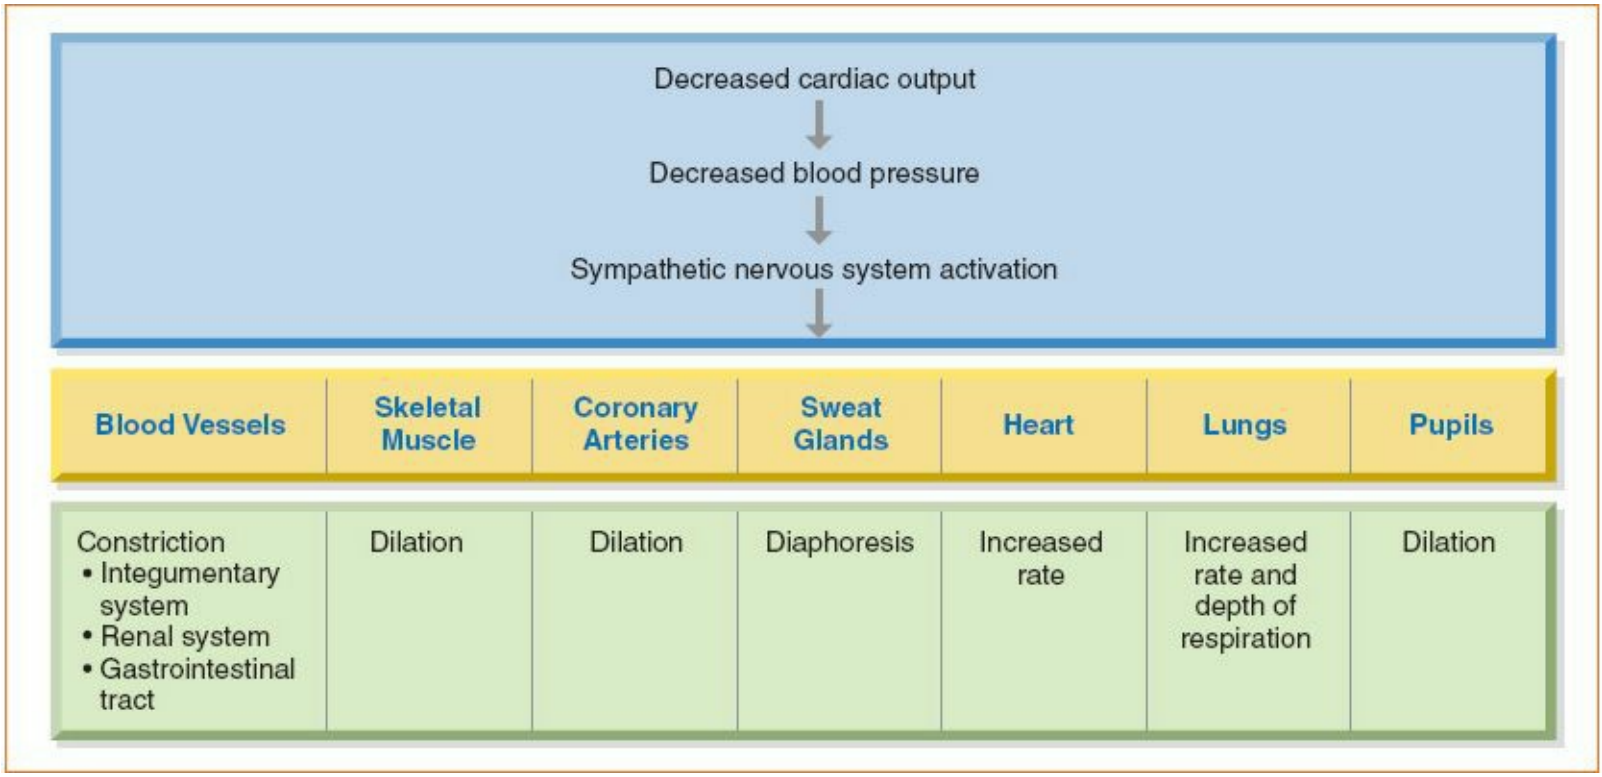

Figure 9-4 Neural compensation.

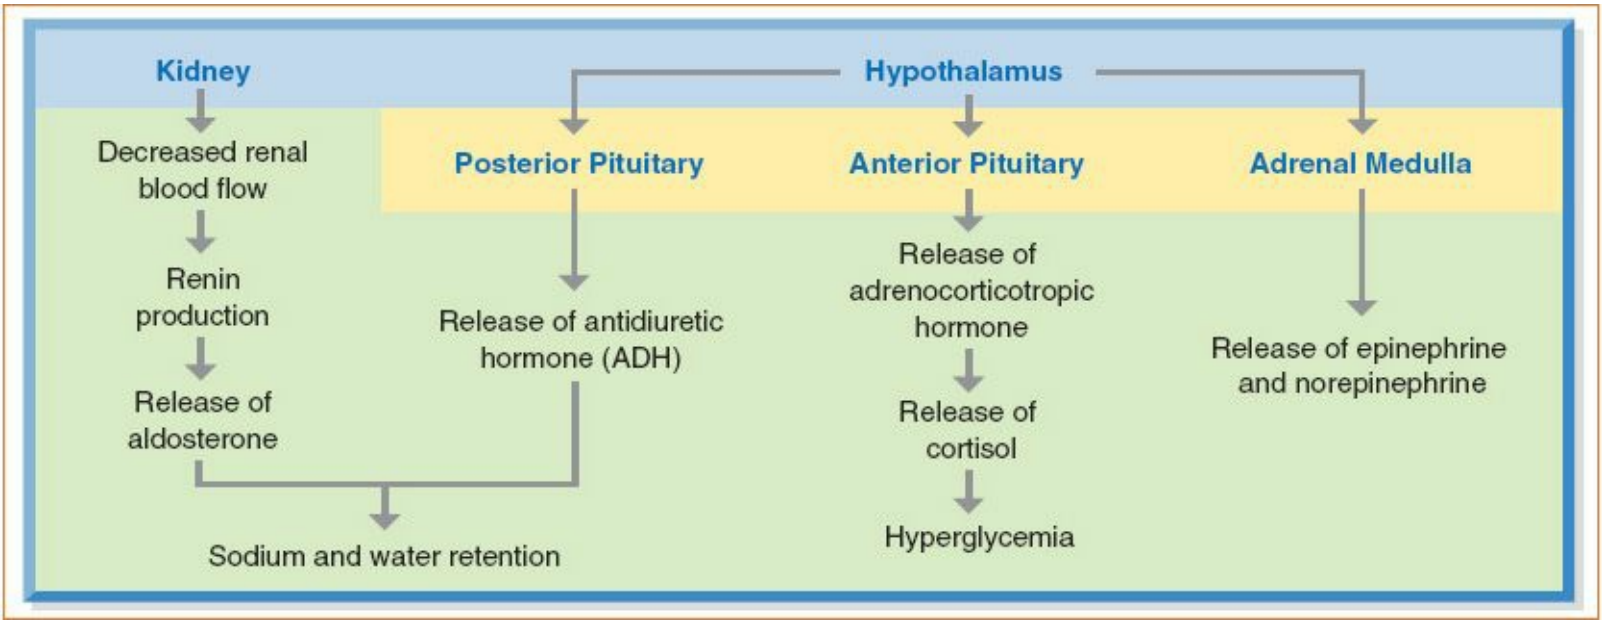

Figure 9-5 Hormonal compensation.

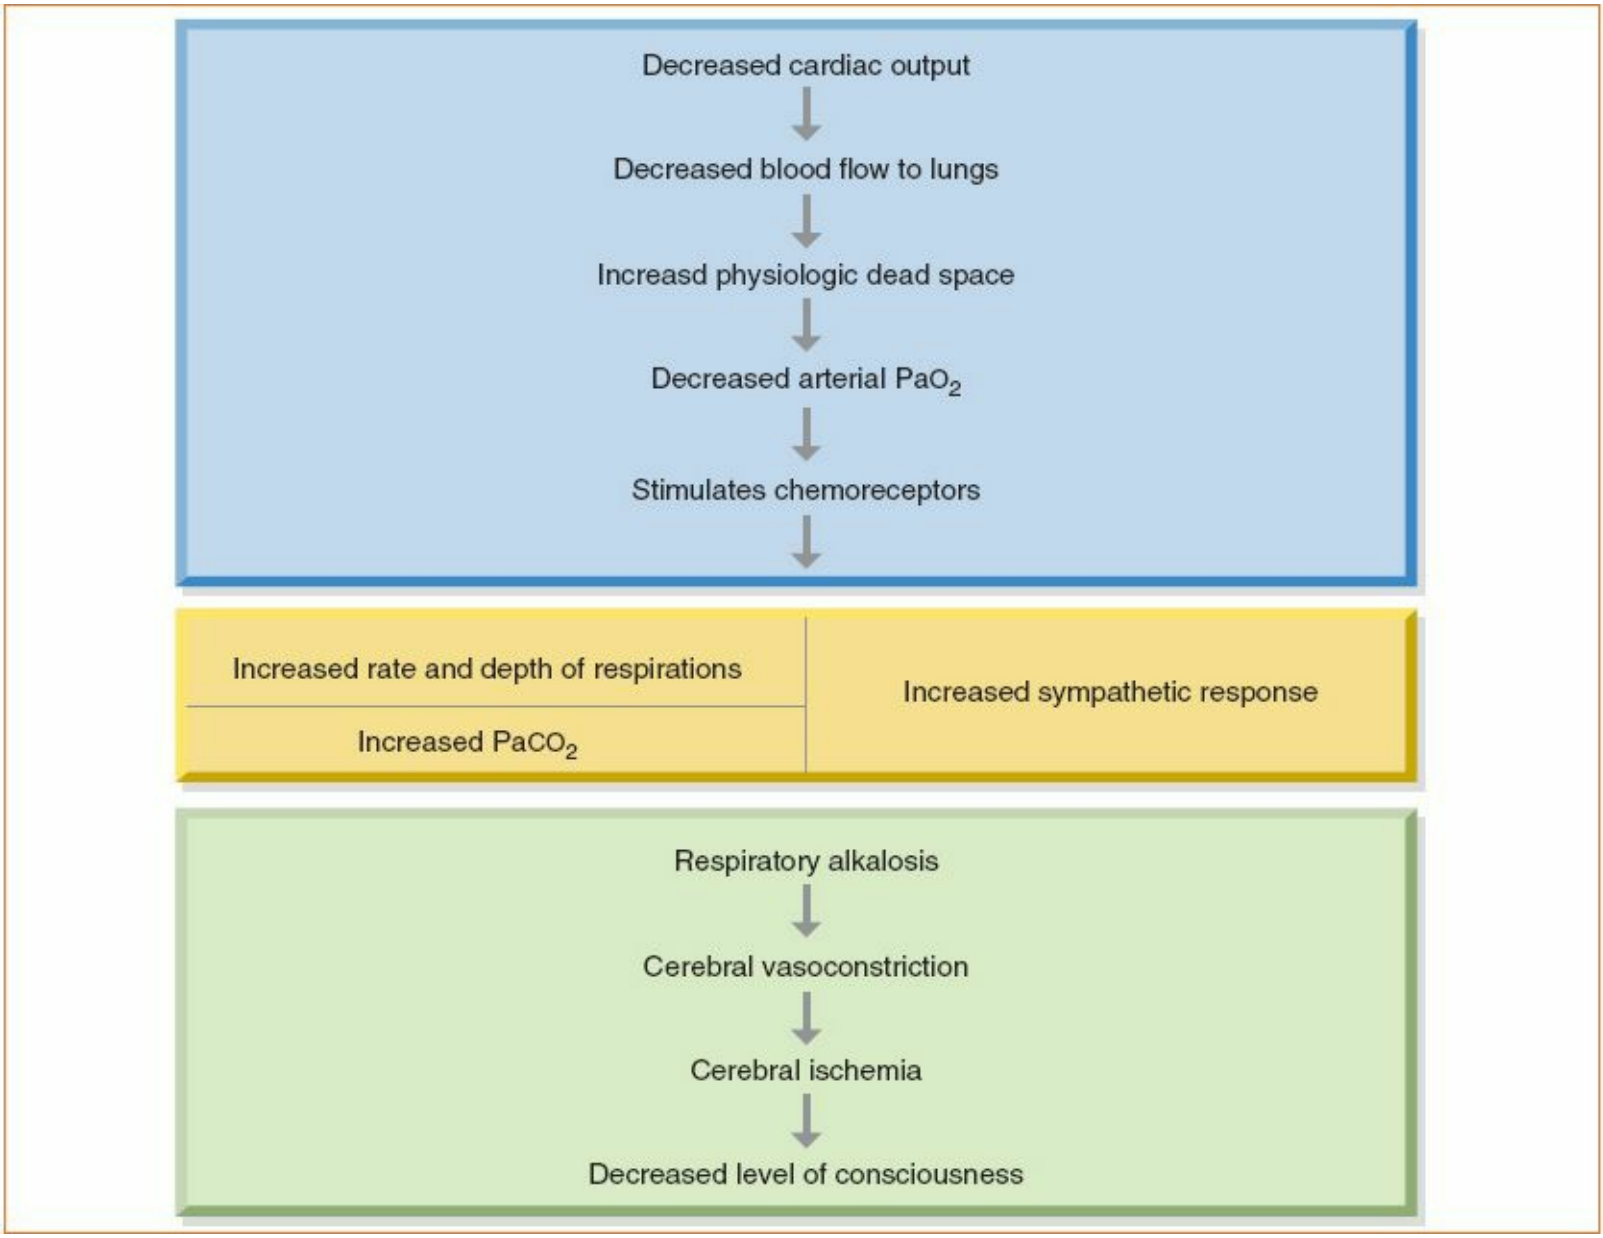

Figure 9-6 Chemical compensation.

While the respiratory system is working to balance pH and pull in more oxygen while exhaling waste, the heart and circulatory system are simultaneously working to maintain cardiac output. When the stroke volume and MAP begin to fall, baroreceptors in the carotid sinus and aortic arch recognize the change in pressure and send a signal to the vasomotor receptors in the medulla. The autonomic nervous system is then activated, stimulating the sympathetic nervous system and the anterior pituitary to release epinephrine and norepinephrine from the adrenal glands. These hormones work together to increase MAP and CO through increased heart rate, contractility, and peripheral vasoconstriction.

The renin-angiotensin-aldosterone system is a hormonal compensatory mechanism that is activated in response to low arterial pressures. Decreased blood pressures stimulate the release of renin, which stimulates the conversion of angiotensinogen to angiotensin I and, finally, angiotensin II. Angiotensin II increases arterial blood pressure through three mechanisms: vasoconstriction, stimulation of the thirst receptors in the hypothalamus, and stimulation of the release of aldosterone from the adrenal glands. Aldosterone increases circulatory volume by stimulating the reabsorption of sodium and water in the renal tubules.

Low arterial pressures also trigger the posterior pituitary gland to release antidiuretic hormone. This hormone increases water reabsorption within the kidneys and assists the adrenal hormones in

vasoconstriction to nonvital areas of the body. When vasoconstriction limits the supply of oxygen and blood flow to peripheral areas, capillary fluid shifts result. Capillary pressure is dependent on an adequate perfusion pressure (MAP). When capillary pressure drops, the pressure balance within the capillary bed is lost. The physiology of the capillary pressures reveals that hydrostatic pressure pushes fluid out and osmotic pressure pulls fluid back in. Normally, the hydrostatic pressure at the arterial end of the capillary is higher than the osmotic pressure, causing interstitial fluid to filter through the capillary endothelium into the interstitial space. At the venous end of the capillary, the hydrostatic pressure is lower than the osmotic pressure, causing fluid to diffuse back into the capillary. When this normal pressure balance is lost, edema may result. Edema results from any disturbance that alters the regulation of fluid transfer in the capillary and interstitial space. These disturbances include inflammation (more porous capillary), decreased colloid osmotic pressure, increased capillary hydrostatic pressure, and lymphatic channel obstruction.

The ability of the body to compensate for shock often masks what is occurring at the cellular level. Compensatory mechanisms can cover up a low circulatory volume, poor stroke volume, and inadequate CO before any noticeable changes in the blood pressure are identified, especially in children and healthy young adults. Laboratory studies may illustrate a clearer picture of what is going on inside the body. The ABGs show a low pH indicative of acidosis. The lactate level continues to climb, and hyperkalemia develops.

The transport treatment of compensated shock includes administering high-flow oxygen, performing good ventilator management, and, possibly, providing fluid replacement, depending on the cause.

Progressive or Decompensatory Stage

Shock will progress to an uncompensated state if the underlying cause remains untreated. At this stage, compensatory mechanisms fail to supply the much-needed oxygen to the cells. Patients have more pronounced signs of shock, including a drop in the MAP of more than 20 mm Hg from baseline, altered mental status, and tachycardia. Laboratory analysis continues to show a progression of acidosis, hyperkalemia, and a climbing lactate level.

This clinical picture develops for many reasons. Hypotension becomes more prominent as the microcirculation loses its ability to autoregulate, leading to increased capillary permeability. Blood starts to pool in the capillary bed, increasing hydrostatic pressure. The marked change in hydrostatic pressure within the microcirculation leads to edema and third spacing, decreasing venous return to the heart, which can be noted in a patient in shock by the presence of mottled skin.

Hemodynamic effects of this decreased preload are reflected in the blood pressure as hypotension and in the pulmonary artery (Swan-Ganz) catheter readings as decreased central venous pressure (CVP) and pulmonary capillary wedge pressure (PCWP). The CVP is a direct measurement of right atrial pressure and an indirect measurement of the preload of the right ventricle (right ventricular end-diastolic pressure). The PCWP reflects the left atrial pressure. At end diastole, pressure equalizes between the left atrium and the left ventricle; therefore, the PCWP can be used as an indirect measurement of the left ventricular pressure. The CVP and PCWP are discussed in more depth in Chapter 14.

Altered blood flow to the capillary bed causes microemboli to develop, which increases ischemia in the tissues and organs. Furthermore, the microclots stimulate the consumption of clotting factors, which may lead to **disseminated intravascular coagulation (DIC)**, a complex coagulopathy that can develop in critically ill patients for a variety of reasons. The patient's underlying condition triggers the coagulation cascade, resulting in microclots. These clots obstruct blood flow through the capillaries of organs and tissues, and microcirculatory thrombosis leads to tissue and organ ischemia, infarction, and organ dysfunction. Simultaneous fibrinolysis occurs in an attempt to reopen the microcirculation. The result is

bleeding *and* thrombosis. During the process, stimulation of the clotting cascade (discussed later in this chapter) rapidly depletes platelets and other coagulation factors, using them faster than the body can replace them. This situation leaves the body vulnerable to bleeding, or hemorrhage.

Hypotension is also a by-product of increased anaerobic metabolism. Anaerobic metabolism is self-limiting, and the cells cannot live in this type of environment for long. Anaerobic metabolism leads to a more acidic environment. Eventually, this environment leads to rupture of the lysosomes, which then spill their content into the cellular cytoplasm, leading to an even more acidic environment. The sodium-potassium pump then begins to fail. Sodium ions begin to accumulate within the cell. When this occurs, fluid is drawn into the cell, causing cellular swelling and, eventually, destruction of the cellular membrane. This is an important consideration in patient management because a number of devastating effects, such as cardiac arrhythmias, can follow. As cellular damage becomes more pronounced, cells start to die and release toxins into the microcirculation. For example, lysosomes, which normally defend cells from invaders, rupture and unleash their digestive enzymes, causing further damage within the microcirculation. Cell mediators attempt to counterattack this release and initiate the inflammatory response. Shock is a widespread condition, and the inflammatory response is not isolated to a specific area but is found throughout the body. When various complex compensatory components fail, vasodilation, smooth muscle contraction, and increased tissue permeability result in hypotension. Unfortunately, this cascade of events only gets worse as clotting mechanisms are activated in response to cell breakdown. The inflammatory response is discussed in more detail in the section on sepsis. These multifaceted systemic responses to cell breakdown can be summarized in a process known as SIRS, discussed in detail later in this chapter.

The progressive stage of shock is a life-threatening emergency requiring immediate treatment. Patients have a chance for recovery, even though the mortality rate increases with each stage of shock. Treatment is targeted at the underlying cause of shock. However, the effects of shock can be seen in nearly every organ **Table 9-3**. This is why fluid resuscitation and, if needed, vasopressor support are necessary early.

Refractory or Irreversible Stage

When a patient reaches the **refractory stage** of shock, compensatory mechanisms have failed. Anaerobic metabolism progresses to permanent organ dysfunction as cells die. Treatment options fail to reverse the mass effects of this stage in shock. Multiple organ failure ensues, and the mortality rate is at its highest.

A patient in the refractory or irreversible stage is unresponsive to verbal stimuli, blood pressure will be inadequate at less than 90 mm Hg systolic, heart rate will be increased, respiratory rate will be increased, and respirations will be shallow. The skin will be cold, cyanotic, and/or mottled, and peripheral pulses will be weak and thready to absent. Urinary output will decrease to less than 20 mL/h, and bowel sounds will be absent.

TABLE 9-3 Effects of Shock on the Body

Organ or System Affected	Progressive Result of Ischemia
Heart	Arrhythmias Cardiac failure
Lungs	Pulmonary hypertension Pulmonary edema Acute respiratory distress syndrome
Brain	Ischemia or infarction

Kidney	Decreased urine output Acute tubular necrosis Renal failure
Gastrointestinal	Stress ulcer Ischemic bowel with release of toxins
Pancreas	Ischemia Myocardial depressant factor released
Liver	Hypoglycemia Toxicity
Hematologic and immune	Initial leukocytosis followed by leukopenia Systemic inflammatory response DIC
Adrenal glands	Adrenal insufficiency, leading to hypotension, and hypoglycemia

Multiple Organ Dysfunction Syndrome

Progressive cell death will result in tissue death and eventual organ failure. When two or more organs stop functioning, **multiple organ dysfunction syndrome (MODS)** is diagnosed. MODS can be classified as primary or secondary. **Primary MODS** results from a direct insult such as trauma. **Secondary MODS** is the more common cause of organ failure and is a slower, more progressive insult to organs. It frequently results from the sepsis cascade. Mortality rates are high in patients with MODS. Patients with two failing organs have a 22% to 33% chance of recovery. When four or more organs are involved, the mortality rate is nearly 100%.

The organs affected early in MODS are the brain, kidneys, liver, adrenal glands, and heart. The kidneys are dependent on having adequate perfusion pressure. Once the MAP drops, the kidneys stop functioning. Oliguria occurs early in shock. Diagnostic studies reflective of renal function show elevated blood urea nitrogen (BUN) and creatinine levels. Many patients need continuous bedside dialysis when renal failure develops. Renal failure by itself increases the risk of death by 30%.

The liver is a complex organ with a lead role in detoxifying and excreting wastes and toxins. It is essential for the synthesis of blood proteins and coagulation proteins, along with the storage of glycogen, iron, and vitamins. When the liver stops working, the body has lost a key manager of the homeostatic process. Laboratory studies in patients with MODS reflect elevated levels of liver enzymes: aspartate aminotransferase, alanine aminotransferase, and total bilirubin. Unfortunately, there are no definitive treatments for liver failure. All treatments are focused on minimizing the effects of the liver damage.

Nearly every course in health care recognizes that a patient's level of consciousness deteriorates quickly in hypoxic states. This is taken to the extreme in MODS. The brain is also considered a peripheral organ and will gladly sacrifice itself in the hope of maintaining adequate blood pressure. As hypoxia ensues, the brain experiences ischemia, and many patients have permanent deficits from anoxic brain injury.

The heart potentially suffers more than any other organ. As the heart struggles to maintain arterial perfusion, it, too, undergoes hypoxia. Hypotension is unable to be managed despite fluids and vasopressors. Compensatory tachycardia cannot exist without oxygen, and bradycardic arrhythmias occur or arrhythmias such as ventricular tachycardia and ventricular fibrillation develop. Relentlessly, the shy pancreas also adds to the progression of cardiac failure. As the pancreas becomes more ischemic, it releases myocardial depressant factor, further altering the ability of the myocardium to contract.

Table 9-4 summarizes common organs affected by hypoperfusion and associated signs.

TABLE 9-4 Common Organs Affected by Hypoperfusion and Associated Signs

System or Organ	Signs of Dysfunction
Neurologic	Altered level of consciousness Confusion
Pulmonary	Tachypnea Hypoxemia • PaO_2 < 70 mm Hg • SaO_2 < 90% • PaO_2/FIO_2 ratio < 300 Respiratory alkalosis
Cardiovascular	Tachycardia Hypotension Altered hemodynamics • Decreased systemic vascular resistance • Decreased cardiac output • Decreased CVP Arteriovenous shunting • Cellular hypoxia • Lactic acidosis
Renal	Oliguria Anuria Elevated creatinine level
Hepatic	Jaundice Elevated enzyme levels Decreased albumin level Prolonged PT
Hematologic	Decreased platelet count Prolonged PT/activated partial thromboplastin time Decreased protein C level Elevated D-dimer level
Adrenal glands	Hypotension Hypoglycemia

Abbreviations: CVP, central venous pressure; PT, prothrombin time.

Classification of Shock

Shock is traditionally classified by cause. The three primary classifications of shock coincide with the conditions that cause them: cardiogenic, hypovolemic, and distributive. Distributive shock, which is

characterized as a relative hypovolemia, can be further broken down into chemical and neural causes. More than one type of shock may be present at the same time. For example, many trauma patients present with hypovolemic shock from sustained injuries. However, these patients may also have cardiogenic or neurogenic shock.

Cardiogenic Shock

Cardiogenic shock is failure of the heart to pump blood effectively. The definition of cardiogenic shock includes the following:

- A sustained systolic blood pressure of 80 to 90 mm Hg for greater than 30 minutes
- An MAP 30 mm Hg below baseline or less than 65 mm Hg over time
- A severe reduction in the **cardiac index** (< 1.8 L/min/m^2 without support or < 2.0 to 2.2 L/min/m^2 with support)
- Elevated ventricular filling pressure (ie, left ventricular filling pressure of > 18 mm Hg or right ventricular filling pressure of > 10 to 15 mm Hg)

The diagnosis of cardiogenic shock is usually made using a PA catheter, but some institutions make the diagnosis with echocardiography, which is an acceptable alternative.

Cardiogenic shock can be the result of a variety of causes. The most common cause of cardiogenic shock is left ventricular failure as a result of a large myocardial infarction (MI). Other causes of cardiogenic shock may be right ventricular failure, valvular disorders, cardiomyopathies, septal defects, papillary muscle rupture, and sustained arrhythmias. The causes may be classified as intrinsic or extrinsic, with the aforementioned examples being intrinsic causes. These conditions manifest with poor contractility, decreased cardiac output, or impaired ventricular filling. Extrinsic causes of cardiogenic shock include pericardial tamponade, effusion, pulmonary emboli, and tension pneumothorax. Some experts, including the American Heart Association, classify extrinsic causes as cardiogenic shock because there is impaired filling or emptying of the ventricles or a combination of the two. The most common cause of cardiogenic shock is an acute MI (AMI) accompanied by 40% dysfunction of the left ventricle. Noncoronary causes include myocardial contusion, pericardial tamponade, ventricular rupture, and pulmonary embolus. Cardiogenic shock may occur in approximately 5% to 8% of patients admitted to the hospital following an MI. Populations at the greatest risk of developing cardiogenic shock are elderly patients, patients with a history of diabetes mellitus, and patients with a history of MI with an **ejection fraction** of less than 35%. Risk stratification of patients in cardiogenic shock formerly was very high, with a mortality rate as high as 80%. Such a high mortality rate led to a very grim prognosis with little chance of survivability. Newer treatment modalities have greatly improved the risk stratification, and the prognosis is no longer grim. Patients with cardiogenic shock now have an excellent chance for long-term survival. Recent data suggest that the average mortality rate for cardiogenic shock is now approximately 50%. The mortality rate varies based on risk factors and demographics. Modern treatment modalities include early percutaneous coronary interventions, early revascularization, hemodynamic management with PA catheters, mechanical support with the intra-aortic balloon pump, and total circulatory support through the use of left-ventricular assist devices, biventricular assist devices, and extracorporeal life support, all of which are discussed in Chapter 15.

Cardiogenic shock results when the ventricles are unable to pump blood forward. Because the ventricles are unable to contract normally, blood remains in the ventricles. As a result, stroke volume is reduced, ultimately decreasing CO. The five major determinants of myocardial oxygen consumption are contractility, preload, wall tension, afterload, and heart rate. With inadequate oxygen supply to the periphery, cells are forced to function in anaerobic conditions, enabling the cascade of events leading to

SIRS and MODS.

Manifestations of cardiogenic shock vary depending on the underlying cause **Table 9-5**. Initially, the patient exhibits signs and symptoms associated with poor CO and low blood pressure. Both right and left heart failure result in hypotension, reflected as a systolic blood pressure of less than 90 mm Hg for a sustained period or an MAP 30 mm Hg below baseline. Altered mental status; cool, pale, diaphoretic skin; and a drop in urine output develop. The first compensatory mechanism to present itself is tachycardia. However, the heart is not able to sustain or improve CO, and the pulse becomes weak and thready. Heart sounds may be distant, or abnormal heart sounds may appear as S_3 or S_4. These extra heart sounds develop from unsynchronized closure of the valves. Preload is elevated from the inability of blood to push forward. This lack of forward movement may cause fluid accumulation in the lungs (acute pulmonary edema), the periphery (jugular venous distention), or both, depending on the ventricle(s) affected. Hypotension becomes more pronounced as compensatory mechanisms create systemic vasoconstriction. This increases afterload, which increases the pressure the already struggling myocardium must pump against.

Controversies

The popular notion that patients with heart failure have rales has recently been challenged. In fact, most patients with chronic heart failure do not have rales. The most reliable sign of volume overload is jugular venous distention. When rales are present in conjunction with other signs of congestion, heart failure is likely. Rales reflect the rapidity of onset of heart failure. Fully 50% of patients with chronic heart failure experience periods of clinically significant volume overload without peripheral edema or rales.

In addition to a systolic blood pressure of less than 90 mm Hg or an MAP of 30 mm Hg below the patient's baseline, other hemodynamic patterns in cardiogenic shock include a narrow pulse pressure, a cardiac index of less than 1.8 L/min/m^2 without support or 2.0 to 2.2 L/min/m^2 with support, and PCWP as measured by a pulmonary artery (Swan-Ganz) catheter of greater than 18 mm Hg. If the right ventricle is affected, the right atrial pressure (RAP) and CVP will also be elevated. Analysis of ABGs may reflect hypoxemia with a low Pa_{O_2} level and a corresponding metabolic acidosis with compensatory respiratory alkalosis. Acidosis develops as a result of poor perfusion due to cardiac dysfunction and the inability of the heart to pump oxygen to the peripheral tissues. Respiratory alkalosis is the compensatory mechanism that develops as the patient becomes tachypneic in attempts to blow off the excess carbon dioxide from increased anaerobic metabolism. Eventually, this compensatory mechanism will fail and the ABGs will reflect metabolic and respiratory acidosis.

TABLE 9-5 Findings in Cardiogenic Shock

	Left Ventricular Heart Failure	Right Ventricular Heart Failure	Biventricular Heart Failure
Heart rate	Increased	Increased	Increased or decreased
Blood pressure	WNL in the initial stage, then decreases as patient decompensates	WNL in the initial stage, then decreases as patient decompensates	Decreased
Pulse pressure	Narrow	Narrow	Narrow
CVP/right atrial pressure	WNL	Increased	Increased
PCWP	Increased	Decreased	Increased
Cardiac output/cardiac index	Decreased	Decreased	Decreased
SVR	Increased	Increased	Increased
Svo_2	Decreased	Decreased	Decreased
Urinary output	Decreased	Decreased	Decreased
Jugular vein distention	Absent	Present	Present
Heart sounds	S_3	Normal	S_3 or S_4
Edema	Pulmonary	Peripheral	Systemic

Abbreviations: CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance; WNL, within normal limits.

Signs and Symptoms

Cardiogenic Shock

- Poor CO
- Low blood pressure (systolic blood pressure of < 90 mm Hg or mean arterial pressure 30 mm Hg below baseline)
- Altered mental status
- Cool, pale, diaphoretic skin
- Decreased urine output
- Weak and thready pulse
- Distant or abnormal S_3 or S_4 heart sounds
- Fluid accumulation in the lungs or limbs (for example, jugular vein distention or pedal edema)
- Tachypnea

Differential Diagnosis

Cardiogenic Shock

- Aortic dissection
- Coronary artery disease
- MI
- Pulmonary embolus
- Acute myocarditis

Transport Management

Cardiogenic Shock

- Perform simple procedures to relieve the cause, including the following:
  - For cardiac tamponade, perform pericardiocentesis if allowed per protocols.
  - For tension pneumothorax, also perform needle decompression and chest tube therapy.
- Provide high-flow oxygen.
- Eliminate chest pain.
- Reduce anxiety.
- Perform hemodynamic and cardiac monitoring.
- Provide antiarrhythmics if arrhythmias are present.
- Provide judicious fluid therapy.
- Consider administering vasopressors to physician-ordered parameters.
- Consider administering inotropic agents to physician-ordered parameters.
  - Use with caution. Research shows that high doses of inotropic support lead to a higher incidence of mortality.
- Consider administering diuretics.
- Consider using agents to decrease afterload.
- Insert an indwelling urinary catheter to monitor urinary output.

Primary management of cardiogenic shock is focused on enhancing CO while decreasing left ventricular workload. If the underlying cause is known, simple procedures to relieve the cause of cardiogenic shock should be taken first. This may require pericardiocentesis for cardiac tamponade (if protocols allow), along with needle decompression, and chest tube therapy for tension pneumothorax. If the cause is an AMI, revascularization should be initiated early (although this is an in-hospital procedure and will not be performed during transport).

Figure 9-7 Administer IV fluids to the critical care shock patient judiciously.

High-flow oxygen therapy should be provided to any patient exhibiting signs of shock. One of the manifestations of cardiogenic shock is pulmonary edema, and when this occurs, mechanical ventilation should be considered as guided by ABG analysis. Supportive therapy is also necessary to eliminate chest pain and reduce anxiety. Arrhythmias are common with cardiogenic shock. Therefore, antiarrhythmics may be necessary to optimize cardiac function.

Fluid therapy is never wrong when done judiciously **Figure 9-7**. Isotonic crystalloids in small 200- to 250-mL (5- to 10-mL/kg) boluses may improve CO. In suspected cardiogenic shock, vital signs, lung

sounds, and heart sounds should be frequently reassessed after fluid boluses to measure adequacy of therapy. Excessive crystalloids may cause pulmonary edema or worsen existing pulmonary edema.

Inotropic support may be needed to improve contractility. Milrinone and dobutamine are two inotropic agents used to increase CO. These agents assist the heart by increasing the cardiac contractile force, thus improving blood pressure. Milrinone has inotropic effects and minimal chronotropic effects but is not a vasoconstrictive agent. Milrinone also causes pulmonary vasodilation and peripheral arterial vasodilation. However, owing to excessive hypotension with a loading dose, loading with milrinone should be avoided in acute heart failure. Dopamine is also used, but more as a supportive agent in conjunction with dobutamine or milrinone. However, dopamine, like all vasopressors, needs to be used with caution. In general, all vasopressors increase afterload through their vasoconstrictive properties and increase oxygen consumption by elevating heart rate and increasing force of contractility.

Preload and afterload reductions are primary concerns in cardiogenic shock. Diuretics are frequently administered to reduce CVP and PCWP. Once the blood pressure is stabilized, vasodilators are started. Venous vasodilators, such as nitroglycerin, reduce preload; however, this agent must be used with caution in patients with a systolic blood pressure of less than 100 mm Hg. Decreasing left ventricular workload with afterload reducers such as nitroprusside (Nipride) or milrinone is also important in improving CO.

When pharmacologic methods are contraindicated or fail to support the failing heart, other methods of afterload reduction are necessary. The intra-aortic balloon pump and ventricular assist device are two mechanical treatments for cardiogenic shock and are discussed in Chapter 15. The intra-aortic balloon pump is a large balloon catheter that lies in the thoracic aorta and inflates during diastole, displacing blood in the aorta. Balloon inflation forces blood in two directions, back toward the aortic arch and the coronary arteries and downward through the descending aorta, forcing blood to the peripheral circulation, including the renal and mesenteric arteries. The balloon deflates during systolic contraction, allowing the heart to pump against very low systemic pressures. If all of these methods fail, the alternatives to support the heart are limited. Extracorporeal membrane oxygenation and ventricular assist device therapies may be needed to provide temporary pressure and oxygenative support to a patient in cardiogenic shock.

Hypovolemic Shock

Hypovolemic shock is present when there is too little circulating blood volume within the vascular system, resulting in hypotension. Hypovolemia may be present when blood or fluid is lost or displaced internally or externally. Examples of conditions associated with hypovolemia are fever, vomiting and diarrhea, hemorrhage, burns, and excessive third spacing.

Manifestations of hypovolemic shock are evident early in shock. The initial stage of hypovolemic shock is characterized by low circulating volume with minimal signs of hypoperfusion. However, as the body begins to compensate for low venous return, decreased stroke volume, and low CO, patients begin to have tachycardia, hypotension, and signs of poor tissue perfusion, including pallor and delayed capillary refill. Patients become more confused and anxious as oxygen supply to the tissues is compromised and cellular metabolism is altered. Compensatory mechanisms continue to increase systemic vascular resistance (SVR) in an attempt to improve hemodynamics. As SVR increases and CO drops, patients have cold, mottled, and pulseless extremities with worsening mental status. Left untreated, the shock will eventually progress to decompensated shock that is refractory to any therapy **Table 9-6**.

TABLE 9-6 Findings in Hypovolemic Shock

Heart rate	Increased
Blood pressure	WNL in the early stages, then decreases as patient

	decompensates
CVP/RAP	Decreased
PCWP	Decreased
Cardiac output/cardiac index	Decreased
SVR/systemic vascular resistance index (SVRI)	Increased
Svo_2	Decreased
Urinary output	Decreased
Jugular vein distention	Flat
Hematocrit (percentage of whole blood components versus plasma)	Decreased (with hemorrhage) Increased (with dehydration)

Abbreviations: CVP, central venous pressure; RAP, renal artery pressure; SVR, systemic vascular resistance; WNL, within normal limits.

The hematocrit value decreases with hemorrhage. A fall in the hematocrit value after blood loss will happen after one to several hours with no fluids (as interstitial and cellular fluid shifts occur). The hematocrit value decreases faster with exogenous fluid challenges.

Hypovolemic shock caused by hemorrhagic trauma has been classified by the American College of Surgeons Committee on Trauma into four classes, each with their own specific characteristics and treatments **Table 9-7**.

Treatment of hypovolemic shock revolves around treating the underlying condition, administering oxygen, and initiating volume replacement. Isotonic crystalloids of normal saline or lactated Ringer's are the preferred solutions used in 250- to 500-mL increments to maintain blood pressure in low normal ranges. Many trauma surgeons prefer lactated Ringer's over normal saline because lactated Ringer's may help decrease the acidosis in patients with severe hemorrhagic hypovolemia. However, this belief remains controversial and either solution will benefit the patient. The use of hypertonic saline, 5 mL/kg of 7.5% sodium chloride, in 250-mL increments may also be effective in treating hypovolemic shock caused by hemorrhage. Studies have shown that hypertonic solutions may optimize blood pressure, CO, intracranial pressure, and microvascular flow without increasing bleeding or volume overloading patients. This is achieved by increasing the osmolarity within the vasculature, causing a shift of interstitial fluid into the vasculature. However, there has been no change in survival rates compared with standard fluid resuscitation. More research in this area may change the face of fluid therapy, but for now, most disciplines in the United States continue to use isotonic crystalloid therapy.

Signs and Symptoms

Hypovolemic Shock

- Tachycardia
- Hypotension
- Signs of poor tissue perfusion (pallor and delayed capillary refill)

- Confusion
- Anxiety
- Cold, mottled, and pulseless extremities
- Decreased mentation

Differential Diagnosis

Hypovolemic Shock

- Fever
- Dehydration
- Hemorrhage
- Burns
- Excessive third spacing

Transport Management

Hypovolemic Shock

- Treat the underlying condition.
- Administer oxygen.
- Maintain the airway and ensure optimal ventilation.
- Initiate volume replacement (normal saline or lactated Ringer's preferred, in 250- to 500-mL increments).
- Administer vasopressors if hypotension is refractory to fluid resuscitation.
- Administer blood products early if hemorrhage is suspected.

TABLE 9-7 Estimated Fluid and Blood Loss for a 70-kg Male

	Class I	Class II	Class III	Class IV
Blood loss (mL)	< 750	750-1,500	1,500-2,000	> 2,000
% Blood loss	< 15	15-30	30-40	> 40
Heart rate (beats/min)	< 100	> 100	> 120	> 140
Blood pressure	Within normal limits	Normal	Low	Low
Pulse pressure	Within normal limits	Narrow	Narrow	Very narrow
Capillary refill	Within normal limits	Delayed	Delayed	Absent
Respiratory rate (breaths/min)	14-20	20-30	30-40	> 35
Central nervous system/mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic
Skin condition	Cool, pink	Cool, pale	Cold, pale, moist	Cold, cyanotic
Urine output (mL/h)	> 30	20-30	5-15	Minimal or none
Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

Modified from: American College of Surgeons Committee on Trauma. *Advanced Trauma Life Support for Doctors: ATLS Student Course Manual*. 8th ed. Chicago, IL: American College of Surgeons; 2009.

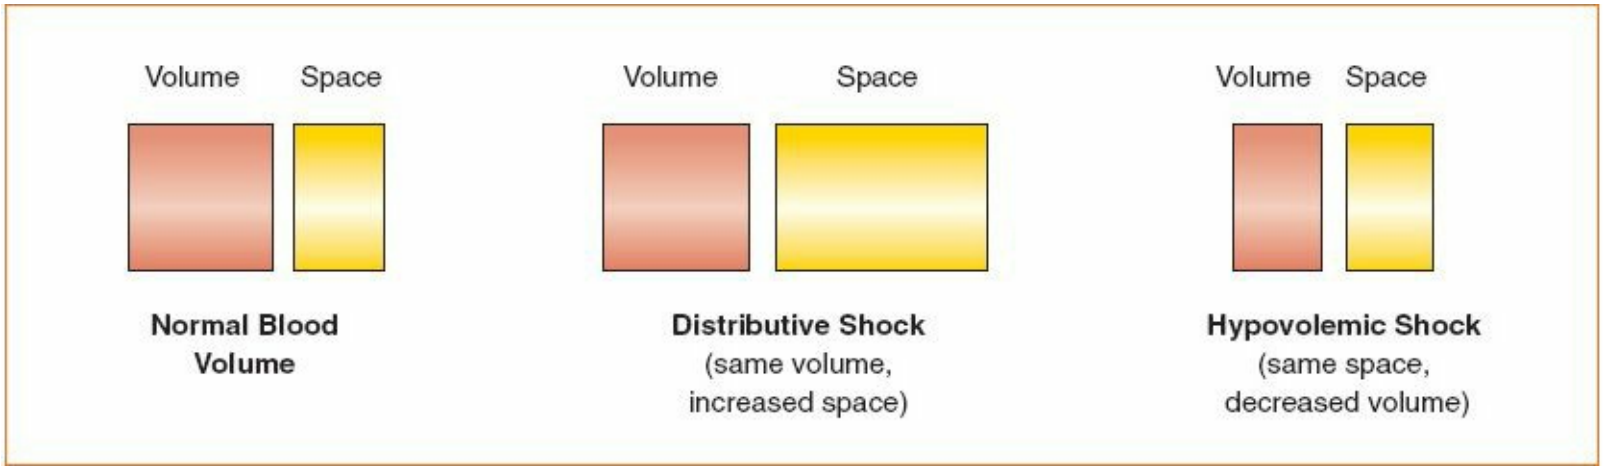

Figure 9-8 Conceptual illustration of distributive vs hypovolemic shock.

Blood products should be started early if hemorrhage is suspected. The American College of Surgeons recommends starting blood products in class III and IV hemorrhage after an initial 2 L of isotonic solution is administered. Colloids have not shown to be of any more benefit than crystalloids in improving patient outcome and, therefore, are not typically recommended.

The next section discusses distributive shock. **Figure 9-8** shows a conceptual illustration of distributive vs hypovolemic shock.

Distributive Shock

Distributive shock is a catch-all term used to describe several types of shock involving loss of vasomotor tone or increased vascular permeability; it includes neurogenic, anaphylactic, and septic shock. The human body has approximately 60,000 miles of blood vessels and 5 to 6 L of blood. Homeostasis involves constant regulation of vessel diameter and flow through capillary beds. When a disruption occurs in the vascular compartment causing widespread vasodilation and relative hypovolemia, distributive shock is present.

Neurogenic Shock

Neurogenic shock is one form of distributive shock caused by loss of sympathetic tone. When sympathetic tone is lost, there is substantial peripheral vasodilation, baroreceptor inhibition, and altered thermoregulation. This type of shock results from conditions that impede the ability of the sympathetic nervous system to control the constriction and dilation of vessel walls. Trauma to the brain or spinal cord is a common condition associated with disruption of sympathetic tone. Spinal cord injuries above the thoracolumbar spinal cord T6 level are the most common spinal cord injuries associated with neurogenic shock. Guly et al found that neurogenic shock was present in 19% of patients with cervical cord injuries and 7% of patients with thoracic and lumbar cord injuries. In the thoracolumbar spinal cord T6 level, the spinal space is narrower, and almost all the space is occupied by nervous tissue. The bony protection is more fragile and the head freely mobile. Neurogenic shock is not limited to trauma. Many pharmacologic agents, such as general and spinal anesthetics, opiates, and barbiturates; insulin shock; various toxins; and extreme parasympathetic stimulation, may also be responsible for neurogenic shock.

Table 9-8 offers a useful reference to vital signs associated with spinal trauma.

Neurogenic shock is characterized by relative hypovolemia as the result of vasodilation. The amount of fluid in the vasculature remains constant, but the container size is increased. As a result, there is a significant drop in the SVR and blood pressure. The signs and symptoms associated with neurogenic shock can be very different from those found in hypovolemic shock **Table 9-9**. One profound difference is

the presence of bradycardia in the face of hypotension. This is caused by the combined loss of sympathetic tone and baroreceptor response. However, the presence of tachycardia with hypotension does not exclude neurogenic shock. It is vital to piece together all possible causes of hypotension to determine the best treatment.

Treatment for neurogenic shock is focused on maintaining an MAP greater than 70 mm Hg or a systolic blood pressure at greater than 90 mm Hg. Fluid therapy with isotonic crystalloids should be started. If large volumes of crystalloid solutions are required to maintain the blood pressure, colloids should be considered. Colloids stay in the vascular system longer than crystalloids and, because of their high colloid osmotic pressure, are able to pull fluid from the cells and interstitial spaces back into the vascular system. Inotropic agents and vasopressors will need to be started if traditional fluid resuscitation is insufficient to maintain MAP. Dopamine, norepinephrine (Levophed), and phenylephrine (Neo-Synephrine) are common vasopressor agents used in neurogenic shock. Norepinephrine and phenylephrine raise the blood pressure by directly stimulating the alpha-adrenergic receptors in the smooth muscle of blood vessels, causing vasoconstriction. Dopamine at moderate doses stimulates the beta 1–adrenergic receptors, increasing the force of contraction and, therefore, increasing CO. Higher dopamine doses stimulate the alpha-adrenergic receptors, mimicking the effects of norepinephrine.

TABLE 9-9 Hemodynamic Findings in Distributive Shock Compared With Hypovolemic Shock

Hemodynamic Findings in Distributive Shock			Comparison With Hypovolemic Shock
	Neurogenic Shock	Anaphylactic Shock	
Heart rate	Decreased	Increased	Increased
Blood pressure	Decreased	Decreased	Within normal limits in the initial stage, then decreases as patient decompensates
Pulse pressure	Normal	Narrow	Narrow
CVP/RAP	Decreased	Decreased	Decreased
PCWP	Decreased	Decreased	Decreased
Cardiac output/cardiac index	Decreased	Decreased	Decreased
SVR/SVRI	Decreased	Decreased	Increased
Svo_2	Decreased	Decreased	Decreased
Urinary output	Decreased	Decreased	Decreased
Skin	Pink, warm, dry	Flushed, warm to hot, pruritis, hives	Cool, pale, moist

Abbreviations: CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; RAP, renal artery pressure; SVR, systemic vascular resistance; SVRI, systemic vascular resistance index.

Signs and Symptoms

Neurogenic Shock

- Relative hypovolemia as the result of vasodilation
- Bradycardia

- Significant drop in blood pressure
- Normal pulse pressure
- Decreased CVP/RAP
- Decreased PCWP
- Decreased CO/cardiac index
- Significant drop in the SVR/SVRI
- Decreased Svo_2
- Decreased urinary output
- Pink, warm, dry skin

Differential Diagnosis

Neurogenic Shock

- Loss of sympathetic tone
- Trauma to the brain or spinal cord
- Pharmacologic agents such as general and spinal anesthetics, opiates, and barbiturates; insulin shock; various toxins; and extreme parasympathetic stimulation

Transport Management

Neurogenic Shock

- Maintain MAP at greater than 70 mm Hg and/or systolic blood pressure at greater than 90 mm Hg.
- Consider administering vasopressors (dopamine, norepinephrine, phenylephrine). Administer inotropic agents and vasopressors if traditional fluid resuscitation is insufficient to maintain MAP.
- Initiate fluid therapy with isotonic crystalloids.
- Consider colloids if large volumes of crystalloid solutions are required to maintain blood pressure.
- Maintain the heart rate (increase heart rate via pacemaker therapy or atropine administration).

The control of heart rate is also important in neurogenic shock. Loss of sympathetic tone may result in profound bradycardia. Methods for increasing heart rate involve pacemaker therapy or atropine. Atropine works by blocking acetylcholine (muscarinic) receptors, creating a temporary increase in heart rate.

Transport considerations for neurogenic shock center on ensuring a patent airway, adequate ventilation, and oxygenation because, depending on the level of involvement, the patient may be unable to breathe without assistance or may have impaired ventilatory capabilities. Care includes cardiac monitoring, administration of IV fluids and vasopressor medications as ordered, and maintenance of spinal immobilization. The patient also needs to have an indwelling urinary catheter.

Anaphylactic Shock

Anaphylactic shock is a severe, life-threatening allergic reaction producing systemic vasodilation in response to histamine release. The list of possible antigens in humans is extensive and includes diagnostic agents, foods, bites, stings, chemical agents, and several classes of medications, such as antibiotics,

immunologic agents, anesthetics, anti-inflammatory agents, narcotics, and hormones. There are two types of anaphylactic shock: true and anaphylactoid. **True anaphylaxis** results when the allergen binds to IgE on the cell membranes of basophils and mast cells, stimulating the release of histamine from the cell. An **anaphylactoid reaction** is a non–IgE-mediated response that causes the rupture of mast cells and basophils, which then release histamine and other defense mediators. Non–IgE-mediated responses can give the same reactions as true shock without prior exposure. Either reaction can be massive and can happen in minutes after exposure, or the response may be delayed for hours or even days and is then called a delayed hypersensitivity response. Histamine, a cell mediator, is responsible for relative hypovolemia caused by widespread vasodilation, increased capillary permeability, and smooth muscle constriction. This smooth muscle constriction is responsible for the bronchoconstriction, laryngeal edema, and angioedema seen with anaphylaxis. As a result, the airway may become quickly compromised.

Rapid treatment is necessary to limit the effects of anaphylaxis. Standard oxygen therapy may not be enough. Patients may need to be intubated, or they may require an emergency cricothyrotomy or tracheostomy to maintain an adequate airway.

Treatment is focused on removing the allergen that caused the severe reaction, including discontinuing the medication causing the reaction or simply removing a stinger after a bee sting. Drug therapy for anaphylaxis requires supporting the cardiovascular system and preventing further mediator release. Epinephrine is the drug of choice for anaphylactic shock because it acts as a physiologic antagonist to the **leukotrienes** and other cell mediators released in anaphylaxis. Epinephrine increases blood pressure through stimulation of alpha-1 receptors, leading to vasoconstriction. It also has bronchodilation effects by activation of the beta-2 receptors. The dose of epinephrine is 0.3 to 0.5 mg (0.3 to 0.5 mL) of a 1:1,000 solution subcutaneously or 0.3 to 0.5 mg (0.3 to 0.5 mL) of a 1:10,000 solution IV. If hypotension persists, an epinephrine drip may need to be started. Epinephrine may not work on patients taking beta-blockers. In these cases, glucagon may be given IV at 5 to 15 μg/min. Glucagon is effective in treating anaphylaxis by increasing heart rate and contractility.

Owing to the increased container size, fluid therapy needs to be started early to maintain an MAP of greater than 70 mm Hg (or a systolic blood pressure of greater than 90 mm Hg). Normal saline should be used to sustain adequate preload volumes. Vasopressor agents may be started if crystalloid therapy is inadequate for maintaining CO.

Other pharmacologic agents are beneficial for treating anaphylactic shock. Antihistamines are routinely used in the treatment of allergic reactions. Diphenhydramine (Benadryl) is used to block histamine release from the H_1 receptors on smooth muscles, gland cells, and some nerve endings. The dose of diphenhydramine is 1 to 2 mg/kg IV, repeated every 4 to 8 hours, but not exceeding 50 mg. Ranitidine (Zantac), an H_2 blocker, is sometimes used to treat severe allergic reactions because of its effects on the heart, decreasing stimulation and decreasing acid secretion within the stomach. Bronchodilators are administered to relieve the shortness of breath associated with anaphylaxis. Albuterol is a beta 2–selective bronchodilator that works as a physiologic antagonist toward leukotrienes and other inflammatory mediators, thereby relaxing smooth muscle. Corticosteroids are given to stabilize the capillary membrane, thus offsetting the inflammatory response and preventing a delayed reaction. Corticosteroids decrease swelling and inflammation in the airway and also decrease IgE-mediated responses that may occur hours after the initial event. Approximately 20% of anaphylactic reactions follow a biphasic course, with an asymptomatic period for 1 to 8 hours after the initial event. After this 1- to 8-hour period, there can be a recurrence of the reaction. Recurrence has even been reported as late as 24 to 38 hours after treatment for the initial episode. (It is possible for a patient to experience a recurrence later than the 1- to 8-hour period following initial onset.) About one third of the second-phase reactions are more severe than the initial event. Another third are equally severe as the initial event, and

the remaining third are less severe. Corticosteroid administration can prevent or minimize these second-phase reactions.

Signs and Symptoms

Anaphylactic Shock

- Increased heart rate
- Decreased blood pressure
- Narrow pulse pressure
- Decreased CVP/RAP
- Decreased PCWP
- Decreased CO/cardiac index
- Decreased SVR/SVRI
- Decreased Svo_2
- Decreased urinary output
- Flushed skin that is warm to hot, with pruritis and hives
- Bronchoconstriction
- Laryngeal edema
- Angioedema
- Airway compromise

Differential Diagnosis

Anaphylactic Shock

- Allergic reaction (from a triggering substance such as a diagnostic agent, specific food, bite, sting, chemical agent, or medication [antibiotics, immunologic agents, anesthetics, anti-inflammatory agents, narcotics, and hormones]
- Massive anaphylactic reaction that occurs in minutes, or lesser reaction that occurs over hours or days

Transport Management

Anaphylactic Shock

- Administer oxygen.
- Maintain an adequate airway.
- Remove the allergen that caused the reaction.
- Administer epinephrine.
- If patient is taking beta-blockers, administer glucagon.
- Initiate fluid therapy early with normal saline to maintain an MAP of greater than 70 mm Hg or a systolic blood pressure of greater than 90 mm Hg.
- Administer vasopressor agents if crystalloid therapy is inadequate for maintaining CO.

- Consider other pharmacologic treatments: antihistamines, ranitidine (Zantac, an H_2 blocker), bronchodilators (such as albuterol, a beta 2–selective bronchodilator), and corticosteroids are other options.
- Perform cardiac monitoring.
- Observe for a possible second-phase reaction.

SIRS, Sepsis, and Septic Shock

The third form of distributive shock is called septic shock. Septic shock is a progressive disease that typically results from an infection. Septic shock usually starts with a localized infection and then develops into a widespread inflammatory process, more commonly referred to as systemic inflammatory response syndrome, or SIRS. When hypotension develops, septic shock is present. Infection is the leading cause of SIRS and septic shock. However, any shock state can cause the beginning of SIRS and lead to sepsis before reaching multiple organ failure. Sepsis is the leading cause of MODS. It is for this reason that more time is spent discussing the sepsis process.

Sepsis

The terminology associated with sepsis continues to evolve. In 1992, the American College of Chest Physicians and the Society of Critical Care Medicine published definitions for **systemic inflammatory response syndrome (SIRS)** and sepsis as a result of a consensus conference on sepsis and organ failure. This meeting established basic criteria for early recognition and diagnosis of SIRS. Another meeting in 2001 established new criteria to better diagnose and classify patients with sepsis-associated conditions in the hospital. Sepsis is defined as having SIRS with a known or highly suspected source of infection.

SIRS is defined as the widespread inflammatory process associated with infectious and noninfectious causes. Acute respiratory distress syndrome (ARDS), burns, pancreatitis, intestinal endotoxin, and major trauma are the most commonly identified triggers for the development of SIRS when there is no known microorganism involved. In 1992, a basic tool was created to identify minimum criteria for early recognition of SIRS **Table 9-10**. Four criteria are included: temperature, heart rate, respiratory rate, and white blood cell (WBC) count. To classify a patient with SIRS, a minimum of two markers need to be met. This basic tool has been used to identify this complex disease for more than a decade and continues to serve as a guideline for research in sepsis.

Sepsis is a mild systemic response to an infection or a suspected infection. The common language used to describe sepsis typically implies a bacterial infection. However, this is not necessarily true because 25% of patients with sepsis have no identifiable source of infection.

Severe sepsis is defined as sepsis with a confirmed or highly suspected diagnosis of infection and organ dysfunction of at least one organ. In severe sepsis, organ dysfunction is caused by hypoperfusion. Any organ may be involved; however, the lungs and the kidneys are typically affected first, with an incidence rate near 20%. At the 2001 International Sepsis Definition Conference, new terminology was created to better define and identify severe sepsis. Experts established the diagnostic criteria in **Table 9-11** incorporating the 1992 minimal diagnostic criteria for severe sepsis.

TABLE 9-10 Systemic Inflammatory Response Syndrome Criteria From the American College of Chest Physicians, 1992

Criteria	Marker

Temperature	> 38°C (100.4°F) < 36°C (96.8°F)
Respiratory rate	> 20 breaths/min $PaCO_2$ < 32 mm Hg
Pulse rate	> 90 beats/min
WBC count	> 12,000/μL < 4,000/μL > 10% immature band forms

Source: Reproduced with kind permission from Springer Science+Business Media: *Intensive Care Med*. 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference, vol. 29, 2003:530–538, Levy MM, et al. Used with permission of Dr. Mitchell Levy, Department of Medicine, Rhode Island Hospital.

Septic shock incorporates hemodynamic instability with SIRS and a confirmed or highly suspected source of infection that is unresponsive to fluid resuscitation. Hypotension is recognized as a systolic blood pressure (SBP) of less than 90 mm Hg, a drop in SBP by 40 mm Hg from baseline, or an MAP of less than 70 mm Hg. Hypotension associated with septic shock is unresponsive to standard fluid challenges of 20 mL/kg.

Sepsis may progress through septic shock and result in organ failure. When two or more organs fail, MODS develops. Once organs begin to shut down, there is a profound increase in mortality.

Epidemiology

The prevalence of sepsis-related infections is increasing. Martin et al identified a steady 13.7% annual increase in the number of sepsis cases between 1979 and 2000. However, the decade up to 2000 reported a 66.3% increase in the number of sepsis-related illnesses. By the year 2020, the Centers for Disease Control and Prevention estimates there will be 1.1 million new cases of sepsis in the United States, and numerous research articles confirm these predictions. These predictions mean that CCTPs will likely be involved with more cases of sepsis.

Sepsis affects all populations and age groups. Martin et al found sepsis to be most prevalent in nonwhite men between the ages of 57 and 70 years. A number of coexisting medical conditions have been associated with sepsis. These are listed in order of their prevalence: diabetes, hypertension, congestive heart failure, chronic obstructive pulmonary disease (COPD), cirrhosis, human immunodeficiency virus (HIV) infection, cancer, and pregnancy.

The mortality rate for sepsis alone is near 15%. However, the mortality rate increases significantly as the severity of sepsis increases. Severe sepsis, defined as infection with failure of at least one organ, is the leading cause of death in non–coronary intensive care units and the 10th leading cause of death in the United States.

TABLE 9-11 Diagnostic Criteria for Severe Sepsis

Variables	Criteria	Marker
General	Fever	Temperature > 38.3°C or 101°F
	Hypothermia	Temperature < 36°C or 96.8°F
	Pulse rate	> 90 beats/min or > 2 SDs above normal for age
	Tachypnea	Respiratory rate > 20 breaths/min
	Altered mental status	Confused, delirious, or changed from baseline mental status
	Significant edema	> 20 mL/kg of fluid in 24 h
	Hyperglycemia	Glucose > 120 mg/dL or 7.7 mmol/L
Inflammatory	Leukocytosis	WBC count > 12,000/μL
	Leukopenia	WBC count < 4,000/μL
	Normal WBC count with immature forms	> 10% immature forms
	Plasma C-reactive protein level	> 2 SDs above normal value
	Plasma procalcitonin level	> 2 SDs above normal value
Hemodynamic	Arterial hypotension	SBP < 90 mm Hg
		MAP < 70 mm Hg
		SBP decrease of > 40 mm Hg in adults or > 2 SDs below the normal range for age
	Svo_2	> 70%
	Cardiac index	> 3.5 L/min/m²
Organ dysfunction	Arterial hypoxemia	Pao_2/Fio_2 < 300
	Acute oliguria	Urinary output < 0.5 mL/kg/h × 2 h
	Creatinine level increase	> 0.5 mg/dL
	Coagulation abnormalities	INR > 1.5
		Activated partial thromboplastin time > 60 s
	Ileus	Absent bowel sounds
	Thrombocytopenia	Platelet count < 100 × 10^3/μL
	Hyperbilirubinemia	Total bilirubin > 4 mg/dL or 70 mmol/L
Tissue	Hyperlactatemia	> 2 mmol/L
	Delayed capillary refill	Mottling

Abbreviations: INR, international normalized ratio; MAP, mean arterial pressure; SBP, systolic blood pressure; SDs, standard deviations; WBC, white blood cell.

There are an estimated 751,000 cases of severe sepsis annually in the United States, with the mortality rate reported at 28.6%. This mortality rate translates to approximately 575 patient deaths daily as a result of severe sepsis in the United States alone. Statistics also indicate that with population adjustments, there will be an annualized increase in the incidence of 8%.

Despite the development of sophisticated technologies and advancements in medical therapies, sepsis remains a challenge to the medical community. Health care professionals must be aware of the many risk factors associated with severe sepsis to keep mortality rates low. The conditions that place people at greatest risk for developing sepsis are listed in **Table 9-12**. Also, prolonged hospitalization is a risk factor for sepsis for any person. The longer a patient is in the intensive care unit (ICU) (especially) or the hospital, the greater the risk for sepsis. Invasive procedures, comorbidities, and use of immunosuppressants increase this risk to even greater proportions.

TABLE 9-12 Risk Factors for Sepsis

Persons with a compromised immune system	Extremes of age: infants and elderly
	Cancer patients
	Transplant recipients
	HIV/AIDS patients
	Immunosuppressed patients

	Alcoholic patients Pregnancy
Chronic and coexisting diseases	Diabetes COPD Cirrhosis Heart failure Renal failure
Infections and exposures	Meningitis Community-acquired pneumonia Cellulitis Urinary tract infections Organisms with antimicrobial resistance
Critically ill patients	Increased use of invasive catheters and prosthetic devices Postoperative abdominal surgery

Pathophysiology

To understand the pathophysiology of sepsis, it is necessary to review some basic anatomy and physiology of the immune system. The immune system is frequently compared with a well-trained military force because it defends the body against attacks. It is one of the most complex and multifaceted systems in the body. Activation of the immune system elicits a cellmediated response through the production of T cells in the thymus gland and a humoral response through B lymphocytes in the plasma. These immune responses are typically classified into innate and adaptive. The **innate immune system** puts up the first line of defense. It poses a generalized, fast-acting response to **antigen** recognition. The **adaptive immune system** offers a precise response to specific antigens but requires more time to mobilize its defense if the pathogen is unknown. This subdivision is called adaptive because it relies on previous exposure to pathogens and lymphocyte memory cells. Memory cells remember specific antigens they have come in contact with, so when an antigen tries to invade again, the adaptive immune system can elicit a faster response. Each of these subdivisions has its own soldiers performing specific tasks. However, many of these soldiers work in the innate *and* adaptive subdivisions of the immune system. This dual function allows the attacks on pathogens to come from multiple directions while simultaneously enhancing the communication within the immune system.

Pathogens

The microorganisms responsible for activating the immune system are referred to as **pathogens**. Severe sepsis can occur as a result of infection at any body site, including the lungs, abdomen, skin, soft tissue, and urinary tract, and as a result of a primary bloodstream infection, such as in patients with meningococcemia. Bacteria are the pathogens most commonly associated with the development of sepsis, although fungi, viruses, and parasites can also cause sepsis. Each pathogen has identifiers on it called antigens. These antigens elicit an immune response within the body. A pathogen is recognized in the body when its antigen binds to special cells within the immune system. It is the responsibility of this system to classify the pathogen as a “self” antigen or a “nonself” antigen. Self antigens are sometimes referred to as normal flora. The body allows self antigens to reside in areas of the body where they will do little harm. These microorganisms live on the skin, in the nasal passages and respiratory tract, and in the digestive system, including the mouth and intestines. However, if the microorganisms start to colonize, they become

pathogens, and the body steps into action to destroy them.

Infectious agents may produce endotoxins and exotoxins that alter the living cells and ultimately destroy them. This is the primary way bacteria affect the immune system stimulus response and cause death. Endotoxins are proteins that are released by gram-negative bacteria when they die; exotoxins are proteins that are secreted by some bacteria and fungi to aid in the death and digestion of other cells.

When a pathogen is identified as nonself, the immune system is activated and a cascade of events begins. Gram-negative and gram-positive bacteria are the two most common organisms responsible for sepsis. The 2000 data from Martin et al identified that 52.1% of sepsis cases were from gram-positive organisms and 37.6% were from gram-negative bacteria. The remaining 10% are caused by other microorganisms, including anaerobes, viruses, and protozoa, and involve polymicrobial and fungal infections.

Infection

Infection is simply an invasion of a host by a pathogen or multiple pathogens. The body's first lines of defense against pathogens are its natural barriers. Typically, when an infection ensues, it is because a pathogen was able to penetrate the natural barriers of the human body. The skin, mucous membranes, and gastrointestinal tract are examples of natural barriers. They mitigate infection by inhibiting the entry of nonself pathogens into the body and by keeping a careful watch of the self antigens.

Isolated infections are confined to a small area, and the invading organisms are destroyed by cells within that location. The first response to a pathogen invasion requires the innate system to stimulate the inflammatory process. Julius Cohnheim, in the 19th century, observed three characteristic changes in the microcirculation (arterioles, capillaries, and venules) near the site of injury secondary to inflammation.

1. Blood vessels dilated, increasing blood flow to the area.
2. Vascular permeability increased, facilitating an influx of fluid and plasma cells (exudate) into the area.
3. Certain WBCs (**neutrophils**) adhered to the inner walls of vessels and then immigrated through vessel walls to the site of injury. When destroying the pathogen, these phagocytic cells cause the release of lytic enzymes, which are potent enough to damage healthy cells near the area of injury.

Inflammation occurs when chemical mediators, also called **cytokines**, are released from injured cells (the endothelium of the microcirculation) in response to tissue insult. Some of these cytokines include interleukins, **tumor necrosis factor (TNF)**, histamine, prostaglandins, and bradykinins. These chemicals cause vasodilation, smooth muscle contraction, increased tissue permeability, and pain **Table 9-13**. Inflammation is an important process because it helps contain the injury, allowing phagocytes and the complement system to clean up the area. Cytokine communicators also send out distress signals informing the body of injury. This signal alerts phagocytic troops, drawing neutrophils and macrophages to the front lines. When neutrophils arrive on the scene, they roll across the endothelium until they come in contact with selectin. This glycoprotein molecule is released from leukocytes (B and T cells) at the area of insult and assists the neutrophils in adhering to the endothelium. After adhesion, neutrophils begin immigrating through the endothelial wall to the site of injury, where they begin their phagocytic role.

TABLE 9-13 The Body's Response to Inflammatory Chemical Mediators

Inflammatory Chemical Mediator Action	Body Response
Vasodilation	Redness and heat production
Smooth muscle contraction	Difficulty breathing

Increased capillary permeability	Edema and swelling
Stimulation of pain receptors	Pain

B lymphocytes initiate an acute response when memory cells recognize the pathogen. If microorganisms are new to the body, helper T cells activate B cells to form antibodies and begin establishing a memory for the specific antigens. Recognition of antigens allows immunoglobulins (antibodies) to release more cytokines and activate the complement system. It is the responsibility of the complement system to assist the phagocytes by neutralizing the pathogen.

Vasodilation and increased capillary permeability activate the clotting pathways. Tissue factor is released, leading to the production of thrombin, a proinflammatory substance that initiates fibrin clot formation in the microvasculature. Fibrin is the final product of the coagulation cascade and is responsible for preventing the spread of infection by building a fibrin clot barrier wall.

Systemic Infection

Systemic infections activate a widespread inflammatory response throughout the body, completely overwhelming and theoretically confusing the immune system. SIRS, sepsis, severe sepsis, and septic shock are part of a dynamic hypermetabolic, hyperinflammatory response to an insult that grossly affects the endothelium. Three identifiable physiologic processes are involved with the development of microvascular abnormalities associated with severe sepsis:

1. Proinflammation
2. Procoagulation
3. Decreased fibrinolysis

Normal inflammatory modulators are disrupted in SIRS and sepsis. Tumor necrosis factors, interleukins 1 and 6, and other cytokines are key contributors to this disruption. Interleukins and TNF, which manifest themselves as fever, edema, and tissue hypoperfusion, are produced rapidly after insult or injury and continue to proliferate as the inflammatory process persists. These chemical mediators lead to activation of neutrophils while simultaneously inhibiting selectin, the protein that adheres neutrophils to the endothelium. As a result of selectin inhibition, neutrophils are neither able to adhere to nor cross through the endothelial wall to the affected areas. This creates neutrophil rolling, which disrupts the finely tuned immune response and leads to a systemic inflammatory response **Figure 9-9**.

The inflammatory process, in association with the complement cascade, damages the endothelium, causing small clots to form in the capillaries. These microclots occur in the tissues and organs, inhibiting cellular respiration and causing more cell damage. The body uses up its clotting factors and fibrinogen faster than the liver is able to produce them. When the imbalance between coagulation and fibrinolysis occurs, DIC results. As mentioned earlier, this is largely because of the coagulation and fibrinolysis processes that occur simultaneously in sepsis states. Stated more technically, in sepsis there is an imbalance between fibrin clot formation and fibrin clot breakdown or fibrinolysis. Clot formation starts as inflammatory cytokines (TNF-α and interleukin 6) stimulate tissue factor, the first step in the extrinsic pathway of coagulation. Tissue factor turns on the coagulation cascade that leads to the production of thrombin, a proinflammatory substance that promotes fibrin clot formation. Once activated, the coagulation system becomes self-sustaining without the need for tissue factor to stimulate clot formation. Normally, this protective mechanism would help wall off an infected area and promote healing. But in severe sepsis, it results in thrombosis and dangerous deposition of fibrin clots in small blood vessels throughout the body. In severe sepsis, microvascular thrombi impair blood flow to the distal tissues, inducing further tissue hypoperfusion and increasing hypoxia. On the opposite end of the spectrum, while thrombin is developing microclots, antithrombin is working to inactivate thrombin. Antithrombin is a

naturally occurring protein found in plasma that binds to thrombin, inhibiting clot formation. Thrombomodulin, found in the vascular endothelium, also works to bind thrombin. When thrombin is bound to thrombomodulin, protein C is activated. Activated protein C (APC) inactivates specific components of the clotting cascade, factors Va and VIIIa, and neutralizes plasminogen activator inhibitor-1 (PAI-1) **Figure 9-10**. However, during the sepsis process, there is a decrease in the amount of available antithrombin and functional APC. Proinflammatory cytokines, TNF, and interleukins shear thrombomodulin from the endothelial surface, thus preventing the activation of protein C. Studies show that adequate circulating levels of APC can directly inhibit the production of TNF and interleukins and reduce mortality rates from about 30% to almost 25%. Without APC and antithrombin to aid anticoagulation, the procoagulant processes go uninhibited. Therefore, coagulation continues to outweigh anticoagulation.

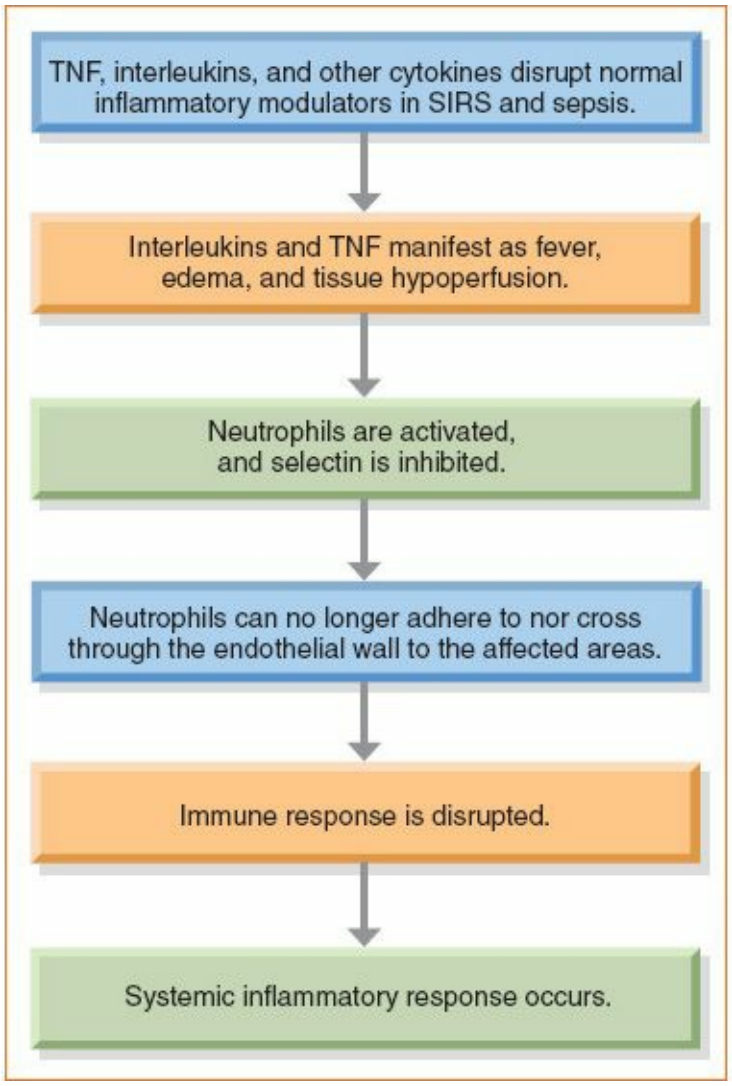

Figure 9-9 Summary of the process leading to a systemic inflammatory response.

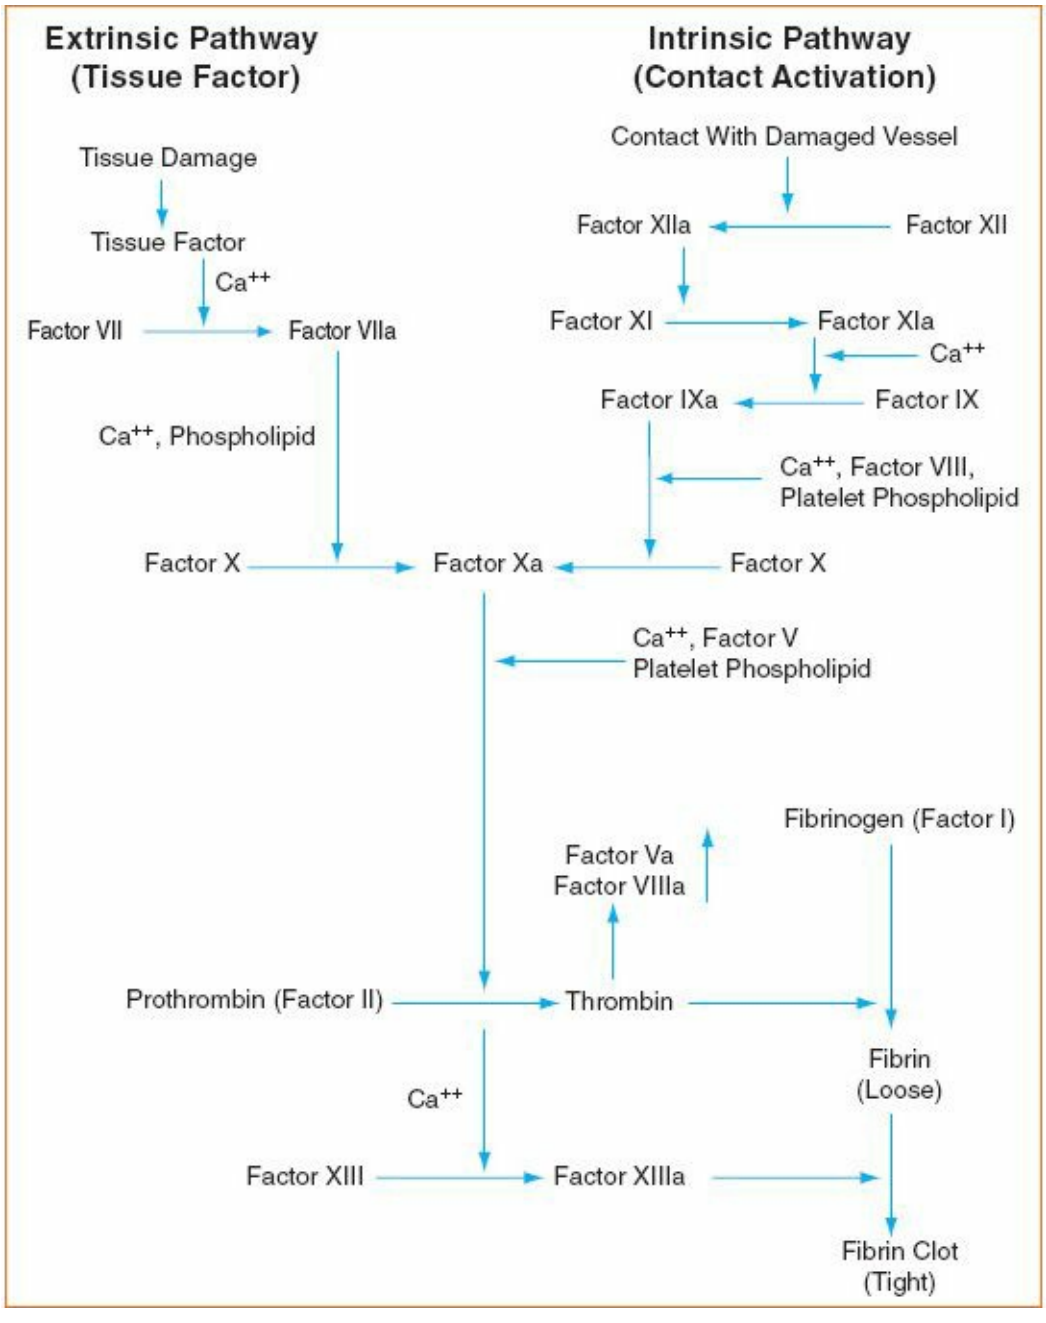

Figure 9-10 Coagulation cascade. Ca^{++} indicates the calcium ion.

In sepsis, there is also decreased fibrinolysis, the process of clot dissolution or lysis. Plasmin is the agent responsible for the breakdown in fibrin clots. Septic states alter the fibrinolytic process in two ways: First, plasmin is inactivated by antiplasmins. Second, PAI-1 is able to stop the conversion of plasminogen to plasmin in the extrinsic and intrinsic pathways. Elevated serum levels of PAI-1 have been correlated with high mortality rates in septic patients.

In summary, microvascular disruption and injury are responsible for hypoperfusion and the shunting of oxygen, resulting in decreased oxygen delivery to the tissues. The profound imbalance between oxygen delivery and consumption causes hypoxia within the cell and tissue. This complex cascade of events is the primary cause of severe sepsis and its progression to organ dysfunction and failure.

Figure 9-11 shows the coagulation imbalance during sepsis.

Assessment

Distributive shock caused by sepsis differs from other shock states in that it has two phases. Phase one is the **hyperdynamic state**, commonly referred to as warm shock. Phase two is the **hypodynamic state**,

commonly referred to as cold shock. The hyper-dynamic (warm) phase is characterized as a high-cardiac-output state that may last for hours or days. This phase may progress to hypodynamic (cold) shock when the patient's condition rapidly deteriorates and there is a sudden drop in cardiac output. The prognosis is much better in hyperdynamic shock than in hypodynamic shock.

The first priority in recognizing sepsis is to maintain a high index of suspicion for the disorder. A thorough patient history correlated with patient presentation can ensure early identification and intervention to break the progression of the sepsis process. Also, infection does not need to be present for sepsis to be present. In fact, in half the documented severe sepsis (SIRS) cases, an infectious cause was not identified. Specimen cultures are obtained from the blood, urine, sputum, and any drainage site to assist in identifying the causative organism. If the pathogen is bacterial, the WBC count is typically elevated and associated with immature neutrophils or bands. Once the pathogen is identified, more direct antimicrobial therapy can be initiated.

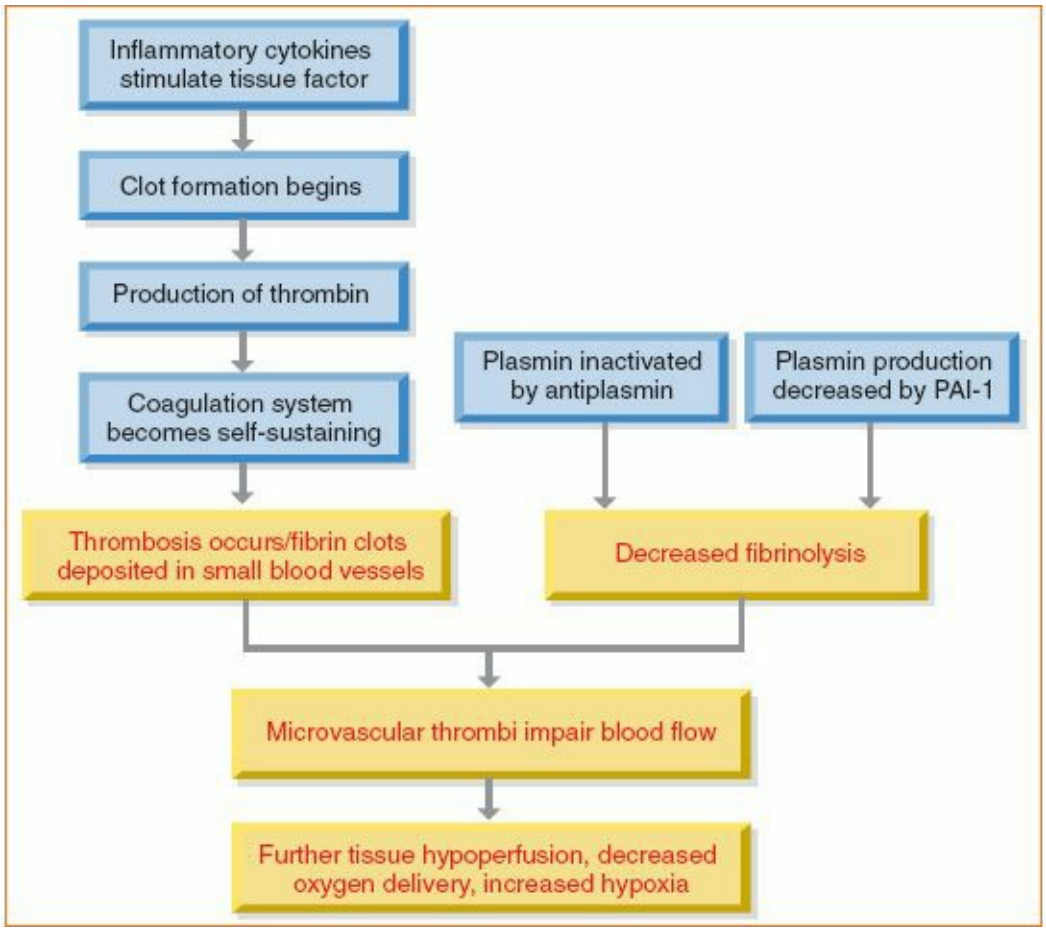

Figure 9-11 The imbalance between coagulation and fibrinolysis in sepsis results in hypoperfusion, decreased oxygen delivery, and increased hypoxia. Abnormal steps and processes are shown in red.

Many health care providers associate infection with fever. Fever is one clinical sign of infection, but it may not be present in geriatric, newborn, and infant populations; patients with chronic renal failure; and patients receiving steroids or other anti-inflammatory drugs. Hypothermia is present in about 10% of SIRS cases and is associated with a poor prognosis.

The cardiovascular and respiratory organs are the hardest hit in severe sepsis and septic shock. Cardiovascular changes result from the inflammatory process of sepsis. The massive vasodilation significantly lowers the SVR. In return, the heart increases CO. Cardiac output is extremely elevated in sepsis states. To produce this high-output state, the heart rate becomes tachycardic, and the stroke volume increases. Initially, normal to low-normal blood pressure is maintained. Skin color and mucous membranes appear normal because of the vasodilation with associated high CO. However, the skin

typically feels warm to the touch as the result of fever. Once hypotension ensues, the patient is in septic shock. Septic shock is refractory to fluid challenges and, therefore, vasoactive agents must be initiated. This is also the progression from hyperdynamic shock into hypodynamic shock. Hypodynamic shock gets its name from the low-cardiac-output state. Patients are hypovolemic in this phase, and their condition rapidly deteriorates as evidenced by low blood pressure, decreased pulse pressure, and low CO. Skin color and temperature change in hypodynamic shock. The patient becomes cold and clammy with pallor or cyanosis. In patients with DIC, petechiae may appear, and blood may ooze from mucous membranes, including the nose and mouth, and from any place where invasive procedures were necessary, including IV sites, indwelling urinary catheters, and chest tubes. Diagnostic patterns in hypodynamic septic shock reveal low levels of hemoglobin, fibrinogen, and platelets and a low hematocrit value. Thrombocytopenia (low platelet count) is an early indicator of progressing DIC and the development of MODS. Prolonged prothrombin time and an elevated D-dimer level are present in more than 90% of severe sepsis cases and, therefore, are a beneficial diagnostic tool. The D-dimer level is monitored throughout the course of sepsis to evaluate the effectiveness of treatment. Levels returning to normal indicate that treatment is working.

The respiratory system also manifests changes. In hyperdynamic septic shock, the respiratory rate increases along with the depth of respiration, leading to respiratory alkalosis. As shock progresses to the hypodynamic phase, ARDS develops, which is a complication of SIRS. Oxygen free radicals are small unpaired electrons that lie in the outer shell of the oxygen molecule and result from the breakdown of the covalent bond between two molecules. When this occurs, each molecule has an unpaired electron within its outer shell that becomes highly reactive. Owing to their reactiveness, the oxygen free radicals damage lung tissue. This damage results from a combined effort of increased oxygen free radicals released in SIRS and from the high percentage of oxygen that must be delivered to enhance oxygen delivery to the cells. Mechanical ventilatory support is needed in sepsis states associated with ARDS. When mechanical ventilatory therapy is initiated, it is important to maintain low tidal volumes at 6 mL/kg, while keeping end-inspiratory plateau pressures lower than 30 cm H_2O. End-inspiratory plateau pressures should also be monitored closely. Studies also show that the positive end-expiratory pressure (PEEP) should be maintained below 14 cm H_2O because higher settings do not change outcomes. Mild **hypercapnia** is allowed in patients with sepsis who have acute lung injury (ALI) or ARDS as long as low tidal volumes and pressure limits are controlled. The FIO_2 will need to be titrated, usually to less than 60%. Therapy goals should be an SpO_2 of greater than 92%. A CCTP may also see higher-than-average end-tidal carbon dioxide readings in patients with severe sepsis.

ALI and ARDS are defined as the following:

- Acute onset of respiratory failure
- Diffuse bilateral infiltrates evident on chest radiography
- Absence of left atrial hypertension (PCWP < 18 mm Hg) or no clinical evidence of left atrial hypertension
- Hypoxemia, defined as PaO_2/SaO_2 of 300 or less for ALI or PaO_2/SaO_2 of 200 or less for ARDS

Hyperlactatemia (> 36 mg/dL) is common in patients with severe sepsis or septic shock. Research has shown that serum lactate levels rise early as a result of anaerobic metabolism, even before hypotension develops. This happens because endotoxins cause the abdominal tissue to shunt blood away from the splanchnic (spleen) tissue while initially not affecting the muscular microvasculature.

Table 9-14 lists sepsis lab abnormalities.

TABLE 9-14 Sepsis Lab Abnormalities

Specimen cultures obtained from the blood, urine, sputum, and any drainage site to identify the causative organism
Elevated WBC count (if the pathogen is bacterial) associated with immature neutrophils or bands
Low hemoglobin level and hematocrit value
Low fibrinogen levels
Thrombocytopenia
Prolonged prothrombin time
Elevated D-dimer level
Hyperlactatemia (> 36 mg/dL)

Signs and Symptoms

Sepsis

- Distributive shock (beginning with hyperdynamic [warm] shock, progressing to hypodynamic [cold] shock)
- Infection confirmed or highly suspicious
- Fever may or may not be present
- Hypothermia may be present in later stages
- Cardiovascular changes
- Significantly lowered SVR
- Tachycardia
- Normal to low-normal blood pressure initially; hypotension once in septic shock
- Normal skin color, normal mucous membrane color, but warm skin initially
- Cold, clammy skin with pallor or cyanosis when sepsis is more progressed
- Petechiae
- Blood oozing from mucous membranes and procedure sites
- Decreased pulse pressure
- Increased respiratory rate
- Increased respiratory depth
- Respiratory alkalosis
- ARDS

Transport Management

Sepsis

- Maintain the following:
  - MAP greater than 70 mm Hg or systolic blood pressure greater than 90 mm Hg;
  - SvO_2 greater than 70%;
  - CVP of 8 to 12 mm Hg;

  - Urine output greater than 0.5 mL/kg/h;
  - SaO_2 greater than 93%; and
  - Cardiac index of 2.5 to 4.0 L/min/m^2.
- Administer oxygen.
- Provide fluid resuscitation (isotonic crystalloids in 20-mL/kg [500–1,000 mL of fluid] increments to stabilize filling pressures).
- Consider colloid therapy.
- Administer vasoactive agents if two 20-mL/kg fluid challenges are inadequate to maintain blood pressure.
- Monitor D-dimer level.
- Provide mechanical ventilatory support if patient has ARDS.
  - Maintain low tidal volumes at 6 mL/kg.
  - Provide high PEEP at ranges of 5 to 14 cm H_2O. The PEEP is increased as the need arises for higher oxygen saturation.
  - Make FIO_2 adjustments for oxygen saturation as needed.
  - Maintain PaO_2 between 55 and 80 mm Hg or SaO_2 between 88% and 95%.
  - Keep end-inspiratory plateau pressures lower than 30 cm H_2O.
  - Monitor $PaCO_2$ closely.
  - The oxygen saturation goal is greater than 92%.
  - Sedation, if needed, must be monitored closely.
- Give antibiotic therapy as ordered.
- Remove potential sources of infection: wound debridement, abscess drainage, and device removal.
- Consider administration of a corticosteroid or recombinant human APC.

Management

Early recognition and early management are vital for a positive patient outcome. Early goal-directed therapy has shown a significant reduction in mortality rates. The primary goal of sepsis treatment is to maintain organ perfusion while enhancing tissue oxygenation. Achieving this requires balancing preload, afterload, and contractility to achieve an optimal level of homeostasis. Target criteria for maintenance levels have been established as follows:

1. MAP greater than 70 mm Hg or systolic blood pressure greater than 90 mm Hg
2. SvO_2 greater than 70%
3. CVP of 8 to 12 mm Hg
4. Urine output greater than 0.5 mL/kg/h
5. SaO_2 greater than 93%
6. Cardiac index of 2.5 to 4.0 L/min/m^2

Figure 9-12 shows an algorithm for the treatment of sepsis.

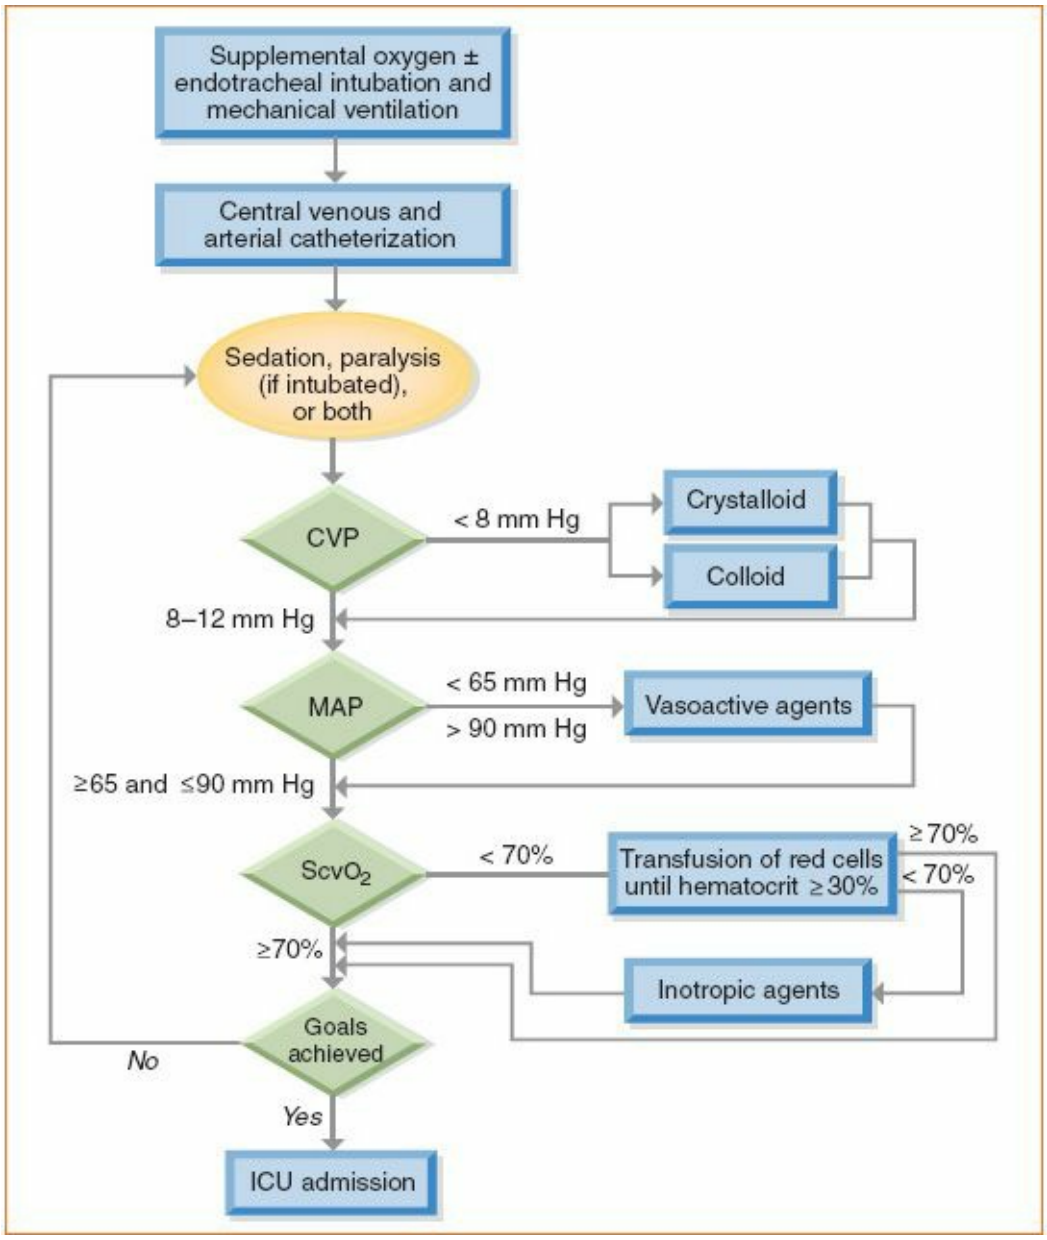

Figure 9-12 Protocol for early goal-directed therapy for sepsis. $ScvO_2$ denotes central venous oxygen saturation. *Source:* Rivers E, Nguyen B, Havstad S, et al. Early goal-directed therapy in the treatment of severe sepsis and septic shock. *N Engl J Med*. 2001;345(19):1371.

Fluid Resuscitation

The components of CO are preload, afterload, and contractility. Initial resuscitation includes volume expansion to optimize CO. Isotonic crystalloids in 20-mL/kg (500-1,000 mL of fluid) increments are used to stabilize filling pressures. When hemodynamic monitoring is performed, this translates to a CVP of 8 to 12 mm Hg with an MAP of greater than 65 mm Hg. Large volumes of crystalloids may be necessary to maintain blood pressure and CVP. If signs of fluid overload develop, colloid therapy may be initiated along with IV fluid. However, the use of colloids shows no significant improvement in outcome when compared with the use of crystalloids. The appeal for colloid use is the reduction in volume required to maintain hemodynamic stability: 1 L of normal saline (crystalloid) adds 275 mL to the vascular volume, whereas 1 L of 5% albumin (colloid) yields a 500-mL increase. The infusion of packed red blood cells should be considered if the hemoglobin level drops below 7.0 g/dL.

Vasopressor and Inotropic Support

Fluid therapy is not always sufficient to maintain blood pressure. Vasopressors should be started if two 20-mL/kg fluid challenges are inadequate for maintaining blood pressure. **Table 9-15** lists vasoactive agents and their doses, actions, and hemodynamic and adverse effects.

Norepinephrine and dopamine are the vasopressors of choice in hypotensive patients with sepsis. Dopamine may stimulate dopaminergic receptors, or beta 1– or alpha 1–adrenergic receptors, depending on the dose. Sepsis cases require stimulation of alpha 1–and beta 1–adrenergic mechanisms to improve MAP. This stimulation requires IV infusion rates between 5 and 30 µg/kg/min. The beta-adrenergic properties of dopamine will increase contractility but will simultaneously increase heart rate. The increase in heart rate is not a desired effect in sepsis because it increases metabolic demands on the heart. Low-dose dopamine to stimulate renal output has been ineffective in patients with severe sepsis and, therefore, is not used in treatment.

Norepinephrine, a sympathomimetic, acts directly on alpha-adrenergic receptors in the smooth muscle of blood vessels to rapidly increase blood pressure. Norepinephrine also stimulates beta-adrenergic receptors that work to increase cardiac output through increased contractility. Another way norepinephrine has proven itself as a treatment for sepsis is its minimal increase of the heart rate when compared with dopamine. Norepinephrine is typically started at 2 µg/kg/min and titrated to a desired MAP of greater than 65 mm Hg. In some cases, the initial dose may be as high as 10 µg/kg/min until the blood pressure stabilizes. Maintenance doses are typically between 2 and 4 µg/kg/min.

Dobutamine is an inotropic agent that has been very beneficial in treating cardiac depression associated with sepsis. This inotropic agent increases cardiac contractility through its selective beta 1–adrenergic properties. Dobutamine is especially useful when used in conjunction with norepinephrine. The heart rate is usually not significantly affected. An IV infusion typically starts at 2.5 µg/kg/min and may be titrated to as high as 40 µg/kg/min. When titrating dobutamine, it is important to monitor MAP, SvO_2, and the CO or cardiac index to establish adequate treatment therapies.

Other vasopressors that may be used in the treatment of severe sepsis include phenylephrine, epinephrine, and vasopressin. The pure alpha-adrenergic properties of phenylephrine increase blood pressure significantly without affecting the heart rate. However, vasoconstriction within the visceral tissue and mesentery may increase lactic acidosis, furthering the hypoxic state in sepsis. Phenylephrine may be a good choice when tachyarrhythmias limit therapy with other vasopressors.

Epinephrine is a nonselective adrenergic activator, meaning it stimulates alpha-1, beta-1, and beta-2 receptors. Epinephrine increases MAP by increasing the cardiac index, stroke volume, SVR, and heart rate. Like phenylephrine, epinephrine must be used cautiously in sepsis because of its vasoconstrictive effects in the abdominal compartment. Administration of this agent is associated with an increase in systemic and regional lactate concentrations. Other undesirable effects include the potential to produce myocardial ischemia and the development of arrhythmias. The use of epinephrine as a single agent is not recommended for patients with septic shock. The use of epinephrine is recommended only for patients who are unresponsive to traditional agents.

Vasopressin may be administered if hypotension is refractory to other therapy. The mechanism of action in vasopressin differs from that of other pressor agents. Vasopressin works as a vasoconstrictor but

has no inotropic or chronotropic effects. Therefore, CO may decrease, resulting in decreased blood to the spleen. For this reason, vasopressin is never used alone or is used when the patient has a cardiac index of less than 2 L/min/m^2.

Septic patients with an elevated blood pressure may require afterload reduction. Nitroglycerin infusions at 5 to 60 μg/min can be used to reduce afterload and preload on the stressed heart.

Infection Control

Antibiotic therapy is initiated with broad-spectrum antibiotics. When specific microorganisms are identified by culture, antibiotic therapy will become more specific to the pathogen. Antibiotic therapy should begin within the first hour of suspecting sepsis to minimize mortality.

Infection control also requires therapy to remove potential sources, such as special interventions for wound debridement, abscess drainage, or device removal. Identifying and removing the potential source of infection is key to treating and lowering mortality in sepsis.

Immune-Specific Therapy

Corticosteroids

Glucocorticoid steroids are used in septic shock when hypotension requires the use of vasopressive agents. In severe sepsis, corticosteroid production drops and relative adrenocortical insufficiency develops. Studies indicate that 56% to 77% of mechanically ventilated patients with septic shock requiring vasopressors have this disorder. Low-dose glucocorticoid or mineralocorticoid therapy is used in selected patients based on serum measurements of endogenous cortisol levels or adrenocorticotropic hormone stimulation tests. Baseline data for cortisol levels or the adrenocorticotropic hormone stimulation test must be obtained before treatment begins. The goal of replacement therapy is to achieve the same physiologic level of glucocorticoids in the blood that would be present under normal conditions. Research studies on the effectiveness of corticosteroids continue. To date, treatment with hydrocortisone, 50 mg IV every 6 hours, and fludrocortisone, 50 μg orally once daily for 7 days, has been effective in treating septic shock.

Recombinant Human Activated Protein C

Drotrecogin alfa (activated) is a relatively new pharmacologic agent used in the treatment of severe sepsis. Tertiary and research centers are more likely to administer this medication than are primary facilities. For this reason, interfacility transport personnel are less likely to see this agent than others. However, this medicine is worth mentioning because research is showing that drotrecogin alfa (activated) is very beneficial for reducing mortality in patients with severe sepsis and corresponding organ failure. The pharmacokinetics of drotrecogin alfa (activated) include anti-inflammatory, anticoagulant, and profibrinolytic properties. There have been multiple studies on early use of recombinant human APC. The Surviving Sepsis Campaign Guidelines of 2008 state that it may have a probable reduction in mortality for patients with the following:

- Multiple organ failure
- Clinical assessment of high risk of death (APACHE [Acute Physiology and Chronic Health Evaluation] score of > 25)

The APACHE score is an in-hospital disease scoring system for adults in the ICU that is based on 12 physiologic measurements during the first 24 hours after ICU admission and other health information.

Blood Administration

Blood administration can be a part of managing shock, as discussed in the previous section. The decision

to give a transfusion to a patient during a critical care transport is more complex than the administration of blood in the hospital setting. The urgency of the transfusion, the "out-of-hospital" time, the availability of the blood products, **type-and-crossmatch** information, and the appropriate transport and care of the blood product must be considered. The risk-benefit analysis of the "right treatment for the right patient at the right time" must be determined.

Blood administration may be required to restore circulating blood volume, improve oxygen-carrying needs, or correct specific coagulation components. It can be in the form of whole blood, red blood cells, white blood cells, platelets, cryoprecipitate, or other blood products. It is uncommon to transfuse whole blood currently owing to the expense, uncommon availability, and the possibility of volume overload during whole blood administration. The need to consider blood administration includes hemorrhagic blood loss as a result of trauma, internal hemorrhage, perioperative and postoperative complications, specific disease entities such as leukemia or other cancers, anemia due to illness, or coagulation disorders.

Many CCT programs carry type O blood for field pickups or will take matched blood with the patient from outlying hospitals; however, the availability of blood products from rural health care settings may be vital in the decision about blood administration. Rural hospitals may have a limited supply of banked blood products, especially of certain blood types and specific blood products required by a critically ill patient. Such limitations alter the desired treatment of the patient.

Time becomes a factor in the transport decisions surrounding a critically ill or injured patient. Awaiting the availability of certain blood products may lengthen the time to definitive care at a tertiary care center; it may be more important to transport the patient urgently than to perform the transfusion. The decision must consider the out-of-hospital time for the patient. For example, if it would take 15 minutes to obtain the needed blood products, but the total transport time would be 20 minutes, it would likely be prudent to transport the patient and forgo the transfusion until the patient is at the receiving facility. If the patient can tolerate the transport without the en-route transfusion, the decision to defer blood administration until arrival at the receiving hospital may be in the best interest of the patient.

Blood administration can result in undesirable complications such as transfusion reactions. Complications of this nature are best handled in the controlled environment of a hospital setting and may be difficult to address adequately during transport. Management of transfusion reactions is covered later in this section.

The transfusion of blood or blood products is a form of human tissue transplantation and, therefore, some states regulate who may initiate blood transfusions. Many state or institution blood bank regulations require two licensed personnel to check blood for proper match of the blood unit to the patient. Each unit is treated as a new transfusion, not the continuation of the previous unit.

Care of the blood products must be considered if the transfusion is not initiated before transport. The specific container and ice provided by the sending facility's blood bank must be used to ensure that the quality of the blood product is maintained. Care must be taken to ensure the blood products stay cold throughout transport. Bags of ice are placed in an insulated ice box with ice beneath and on top of the blood products when transporting whole blood, packed red blood cells, or platelets. Care must be taken to prevent the ice from melting. This includes placing the ice box in a cool area and away from direct sunlight during transport. Fresh-frozen plasma and cryoprecipitate are thawed by the blood bank under specific guidelines. After thawing, fresh-frozen plasma must be transfused within a 24-hour period and cryoprecipitate must be transfused within a 6-hour period. Blood products are best stored in a refrigerator specially designed to store blood, with strict temperature regulations and consistently monitored temperature recording systems with required alarm systems in case the refrigerator fails to maintain the temperature settings. The extensive requirements for proper storage of banked blood products allow for little tolerance of deviation when blood administration occurs outside the hospital setting. Consequently,

the inability to adhere to the stringent care, storage, and temperature monitoring of blood products during transport results in refusal and waste of transferred blood products by the receiving facility's blood bank. If blood products may be needed during transport, but it is not certain whether they will be administered, the decision to transport the blood should be made with caution. In this circumstance, the receiving facility's blood bank will most likely destroy blood products that have been removed from a blood bank and transferred to another blood bank for acceptance. Policies in many institutions forbid the acceptance of transferred blood products from outside blood banks. The possible wasting of a scarce resource, such as blood products, may be important in the decision to transport blood products that may not be absolutely necessary for a patient during transport.

The final consideration is that blood administration requires a skilled health care provider with knowledge and experience in blood product administrations. Therefore, the expertise of the CCTP, medical direction, and prevailing medical protocol may further influence the decision to transfuse blood products during transport.

Once the decision to administer blood products has been made, the steps to proper blood administration must be followed. These include appropriate typing and crossmatching through laboratory analysis. An exception to the required crossmatching of the patient before transfusion may occur during emergency resuscitation for hemorrhagic shock when type O, Rh negative, known as the universal donor type, may be administered owing to the urgency of blood replacement surpassing the time necessary for typing and crossmatching the patient before transfusion. The appropriate IV access, blood tubing administration sets, priming of the tubing with normal saline, validation of the blood product's match with the specific patient before administration, and continued supervision by a skilled health care provider are required **Figure 9-13**.

ABO System

Blood transfusions became possible in the early 1900s after discovery of the A, B, O, and AB blood types. The first blood bank was founded in the United States in 1937. The use of whole blood and plasma was prevalent during World War II. The introduction of plastic blood storage containers and apheresis instruments allowed for the creation of blood component therapy options. The use of blood component therapy gained acceptance and surpassed the use of whole blood by the 1970s and remains the most common transfusion option today.

Blood contains a variety of antigens, with more than 400 red blood cell antigens identified. These antigens influence the compatibility of blood between individuals. Three types of blood antigens are considered, including the ABO blood group, Rh factor, and the human leukocyte antigen blood group. The crossmatch laboratory testing considers these antigen group characteristics. Identification and compatibility of ABO grouping is the most important step in the type and crossmatch process. Incompatibility at this step may cause the most severe transfusion reaction, known as acute **hemolysis**.

The ABO method of blood typing identifies two antigens on a red blood cell, known as A and B. If a person has only an A antigen identified, that person is type A. A person who has only a B antigen identified is type B. If both A and B antigens are identified, the person is type AB. When neither an A nor B antigen is identified, the blood type is O. The most common blood types in the United States are A and O, with 85% of the population falling within these two blood types. Type O is the most common blood type. Type B is found in 10% of the US population, with type AB noted in only 5% of the population.

Figure 9-13 Proper procedures for blood administration include appropriate IV access, appropriate blood tubing administration sets, priming of the tubing with normal saline, validation of the blood product's match with the specific patient before administration, and continued supervision by a skilled health care provider.

A blood transfusion reaction may occur when a patient possesses antigens to a blood type and receives that blood type. **ABO-incompatible transfusion reactions** contribute to approximately 25 deaths per year as a result of the misidentification of crossmatch samples or recipients. A patient with A antigens in his or her blood also has anti-B antibodies in his or her plasma. A patient with B antigens in his or her blood also has anti-A antibodies in his or her plasma. Transfusion reactions may occur if patients receive a blood type for which they have antibodies.

People who have type AB blood do not have antibodies and are known as **universal recipients**. They can receive blood types A, B, AB, and O without the threat of an ABO reaction. People who have type O blood are considered **universal donors** because their blood can be transfused into patients with types A, B, and AB blood. However, people with type O blood have antibodies to blood types A and B and can, therefore, only receive type O blood.

Patients should receive transfusions of their own blood type to minimize possible transfusion reactions. In an emergency situation in which the time necessary for crossmatching of blood cannot be taken, type O, Rh-negative blood, or plasma can be transfused until crossmatched blood becomes available.

Rh factors are antigens found on the cell membrane of red blood cells. These antigens are present in approximately 85% of the US population and are considered Rh positive. People lacking the Rh antigen are termed Rh negative. There are no natural Rh antibodies. An Rh-negative person may develop an Rh antibody if exposed to Rh-positive blood. This first exposure to Rh-positive blood allows a person to become sensitized. A second Rh-positive exposure could result in a fatal hemolytic reaction. This type of

reaction may occur during a transfusion or pregnancy.

Human leukocyte antigen (HLA) is present on the cell membrane surface of circulating platelets, white blood cells, and most tissue cells. Patients receiving platelets from multiple donors may experience febrile transfusion reactions as a result of HLA. This type of reaction causes an antigen-antibody reaction that destroys the platelets, reducing the benefit of the transfusion. HLA-matched platelet transfusions dramatically diminish this antigen-antibody reaction and are optimal for patients receiving multiple transfusions.

Blood Products

Blood component therapy has become common in the United States, with more than 22 million transfusions each year. A great number of these transfusions occur in surgical and obstetric patients. These transfusions are considered beneficial for increased tissue oxygenation, decreased blood loss, and improved clinical outcomes. The risks and costs of transfusions must always be considered. Transfusion reactions and the transmission of multiple infectious diseases must be factored into any decision to transfuse blood products. The seven blood components are discussed next.

Blood Components and Derivatives

Whole Blood

Whole blood contains all blood components, including red blood cells, white blood cells, platelets, plasma, and electrolytes. The usual volume is approximately 450 to 500 mL/U. Transfusion involving the use of whole blood is uncommon and indicated only in acute massive blood loss for blood volume expansion and increased oxygen-carrying capacity. Whole-blood transfusions should only be considered when patients have lost at least 25% of their total blood volume. Whenever possible, blood loss should be treated with options other than whole blood and should include blood components, crystalloids, or colloid solutions. Administration of whole blood may cause fluid volume overload in patients with cardiac compromise. Also, whole blood begins to degrade after 24 hours of storage. This cell breakdown causes elevated potassium levels, the formation of microaggregates, damaged platelets and granulocytes, and decreased clotting factors. Whole-blood transfusions must be ABO matched with the recipient as a result of the presence of antibodies. Hemoglobin levels should rise 1 g/dL per infusion of each unit of whole blood. Whole blood is stored at a temperature between 1°C and 6°C (34°F and 43°F). The expiration depends on the anticoagulant preservative. Administration should be delivered as rapidly as possible while maintaining hemodynamic stability. If necessary, multiple large-bore (14- or 16-gauge) catheters can be used to administer multiple units of blood simultaneously. The use of pressure bags or rapid infusion devices may be applied to enhance the flow of the transfusion under emergent resuscitation conditions. Whole blood may be administered through an IV catheter as small as 20 gauge, with normal saline solution, and within a 4-hour period. Close monitoring of the patient during infusion for possible fluid volume overload and transfusion reactions is essential.

Special Populations

Pediatric patients have proportionately higher blood and plasma volumes compared to adults. Transfusion of packed red blood cells is calculated by weight. Children younger than 4 months are initially given 10 mL/kg of PRBCs, whereas children 4 months of age or older can be transfused with 10 to 20 mL/kg depending on lab values and clinical condition. Increased attention to volume overload during blood product administration is particularly important in the pediatric population.

Packed Red Blood Cells

Packed red blood cells (PRBCs) retain all of the characteristics of whole blood with the exception of the extraction of approximately 250 mL of platelet-rich plasma from each unit of whole blood. This constitutes the removal of nearly 90% of the fluid around the RBCs. An anticoagulant preservative is then added. Each unit of PRBCs retains the same concentration of RBCs as a unit of whole blood. One unit of PRBCs is approximately 250 mL and is indicated in the restoration and maintenance of the oxygen-carrying quality of the blood. Anemia and blood loss are possible indications for PRBC administration. A patient's hemoglobin level is expected to raise 1 g/dL per unit of administered PRBCs. PRBCs have nearly 70% of the leukocytes removed from each unit, thus reducing the risk for febrile, nonhemolytic reactions. Proper ABO compatibility and Rh factor matching are required prior to administration.

Platelets

Platelets are blood components developed in the bone marrow and consist of cytoplasmic fragments that contain enzymes necessary for normal clotting response. In the United States, more than 7 million units of platelets are transfused annually. Indications for platelet transfusions include patients who are bleeding because of thrombocytopenia or, in rare cases, the presence of abnormally functioning platelets. Patients experiencing low platelet counts below 5,000 to 10,000/μL may benefit from platelet transfusions on a prophylactic basis. Platelet therapy may also be considered prior to surgery or extensive invasive procedures in those patients with platelet levels below 50,000/μL. Situations that involve chemotherapy, disseminated intravascular coagulation, and massive transfusion may require platelet therapy considerations. ABO identical platelets are ideal whenever available, with Rh-negative platelets matched to Rh-negative patients as frequently as possible for transfusion. If a patient must receive multiple transfusions of platelets, single-donor platelets should be administered. Each bag of platelet concentrate contains 5.5 × 1010 of platelets in 50 to 70 mL of plasma. A single unit raises the platelet count by 5,000/μL. Calculation for dosing of platelet therapy is 6 to 10 U and 1 U/10 kg of body weight.

Administration of platelets requires a filtered component IV drip set with normal saline solution. Premedication of the patient prior to transfusion may include antihistamines or acetaminophen to reduce or prevent chills, fever, and allergic reactions.

Fresh-Frozen Plasma

Fresh-frozen plasma (FFP) is uncoagulated plasma separated from the RBCs. This plasma is primarily composed of water, proteins, salts, and metabolites, and is rich in clotting factors. Annually, approximately 2 million units of FFP are transfused in the United States. Indications for the administration of FFP may include blood loss, coagulation deficiencies, warfarin reversal, and thrombotic thrombocytopenic purpura. Transfusions must be ABO compatible; Rh matching is not required. Blood administration sets and normal saline solution are required for rapid infusion. The citric acid preservative in FFP may bind with calcium during transfusion and can lead to hypocalcemia. Close patient monitoring for hypocalcemia is required during transfusion. FFP must be infused within 24 hours of being thawed.

Cryoprecipitate

Cryoprecipitate is a frozen blood product created from the plasma of a donor. It contains factor VIII, fibrinogen, von Willebrand factor, and factor XIII; it follows that indications for administering cryoprecipitate include hemophilia A, fibrinogen deficiency, von Willebrand's disease, and factor XIII deficiency. Cryoprecipitate is useful in treating patients with clotting disorders, because it replaces fibrinogen. It is typically given to patients with fibrinogen levels of less than 50 to 60 mg/dL. Each bag contains 80 to 100 U of factor VIII. As many as 10 U of cryoprecipitate may be needed to restore the fibrinogen level to 100 mg/dL. Administration of cryoprecipitate does not require compatibility testing,

but ABO compatibility is preferred. An Rh match is not necessary. A blood administration set can be used for infusion, and cryoprecipitate should be administered as rapidly as tolerated. Cryoprecipitate must be administered within 6 hours of thawing. Whole blood donor requirements and the preparation for cryoprecipitate are the same as those for platelets and FFP.

Albumin

Albumin is prepared by the fractionation of pooled plasma. Albumin is available as a 5% or 25% solution and is used for volume replacement in conditions such as burns, trauma, surgery, or infections. The addition of albumin to enhance diuresis in hypoproteinemia is of value. The 25% solution will produce five times its volume from extravascular water into the vascular space. It is important that patients receiving 25% albumin have adequate extravascular water and the compensatory abilities to handle this blood volume expansion.

ABO and Rh compatibility are not a consideration with albumin products. The manufacturer-provided administration tubing should be used for albumin administration, and the infusion rate should be set in accordance with the patient's condition and response. Patients with cardiac and pulmonary disease must be monitored closely during albumin administration because the possibility of heart failure from volume overload.

Plasma Protein Fractions

Plasma protein fraction contains 83% albumin and 17% globulins. Plasma protein fraction is available in a 5% preparation and is indicated for volume expansion in patients with hypovolemia and hypoproteinemia. Clinical settings for the administration of plasma protein fraction may include shock and burn patients. Plasma protein fraction is available in 250-mL containers and can be stored for 5 years at 2°C to 10°C. No transmission of human immunodeficiency virus or hepatitis has been reported with this product.

Synthetic Blood Substitutes

The quest for synthetic substitutes for blood transfusions has been ongoing for the past decade. One promising product known as PolyHeme remains in trial studies with the Food and Drug Administration. PolyHeme is a solution of human hemoglobin extracted from modified RBCs. The product is derived from expired human blood from which the hemoglobin is extracted and purified. The need for ABO antigens, crossmatching, or patient blood typing is not necessary because PolyHeme does not contain intact RBCs. This product can be stored at room temperature for 1 year. This shelf life, when compared with traditional blood products, allows greater versatility in storage locations, making it rapidly available for emergency situations and combat casualties. The processing of this product diminishes the likelihood of viral infection transmission compared with traditional banked blood products and remains an additional benefit to the potential use of this product. PolyHeme continues to be trialed with investigators noting promising results for use during emergency situations when banked blood products are not readily available.

Procedure

The procedure for administering blood is discussed in this section.

Indications

Indications for administering blood include the following:

- Significant hypovolemia as the result of acute blood loss
- Symptomatic anemia

- Decreasing hemoglobin level
- Decreasing hematocrit value
- To increase oxygen-carrying ability
- Decreased clotting factors
- Presurgical care in select cases

Equipment

The following equipment is needed for performing blood administration:

Physician's orders

- Blood product, typed and crossmatched (in some cases may be cryoprecipitate, platelets, or plasma)
- Dedicated venous access line (18-gauge or larger needle)
- Filtered administration set
- Normal saline solution
- Thermometer

Complications

Complications of administering blood include the following:

- Anaphylaxis
- Hemolytic reaction
- DIC
- Transfusion reaction
- Infection

Signs of complications include the following:

- Body temperature of 2°F (1°C) or more above the baseline temperature
- Hives, itching, or skin symptoms
- Swelling, soreness, or hematoma at the venous site
- Flank pain
- Tachycardia
- Respiratory distress (wheezing and dyspnea)
- Hypotension
- Bleeding from widely varied sites or previously clotted wounds
- Blood in the urine
- Anaphylaxis
- Nausea and vomiting

Steps

Skill Drill 9-1 shows the steps for administering blood products. These steps are also described here: Prepare the patient by doing the following four steps.

1. Confirm the order or protocol **Step 1**.

2. Check the patient for the following: right patient, right blood product, and right type. Have a second provider confirm steps 1 and 2 with you **Step 2**.
3. Assess baseline vital signs and temperature **Step 3**.
4. Ensure suitable venous access (usually requires 18-gauge or larger) **Step 4**. At this point, patient preparation is complete and the transfusion procedure begins.
5. Check the blood for the following: right patient, right blood product, right type, and expiration date.
6. Assess the patient for the possibility of a transfusion reaction, and consider the prophylactic administration of ibuprofen or acetaminophen and diphenhydramine.
7. Maintain the temperature of the blood product.
8. Flush the tubing with normal saline **Step 5**.
9. Cover the administration filter with the blood.
10. Connect the blood to the tubing **Step 6**.
11. Piggyback into the IV line of normal saline **Step 7**.
12. Start the transfusion slowly **Step 8**.
13. Monitor every 5 minutes for adverse reactions.

It is important to follow these transfusion precautions:

- Do not mix blood with 5% dextrose in water (causes hemolysis).
- Do not mix with lactated Ringer's (causes clotting).
- Do not mix with medications (may react).
- Have a second venous access available.

Transfusion Reactions

Transfusion reactions are of great concern and play a significant role in the decision to administer blood products. These reactions can be as mild as chills or as catastrophic as death. Reactions can include both endogenous reactions caused by antigen-antibody reaction in the recipient and exogenous reactions caused by external factors related to the transfused blood.

Allergic Reaction

Allergic reactions are caused by allergens in the donated blood with symptoms of anaphylaxis, including chills, facial and laryngeal edema, pruritus, urticaria, and wheezing, as well as fever, nausea, and vomiting. Management includes the use of antihistamines and careful patient monitoring and assessment. Additionally, the indications for epinephrine and corticosteroid administration must be considered.

Isolated reactions such as urticaria or hives may occur during transfusion without additional signs or symptoms of anaphylaxis and without further sequelae. The transfusion does not need to be discontinued and treatment with an antihistamine is usually adequate. When a patient has a known history of this type of allergic reaction, premedication with an antihistamine should be performed prior to the transfusion.

Bacterial Contamination

Bacterial contamination of blood components usually occurs during one of the following phases of blood administration: phlebotomy, during the component preparation or processing, or during thawing of the blood components.

The frequency of bacterial contamination is low. When it does occur, it may have a rapid onset and lead to death. Of the deaths caused by bacterial contamination of blood components reported to the Centers for Disease Control and Prevention, most are contaminated by *Yersinia enterocolitica*. Since

1987, there have been 20 such cases reported, 12 of which resulted in deaths.

Bacterial contamination usually results from endotoxins produced by organisms capable of surviving the cold, such as *Pseudomonas, Staphylococcus*, and *Y enterocolitica*. Presenting symptoms may occur rapidly or within 30 minutes after transfusion and include chills, fever, vomiting, abdominal cramping, bloody diarrhea, hemoglobinuria, shock, renal failure, and DIC. It is essential to rapidly recognize sepsis caused by blood products contaminated by bacteria. The transfusion must be stopped immediately upon the onset of symptoms. The IV line should be kept open, and the protocol for transfusion reactions should be implemented. The blood component unit, any associated fluids, and the transfusion equipment should be sent to the blood bank immediately for thorough inspection, Gram staining, and culture. Blood cultures should be drawn from the patient as soon as possible for the detection of aerobic or anaerobic organisms. The administration of broad-spectrum antibiotics, corticosteroids, and vasopressors; treatment for shock; fluid support; respiratory ventilation; and maintenance of renal function should be considered in the management of these patients.

Febrile Transfusion Reactions

Febrile transfusion reactions are caused by bacterial lipopolysaccharides or antileukocyte recipient antibodies directed against donor WBCs. Temperatures as high as 104°F (40°C), chills, headache, facial flushing, palpitations, cough, chest tightness, increased pulse rate, and flank pain may be present. Treatment of these patients includes administration of antipyretics and antihistamines. Modifications must be considered if future blood transfusions are anticipated in these patients, including the administration of frozen RBCs and the use of leukocyte filters as modifiers.

Hemolytic Transfusion Reactions

Hemolytic transfusion reactions are caused by ABO or Rh incompatibility, intradonor incompatibility, improper crossmatching, or improper blood storage. These reactions may occur during transfusion or within 3 to 7 days following transfusion.

Immediate hemolytic transfusion reactions usually occur soon after the transfusion of incompatible RBCs. The RBCs are quickly destroyed, resulting in the release of hemoglobin and RBC remnants into the bloodstream with the onset of hemoglobinuria and abnormal bleeding from open sites accompanied by hypotension. The reaction time varies between 1 and 2 hours, with the onset of symptoms within minutes after the blood transfusion begins. Symptoms include chest pain, facial flushing, shortness of breath, chills, fever, hypotension, flank pain, hemoglobinuria, oliguria, bloody oozing at the infusion site, burning along the vein receiving the blood, shock, signs of renal failure, and DIC. A breakdown of these symptoms notes that approximately 35% of the patients with immediate hemolytic transfusion reactions experience fever with or without chills and oliguria with complete recovery, 13% develop anuria, 8% experience coagulopathy, and 10% die after sustained hypotension. Treatment of immediate hemolytic transfusion reactions is directed toward prevention and supportive management. The use of diuretics to augment renal diuresis in an effort to prevent renal failure is recommended. Close monitoring of the patient for the risk factors related to DIC and hypotension is required. Hypotension is managed with fluid resuscitation and vasoactive agents such as dopamine may be required. The use of blood component therapy, including FFP, cryoprecipitate, and platelets, should be considered in patients with bleeding complications or significant coagulation abnormalities. Human error is the cause of most cases of immediate hemolytic transfusion reactions; therefore, these reactions are considered preventable. The extensive policies and procedures necessary to ensure proper patient identification, sample collection and labeling, unit identification, patient testing, handling, and correct transfusion must be strictly enforced.

Skill Drill 9-1

Administering Blood Products

1 Confirm the order or protocol.

2 Check the patient for the following: right patient, right blood product, and right type. Have a second provider confirm steps 1 and 2 with you.

3 Assess baseline vital signs and temperature.

4 Ensure suitable venous access. Check the blood for the following: right patient, right blood product, right type, and expiration date. Assess the patient for the possibility of a transfusion reaction, and consider prophylactic administration of medications. Maintain the temperature of the

blood product.

5 Flush the tubing with normal saline. Cover the administration filter with blood.

6 Connect the blood to the tubing.

7 Piggyback into the IV line of normal saline.

8 Start the transfusion slowly. Monitor for adverse reactions.

Delayed hemolytic transfusion reactions most often occur in patients who have been sensitized through a previous transfusion, pregnancy, or transplant and who also possess an antibody undetectable by standard pretransfusion testing. In cases of delayed hemolytic transfusion reactions caused by secondary

response, the onset of symptoms does not occur until 3 to 7 days after transfusion. The production of antibodies sufficient to generate the signs and symptoms of delayed hemolytic transfusion reactions occurs during this time period. Generally, they are mild. Severe cases and death are rare. Clinical signs and symptoms usually consist of mild fever, chills, and moderate jaundice with treatment focused on the prevention and the treatment of severe complications should they arise. Support of renal function includes IV fluids to maintain adequate fluid status.

Plasma Protein Incompatibility

Plasma protein incompatibility results from immunoglobulin A incompatibility. Clinical presentations include abdominal pain, diarrhea, shortness of breath, chills, fever, flushing, and hypotension. Management of this form of incompatibility includes oxygen administration, fluids, epinephrine, and corticosteroids as indicated.

Other Causes

Additional exogenous transfusion reactions include bleeding tendencies, circulatory overload, hypocalcemia, hypothermia, and potassium intoxication. Bleeding tendencies may be caused by low platelet counts in banked blood causing thrombocytopenia. Clinical presentations include abnormal bleeding and oozing from breaks in the skin or gums, abnormal bruising, and petechiae. Management involves the consideration of transfusion of platelets, FFP, or cryoprecipitate as needed.

Management Considerations

Circulatory overload is a potential complication during blood administration. As mentioned, the decision to administer whole blood has the possible disadvantage of an increased total volume of blood product that may be poorly tolerated by certain patients. Caution with the administration of whole blood should be noted in those patients with cardiac and pulmonary disease who possess the potential for experiencing congestive heart failure. The use of PRBCs in lieu of whole blood administration is recommended in this patient group. The use of diuretics should be considered if circulatory overload is suspected.

Hypocalcemia results from citrate toxicity during blood transfusions when blood products containing citrate are infused too quickly and bind calcium. The depletion of circulating calcium results in calcium deficiency. This calcium deficit may lead to arrhythmias, hypotension, muscle cramping, nausea, vomiting, seizure activity, and/or a tingling sensation in the fingers. Should the onset of such symptoms occur, slowing or stopping the transfusion may be indicated if ordered. These reactions may be more severe in patients with hypothermia or in those with elevated potassium levels. Management considerations include the administration of calcium gluconate IV infused slowly.

High potassium levels in stored plasma caused by the hemolysis of RBCs may result in potassium intoxication during blood administration. Clinical manifestations may include diarrhea, intestinal colic, flaccidity, muscle twitching, oliguria, signs of renal failure, bradycardia, ECG changes with visible tall peaked T waves, and/or cardiac arrest. Management considerations include a diagnostic 12-lead electrocardiographic (ECG) tracing, sodium polystyrene (Kayexalate) administration, administration of an albuterol nebulizer, administration of furosemide, and the infusion of 50% glucose, insulin, sodium bicarbonate, or calcium in an effort to reduce serum potassium by shifting potassium into cells, as well as reducing total body potassium and making the heart less reactive to high potassium.

The induction of hypothermia is possible during the rapid infusion of large amounts of cold blood products. Hypothermia symptoms include chills, shivering, hypotension, arrhythmias, bradycardia, and/or cardiac arrest if body temperatures fall below 30°C (86°F). Treatment considerations may include stopping the transfusion, warming the patient, obtaining a diagnostic 12-lead ECG, and warming the blood if the transfusion is resumed.

The risk-benefit analysis of blood administration must be met with caution. Blood transfusion can be

a life-saving intervention; however, the many complications and adverse reactions that accompany the decision to deliver blood products to a patient require highly skilled health care providers and vigilance in the health care setting.

Flight Considerations

In the transport environment, a patient in shock or with sepsis or MODS will most likely be very labile and require diligence in monitoring and adjustments to therapy to maintain oxygenation and hemodynamic status. It is important to give close attention and ensure that all infusions are dosed properly and are compatible. Care with ventilator transfers and settings must also be maintained because oxygen desaturation may occur easily. Patients can be negatively affected by movement and agitation.

Although patients with sepsis are infrequently transported long distances by fixed-wing transport, when they are, altitude and cabin pressure require ventilator adjustments to compensate for pressures at altitude.

Summary

Often in the transport environment, a patient with sepsis will be critically ill, and multiple support devices and treatments will be in progress. The referring facility may have exhausted its resources to care for the patient. CCTPs must be well versed in many aspects of the management of shock, sepsis, SIRS, and MODS. Multiple therapies may be needed concurrently in the care of patients in critical condition because of these disorders.

Case Study

YOU ARE CALLED TO A REGIONAL HOSPITAL ICU for emergency ground transfer of a man to a tertiary facility. Three days earlier, the patient fell, sustained splenic trauma, and underwent emergency repair of a splenic tear. Transport time by ground will be 1 hour.

Upon arrival, staff reports this is a 35-year-old, 77-kg man who fell from a scaffold 3 days ago and was brought by EMS to the emergency department. He has no medical history and is a half-pack-a-day smoker and an occasional drinker. He was diagnosed with a splenic tear and underwent surgical repair. He was admitted to the ICU after surgery, has had worsening hemodynamic status, and is being referred to a tertiary facility for ongoing care. During his stay, he received packed RBCs, normal saline, and FFP for surgery and stabilization. A PA catheter was inserted, and dopamine therapy was initiated to maintain hemodynamic status. Cefazolin (Ancef) was given as surgical prophylaxis. He continues to need a ventilator as well.

He is currently mildly responsive, with a Glasgow Coma Scale score of 7T (T indicates that the patient is intubated). He is intubated with a 7.5 endotracheal tube and ventilated with synchronized intermittent mandatory ventilation. The tidal volume is 700 mL, the rate is 10 breaths/min, FIO_2 is 50%, and PEEP is 5 cm. Occasional suctioning is required. Two peripheral lines are in place, with normal saline running at 100 mL/h. Dopamine is infusing at 6 µg/kg/min. He is receiving enteral nutrition via a nasally inserted duodenal tube. His PA catheter is revealing lowered PCWP, decreased SVR, and increased CO. An available chest x-ray reveals bilateral diffuse infiltrates. His temperature is 102°F (38.9°C). Current monitoring reveals the following: heart rate, 133 beats/min; blood pressure, 84/43 mm Hg; temperature, 38.9°C; MAP, 55 mm Hg; CVP, 3 mm Hg; PA pressure, 20/10 mm Hg; PCWP, 7 mm Hg; SpO_2, 89%; and end-tidal carbon dioxide, 35 mm Hg. Current available lab values are as follows: hemoglobin, 11.0 g/dL; hematocrit, 33.1%; WBC count, 24, 100/µL; platelet count, 51 × 103/µL; BUN,

61 mg/dL; creatinine, 2.1 mg/dL; Na^+, 146 mEq/L; K^+ 4.8 mEq/L; Cl^-, 111 mEq/L; glucose, 225 mg/dL; pH, 7.29; P_{CO_2}, 52 mm Hg; Pa_{O_2}, 47 mm Hg; and HCO_3^-, 14 mEq/L. Urine output has been scant, at less than 50 mL/h.

Your assessment confirms the preceding information. The patient feels febrile to touch. The examination reveals equal and reactive pupils at 5 mm. The enteral feeding tube is placed nasally and secured. The endotracheal tube is secured at 22 cm at the lip line. The trachea is midline. Other portions of the head, eye, ear, nose, and throat exam have normal findings. The chest has equal rise and fall with ventilations. A PA catheter is placed in the right side and is secure. Lung sounds reveal bilateral, diffuse, light crackles. The abdomen reveals a splenic surgical incision that is intact and dressed. No exudate is noted. An indwelling urinary catheter is noted with a pelvic exam. The lower extremities are cool and pale. Pedal pulses can be detected by Doppler only. Faint radial pulses are noted. Capillary refill is delayed.

You transfer his IVs to your pumps. The ECG and hemodynamic lines are transferred and calibrated to your monitors. The patient is moved to your litter, and ventilator settings are duplicated on your portable ventilator, increasing the FIO_2 to 80%. You discharge the patient from the ICU, obtain all records, and move to your mobile ICU. He is placed in the mobile ICU, all oxygen and power needs are transferred to onboard systems, and transport is begun.

En route, no change in the preceding hemodynamic status is noted, and the patient continues to be hypoxic, with an oxygen saturation of 89%. Contact with medical control is made, and standing protocols are initiated.

Immediate attention is given to increasing the oxygenation and perfusion. Dopamine is increased to 10 µg/kg/min, and norepinephrine is considered as another pressor agent to increase the blood pressure and SVR. The ventilator F_{IO_2} is increased to 100% and PEEP to 10 cm. Only slight improvements of oxygenation (90%) and hemodynamics (blood pressure, 88/46 mm Hg) are noted. Hydrocortisone is also considered. Further discussions were to maintain current patient status, and further therapy will ensue on admission to the tertiary facility. No further changes are noted during the transport course, and the patient is delivered to the tertiary facility ICU without further incident.

1. What is your differential diagnosis?
2. What other treatment may be beneficial to this patient?
3. Is this an appropriate transfer based on the patient's condition?

Analysis

This patient is most likely experiencing sepsis and SIRS. MODS should be considered because of the respiratory failure and renal insufficiency. The infection could be secondary to the surgical exploration, or a result of mechanical ventilation (pneumonia) or perhaps an invasive line or catheter (intravascular or urinary).

Treatments en route to the receiving facility may include the following:

- Further increases in ventilator support by increasing F_{IO_2}, minute volume, and PEEP. Tidal volume should not be increased.
- Administration of chemical paralytics to facilitate ventilation. Sedative agents must be used with caution owing to the potential hypotensive qualities of these drugs.
- Ensuring that adequate fluid resuscitation has been performed *before* increasing any vasopressor doses; 4 to 6 L may be required. Blood products would be considered if the hematocrit value is less than 30%.

- Adding an infusion of another vasopressor agent, such as norepinephrine, epinephrine, phenylephrine, or vasopressin *after* adequate fluid resuscitation.
- Dobutamine therapy may be instituted only after adequate fluids and vasopressor support and may enhance tissue oxygen delivery.
- Steroid therapy may be instituted to combat inflammatory responses.
- Blood glucose management because patients with sepsis often are hyperglycemic.

This is an appropriate transfer because the patient will benefit from further treatment at a tertiary facility, such as the following:

- Further ventilator support
- Studies and determination of appropriate antibiotic therapy
- Possible surgical consult and intervention
- Anticoagulation and inflammatory therapies

Sepsis and MODS continue to be complex challenges to CCTPs. Despite recent advances in the critical care arena, sepsis and MODS continue to have high mortality and morbidity rates. New therapies are helpful, but early detection and intervention are still the mainstay of positive outcomes. Identification of risk factors and subtle changes in the condition of the patient are required to identify early onset of one of the disorders and for initiation of aggressive therapy to reverse the process and gain a favorable outcome. Although the critical care transport arena is limited in therapy that may reverse the process, it still serves a vital role in support of patients. Transport staff have the resources and must remain vigilant in the support of failing organ systems, restoration of intravascular volume, and adequate oxygenation to meet metabolic demand.

Prep Kit

Ready for Review

- All cells require energy, a continuous supply of oxygen, and nutrients. From those nutrients, mitochondria manufacture energy in the form of adenosine triphosphate (ATP). That process is called cellular respiration.
- Cellular respiration has three parts: glycolysis, the citric acid cycle, and the electron transport chain (oxidative phosphorylation). Unlike the other two parts of cellular respiration, which require oxygen, glycolysis also can occur in an anaerobic environment. But this solo attempt to support cellular respiration causes a reduction in ATP and an increase in lactic acid, which can result in cell damage, impaired function of tissue, and a cascade of injurious effects.
- To get oxygen to the body's cells, the respiratory system must allow oxygen and carbon dioxide exchange across the alveolar-capillary membrane. Once this transfer occurs, arterial blood transports oxygen to the tissues (the oxygen is dissolved in plasma [3%] or is bound to hemoglobin [97%]).
- Various factors can affect the delivery of oxygen-rich blood to the tissues, including blood volume, viscosity, and arterial elasticity. However, the primary determinates of transport are blood pressure (it must be stable) and cardiac output (it must be adequate).
- Under normal conditions, only 25% of the oxygen delivered to the tissues of the body is actually extracted. This allows the body a buffer zone for periods of low oxygen delivery, during which the cells must extract more oxygen. Therefore, management of shock is geared toward maximizing oxygen

consumption by maintaining adequate oxygen supply, providing hemoglobin through administration of blood products, and optimizing cardiac output. If there is a breakdown in one or more of these components, homeostasis is lost.

- Shock is a progressive, whole-body response to an inadequate supply of oxygen within cells, tissues, and organs, from one or multiple causes. It is commonly classified in four stages, and the mortality rate increases with progression:
  - During initial or early shock, blood flow into the micro-circulatory beds decreases and lactic acid levels begin to rise. However, compensatory mechanisms, such as an increase in oxygen consumption, are able to keep vital signs at baseline.
  - During the compensatory stage of shock, neural, hormonal, and chemical mechanisms attempt to compensate for the now severely reduced delivery of oxygen. They, in effect, cover up low circulatory volumes, poor stroke volume, and falling cardiac output, especially in children and healthy young adults. Common signs and symptoms are as subtle as mild tachypnea and tachycardia. The MAP may decrease 10 to 15 mm Hg from baseline. Cardiac output also may drop slightly.
  - During the progressive or decompensating stage of shock, multifaceted systemic responses to cell breakdown occur, affecting nearly every organ of the body. Compensatory mechanisms have begun to fail. Patients have more pronounced signs of shock, including altered mental status, tachycardia, and a drop in MAP of more than 20 mm Hg from baseline. Laboratory analysis shows a progression of acidosis, hyperkalemia, and climbing lactate levels. This is a life-threatening emergency that requires immediate treatment.
  - During the refractory or irreversible stage of shock, compensatory mechanisms have failed. At this stage, the patient is unresponsive to verbal stimuli. Blood pressure will be inadequate and the heart rate will be increased. The respiratory rate is increased and respirations are shallow. Skin will be cold, cyanotic, and/or mottled and peripheral pulses are weak and thready to absent. Urinary output will decrease and bowel sounds will be absent. Anaerobic metabolism progresses to permanent organ dysfunction and treatment no longer can reverse the mass effects. Multiple organ failure ensues and the risk of mortality is at its highest.
- MODS is diagnosed when two or more organs stop functioning. The organs affected early in MODS are the brain, kidneys, liver, adrenal glands, and heart. Sepsis is the leading cause of MODS.
- Shock traditionally is classified by cause. More than one type of shock may be present at the same time.
- Cardiogenic shock results when the ventricles are unable to pump blood forward, ultimately decreasing cardiac output. Manifestations vary depending on the underlying cause, but common signs and symptoms are low blood pressure; altered mental status; cool, pale, diaphoretic skin; decreased urine output; weak and thready pulse; distant or abnormal S_3 or S_4 heart sounds; fluid accumulation in the lungs or limbs; and tachypnea. Management focuses on enhancing cardiac output while decreasing left ventricular work load. Hypovolemic shock is present when there is too little circulating blood volume within the vascular system, resulting in hypotension. Manifestations include tachycardia; hypotension; signs of poor tissue perfusion; altered mental status; and cold, mottled, and pulseless extremities. Management revolves around treating the underlying condition, administering oxygen, and initiating volume replacement.
- Distributive shock is a term used to describe several types of shock involving loss of vasomotor tone or increased vascular permeability: neurogenic shock, anaphylactic shock, and septic shock.
- Neurogenic shock results from conditions that impede the ability of the sympathetic nervous system to control the constriction and dilation of vessel walls, such as trauma to the brain or spinal cord. The signs and symptoms associated with neurogenic shock can be very different from those found in

hypovolemic shock; most profound is the presence of bradycardia in the face of hypotension. It is vital to piece together all possible causes of hypotension to determine the best treatment, which generally focuses on maintaining an MAP of greater than 70 mm Hg or a systolic blood pressure of greater than 90 mm Hg.

- Anaphylactic shock is a severe, life-threatening allergic reaction producing systemic vasodilation in response to histamine release. The reaction can be massive, and it can occur minutes after exposure or it may be delayed for hours or days. Manifestations include bronchoconstriction, laryngeal edema, and angioedema resulting in airway compromise, which requires rapid treatment to limit effects. Standard oxygen therapy may not be enough; patients may require intubation, an emergency cricothyrotomy, or tracheostomy to maintain an adequate airway.
- Septic shock is a progressive disease that typically occurs from an infection. Septic shock usually starts as a localized infection and then develops into a widespread inflammatory process, referred to as systemic inflammatory response syndrome (SIRS). When hypotension develops, septic shock is present.
- Infection is the leading cause of SIRS and septic shock. However, any shock state can cause the beginning of SIRS and lead to sepsis before reaching multiple organ failure. The minimum criteria for early recognition of SIRS relate to body temperature, respiratory rate, pulse rate, and white blood cell count.
- A patient who has SIRS with a known or highly suspected source of infection has sepsis. Sepsis may be a mild systemic response to infection or suspected infection. In contrast, severe sepsis is sepsis with a confirmed or highly suspected diagnosis of infection and organ dysfunction of at least one organ. Septic shock incorporates hemodynamic instability with SIRS and a confirmed or highly suspected source of infection that is unresponsive to fluid resuscitation. Sepsis may progress through septic shock and result in organ failure and MODS.
- The prevalence of sepsis-related infections is increasing. They affect all populations and age groups and are associated with (in order of prevalence) diabetes, hypertension, congestive heart failure, COPD, cirrhosis, HIV infection, cancer, and pregnancy. Prolonged hospitalization is a risk factor, as are invasive procedures, comorbidities, and use of immunosuppressants. The mortality rate for sepsis increases with severity; sepsis is the leading cause of death in noncoronary ICUs and the 10th leading cause of death in the United States.
- Bacteria are the pathogens most commonly associated with the development of sepsis, although fungi, viruses, and parasites also can cause sepsis. Infection can occur at any body site, including lungs, abdomen, skin, and urinary tract, and as a result of primary bloodstream infection. Gramnegative and gram-positive bacteria are the two most common organisms responsible for sepsis.
- Sepsis is part of a dynamic hypermetabolic, hyperinflammatory response to an insult that grossly affects the endothelium. The three identifiable physiologic processes involved with the development of microvascular abnormalities associated with severe sepsis are proinflammation, procoagulation, and decreased fibrinolysis.
- Microvascular disruption and injury are responsible for hypoperfusion and the shunting of oxygen, resulting in decreased oxygen delivery to the tissues. The profound imbalance between oxygen delivery and consumption causes hypoxia within the cells and tissues. This complex cascade of events is the primary cause of severe sepsis and its progression to organ dysfunction and failure.
- The first priority in recognizing sepsis is to maintain a high index of suspicion for distributive shock in two phases: hyperdynamic (warm) and hypodynamic (cold). The hyperdynamic phase has high cardiac

output lasting hours or days. It can progress to the hypodynamic phase, a rapid deterioration with a sudden drop in cardiac output. Other manifestations of sepsis include fever (may or may not be present), hypothermia in later stages, tachycardia, normal-to-low blood pressure progressing to hypotension, normal skin progressing to cold and clammy skin with pallor or cyanosis, petechiae and blood oozing from mucous membranes and procedure sites, decreased pulse pressure, increased respiratory rate and depth, respiratory alkalosis, and ARDS.

- The management of sepsis is aimed at maintaining organ perfusion while enhancing tissue oxygenation. Management requires balancing preload, afterload, and contractility to achieve targeted criteria for an optimal level of homeostasis.
- Blood administration is sometimes performed to manage shock and should be considered in cases of hemorrhagic blood loss as a result of trauma, internal hemorrhage, perioperative and postoperative complications, specific disease entities, anemia due to illness, or coagulation disorders.
- The decision to give a transfusion during transport is complex. Factors to consider include the urgency of the transfusion, the "out-of-hospital" time, availability of the blood products, type and crossmatch information, and appropriate transport and care of the blood product.
- Steps for proper blood administration include appropriate typing and crossmatching, appropriate IV access, blood tubing administration sets, priming of the tubing with normal saline, validation of the blood product's match with the specific patient before administration, and continued supervision by a skilled health care provider.
- In an emergency situation in which the time for crossmatching cannot be taken, the use of the universal donor type O, Rh-negative blood or plasma can be transfused until crossmatched blood becomes available.
- Blood contains a variety of antigens that influence the compatibility of blood between persons. Three types of blood antigens are the ABO blood group, Rh factor, and the HLA blood group. These are considered when crossmatching.
- A person with only an A antigen is type A. A person who has only a B antigen is type B. If both A and B antigens are identified, the person is type AB. When neither A nor B are identified, the person's blood type is O.
- People with type AB blood are universal recipients; they can receive blood types A, B, AB, and O without the threat of an ABO reaction. Persons with type O blood are universal donors; their blood can be transfused into patients with type A, B, and AB blood.
- Rh factors are antigens found on the cell membrane of red blood cells. An Rh-negative person may develop an Rh antibody if exposed to Rh-positive blood. A second Rh-positive exposure could result in a fatal hemolytic reaction.
- HLA is present on the cell membrane surface of circulating platelets, white blood cells, and most tissue cells. Patients receiving platelets from multiple donors may experience febrile transfusion reactions as a result of HLA. This type of reaction destroys the platelets, reducing the benefit of the transfusion.
- Blood administration can occur in many different forms: whole blood, packed red blood cells, platelets, FFP, cryoprecipitate, albumin, plasma protein fractions, and synthetic blood substitutes.
- Whole blood contains all blood components (red blood cells, white blood cells, platelets, plasma, and electrolytes). Transfusion with whole blood is uncommon and indicated only in acute massive blood loss for blood volume expansion and increased oxygen-carrying capacity. Disadvantages are significant, including fluid volume overload in patients with cardiac compromise and degradation after 24 hours of storage.

- PRBCs retain all of the characteristics of whole blood with the exception of the extraction of approximately 250 mL of platelet-rich plasma from each unit of whole blood. Anemia and blood loss are possible indications for PRBC administration.
- Platelet therapy may be considered for patients with extremely low platelet levels, those who are bleeding due to thrombocytopenia, or patients with abnormally functioning platelets. If a patient must receive multiple transfusions of platelets, single-donor platelets should be administered.
- FFP is uncoagulated plasma separated from the red blood cells. Indications for the administration of FFP may include blood loss, coagulation deficiencies, warfarin reversal, and thrombotic thrombocytopenia purpura. Close patient monitoring for hypocalcemia is required during transfusion.
- Cryoprecipitate is a frozen blood product created from the plasma of a donor. It contains factor VIII, fibrinogen, von Willebrand factor, and factor XIII, and is useful in treating patients with clotting disorders. Administration of cryoprecipitate does not require compatibility testing.
- Albumin is prepared by the fractionation of pooled plasma. Albumin is used for volume replacement in conditions such as burns, trauma, surgery, or infections. Patients with cardiac and pulmonary disease must be monitored closely during albumin administration.
- Plasma protein fraction contains 83% albumin and 17% globulins. Plasma protein fraction is indicated for volume expansion in patients with hypovolemia and hypoproteinemia. Clinical settings for the administration of plasma protein fraction may include shock and burn patients.
- When performing blood administration, it is important to follow transfusion precautions:
  - Do not mix blood with 5% dextrose in water (causes hemolysis).
  - Do not mix with lactated Ringer's solution (causes clotting).
  - Do not mix with medications (may react).
  - Have a second venous access line available.
- Blood administration can result in transfusion reactions. Transfusion reactions can be as mild as chills or as catastrophic as death. Signs include body temperature of 2°F (–16°C) or more above the baseline temperature; hives, itching, or skin symptoms; swelling, soreness, or hematoma at the venous site; flank pain; tachycardia; respiratory distress (wheezing and dyspnea); hypotension; bleeding from widely varied sites or previously clotted wounds; blood in the urine; anaphylaxis; and nausea and vomiting.
- Main types of transfusion reactions include allergic reactions, bacterial contamination, febrile transfusion reactions, hemolytic transfusion reactions, and plasma protein incompatibility.
- Allergic reactions caused by allergens in the donated blood have symptoms of anaphylaxis (ie, chills, facial and laryngeal edema, pruritus, urticaria, and wheezing) as well as fever, nausea, and vomiting. Management includes the use of antihistamines, careful patient monitoring and assessment, and possible epinephrine and corticosteroid administration.
- Bacterial contamination of blood components usually occurs during phlebotomy, component preparation or processing, or thawing of the blood components. Presenting symptoms may occur within 30 minutes after transfusion begins and include chills, fever, vomiting, abdominal cramping, bloody diarrhea, hemoglobinuria, shock, renal failure, and DIC. It is essential to rapidly recognize these symptoms, stop the transfusion immediately, and implement the protocol for transfusion reactions.
- Febrile transfusion reactions occur when symptoms include a temperature as high as 104°F (40°C), chills, headache, facial flushing, palpitations, cough, chest tightness, increased pulse rate, and flank pain. Treatment includes the administration of antipyretics and antihistamines.
- Hemolytic transfusion reactions are caused by ABO or Rh incompatibility, intradonor incompatibility,

improper crossmatching, or improper blood storage.

- Immediate hemolytic transfusion reactions may occur during transfusion or within 3 to 7 days following transfusion. Red blood cells are destroyed, and hemoglobin and red blood cell remnants are released into the bloodstream. Symptoms include chest pain, facial flushing, shortness of breath, chills, fever, hypotension, flank pain, hemoglobinuria, oliguria, bloody oozing at the infusion site, burning along the vein receiving the blood, shock, signs of renal failure, and DIC. Treatment of immediate hemolytic transfusion reactions is directed toward prevention and supportive management.
- Delayed hemolytic transfusion reactions do not occur until 3 to 7 days after transfusion. Signs and symptoms are usually mild and include mild fever, chills, and moderate jaundice, with treatment focused on the prevention and the treatment of severe complications should they arise.
- Plasma protein incompatibility is caused by immunoglobulin A incompatibility. Clinical presentations include abdominal pain, diarrhea, shortness of breath, chills, fever, flushing, and hypotension. Management includes oxygen administration, fluids, epinephrine, and corticosteroids as indicated.
- Hypocalcemia may occur when blood products containing citrate are infused too quickly and bind calcium, causing calcium deficiency and leading to arrhythmias, hypotension, muscle cramping, nausea, vomiting, seizure activity, and/or a tingling sensation in the fingers. Slowing or stopping the transfusion may be indicated. Management considerations include the administration of calcium gluconate IV infused slowly.
- High potassium levels in stored plasma may result in potassium intoxication during blood administration. Clinical manifestations include diarrhea, intestinal colic, flaccidity, muscle twitching, oliguria, signs of renal failure, bradycardia, ECG changes with visible tall peaked T waves, and/or cardiac arrest. Management considerations include a diagnostic 12-lead ECG tracing; Kayexalate administration; administration of an albuterol nebulizer; administration of furosemide; and the infusion of 50% glucose, insulin, sodium bicarbonate, or calcium.
- Hypothermia may result from a rapid infusion of large amounts of cold blood products. Hypothermia symptoms include chills, shivering, hypotension, arrhythmias, bradycardia, and/or cardiac arrest. Treatment may include stopping the transfusion, warming the patient, obtaining a diagnostic 12-lead ECG, and warming the blood if the transfusion is resumed.

Vital Vocabulary

ABO-incompatible transfusion reactions A type of transfusion reaction in which the patient possesses antigens to a blood type and receives that blood type.

adaptive immune system The secondary mechanism that protects the host by reacting with and eliminating specific antigens after requiring more time than the innate immune system to mobilize its defense against unknown pathogens.

aerobic metabolism A form of energy production in which mitochondria utilize glucose, amino acids, and fatty acids combined with oxygen and ADP to produce ATP, carbon dioxide, water, and heat.

albumin A blood product containing this specific protein found in the blood, and prepared by the fractionation of pooled plasma; used for volume replacement in certain conditions.

anaerobic metabolism A less efficient form of energy production in which an alternative pathway converts glucose to pyruvic acid with the simultaneous production of ATP and that also results in the production of lactate.

anaphylactic shock A severe hypersensitivity reaction that involves bronchoconstriction and cardiovascular collapse.

anaphylactoid reaction A non–IgE-mediated response that causes the rupture of mast cells and basophils, which then release histamine and other defense mediators.

antigen Any substance that can create an immune response in the body.

arterial oxygen content (CaO_2) The total amount of oxygen in the arterial blood.

cardiac index A hemodynamic value that adjusts a patient's cardiac output to take into accout his or her total body surface area.

cardiac output (CO) The amount of blood pumped by the heart per minute, calculated by multiplying the stroke volume by the heart rate per minute.

cardiogenic shock A condition caused by loss of 40% or more of the functioning myocardium; the heart is no longer able to circulate sufficient blood to maintain adequate oxygen delivery.

cryoprecipitate A blood product created from plasma and in which clotting factors, especially factor VIII, are concentrated; used to treat patients with coagulation disorders.

cytokines Chemical messengers that enhance cell growth, promote cell activation, direct cellular traffic, stimulate macrophage function, and destroy antigens; interleukins are a type of cytokine.

delayed hemolytic transfusion reactions A type of transfusion reaction that does not occur until 3 to 7 days after transfusion.

disseminated intravascular coagulation (DIC) A complex condition arising from different causes that activate coagulation mechanisms, resulting in obstructed blood flow as a result of microdots; in fibrinolysis, the attempt by the body to reopen the microcirculation. Bleeding and thrombosis and, potentially, organ dysfunction result.

distributive shock A condition that occurs when there is widespread dilation of the resistance vessels, the capacitance vessels, or both.

ejection fraction The portion of the blood ejected from the ventricle during systole.

fresh-frozen plasma (FFP) A blood product in which uncoagulated plasma has been separated from the red blood cells; primarily composed of water, proteins, salts, metabolites, and clotting factors.

hemolysis A situation in which red blood cells are destroyed, resulting in the release of hemoglobin and red blood cell remnants into the bloodstream.

hemolytic transfusion reaction A type of transfusion reaction caused by ABO or Rh incompatibility, intradonor incompatibility, improper crossmatching, or improper blood storage.

human leukocyte antigen (HLA) An antigen present on the cell membrane surface of circulating platelets, white blood cells, and most tissue cells.

hypercapnia Greater than normal amounts of carbon dioxide in the blood.

hyperdynamic state A condition that occurs as the first stage of distributive shock and is characterized primarily by high cardiac output and low peripheral vascular resistance; also known as warm shock.

hypodynamic state A condition that occurs as the second stage of distributive shock and is characterized primarily by a subnormal temperature, a low white blood cell count, profound hypotension and hypoperfusion, and a sudden drop in cardiac output; also known as cold shock.

hypovolemic shock A condition that occurs when the circulating blood volume is inadequate for delivering adequate oxygen and nutrients to the body.

immediate hemolytic transfusion reactions A type of transfusion reaction that usually occurs soon (between 1 and 2 hours) after the transfusion of incompatible red blood cells.

innate immune system The primary antigen and immunogen-nonspecific defense mechanism that protects the host by eliminating microbes to prevent infection and other antigens in an attempt to prevent allergic reactions.

leukotrienes A class of biologically active compounds that occur naturally in leukocytes and that produce allergic and inflammatory reactions.

mean arterial pressure (MAP) The average (or mean) pressure against the arterial wall during a cardiac cycle.

microcirculation Circulation that occurs in the microvasculature, the body's smallest vessels (arterioles, capillaries, and venules).

multiple organ dysfunction syndrome (MODS) Altered organ function in acutely ill patients, which is diagnosed when two or more organs stop functioning.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, leading to widespread dilation; seen in spinal cord injuries.

neutrophils One of the types of leukocytes (white blood cells); these numerous phagocytic microphages usually are the first of the mobile phagocytic cells to arrive at an area of injury or infection.

oxygen consumption ($\dot{V}O_2$) The amount of oxygen used by the cells and tissues.

oxygen delivery (DO_2) The amount of oxygen delivered to the tissues each minute.

oxygen extraction ratio (ERO_2) The relationship between oxygen consumption and oxygen delivery, or the cells' ability to utilize oxygen.

packed red blood cells (PRBCs) A blood product that retains all of the characteristics of whole blood with the exception of the extraction of approximately 250 mL of platelet-rich plasma from each unit of whole blood.

pathogens The microorganisms responsible for activating the immune system and that cause disease; includes viruses, parasites, fungi, and bacteria.

plasma protein fraction A blood product that contains 83% albumin and 17% globulins.

primary MODS Multiple organ dysfunction syndrome that results from a direct insult such as trauma.

refractory stage A stage in shock in which there is persistently low mean arterial blood pressure despite vasopressor therapy and adequate fluid resuscitation.

Rh factors Antigens found on the cell membrane of red blood cells.

secondary MODS Multiple organ dysfunction syndrome that is a slower, more progressive insult to organs and frequently results from the sepsis cascade.

sepsis Systemic response to infection manifested by two or more symptoms noted with SIRS.

septic shock A form of shock that occurs in septicemia when endotoxins or exotoxins are released from certain bacteria in the bloodstream, resulting in a persistently low mean arterial blood pressure despite adequate fluid resuscitation.

severe sepsis A type of sepsis with associated acute organ failure; hypoperfusion or hypertension is present.

systemic inflammatory response syndrome (SIRS) A widespread inflammatory process associated with

infectious and noninfectious causes, without end-organ damage.

transfusion reaction A reaction resulting from an endogenous or exogenous factor related to transfused blood.

true anaphylaxis An anaphylactic reaction that results when the allergen binds to IgE on the cell membranes of basophils and when mast cells stimulate the release of histamine from the cell.

tumor necrosis factor (TNF) A protein mediator released primarily by macrophages and T lymphocytes that help regulate the immune response.

type-and-crossmatch The test to determine compatibility between patient serum and donor red blood cells prior to transfusion.

universal donors Persons who have type O blood.

universal recipients Persons who have type AB blood.

Objectives

1. Understand the CCTP's impact on preventing trauma deaths by performing proper prehospital care and transporting to the appropriate trauma center (p 308).
2. Understand the significance of trauma management on morbidity and mortality (p 308).
3. Understand the various trauma scoring systems, including the Glasgow Coma Scale, the trauma score, the revised trauma score, the abbreviated injury scale, the injury severity score, and the trauma injury severity score, and how they are used (p 314–316).
4. Understand Newton's first, second, and third laws of motion and how they relate to patterns of injury (p 308–309).
5. Discuss the types of trauma (p 309).
6. Describe the steps of the assessment process that are specific to critical care trauma patients (p 309–310).
7. Explain the concept of triage and standard triage systems (START and JumpSTART) (p 310–313).
8. Discuss the classifications of trauma centers defined by the American College of Surgeons' Committee on Trauma, including level I, II, III, and IV trauma centers (p 316–317).
9. Discuss the American College of Surgeons' Committee on Trauma patient classifications (p 316–317).
10. Understand how to assess a trauma critical care patient (p 317).
11. Know how to recognize, assess, and manage the most common critical care injuries, including pneumothorax (open, tension, and simple), hemothorax, flail chest, pericardial tamponade, aortic dissection, myocardial contusion, diaphragmatic rupture, tracheobronchial disruption, pulmonary contusion, esophageal perforation, and traumatic asphyxia (p 321–327, 330–337).
12. Know how to recognize, assess, and manage critical care ear, eye, neck, throat, and thyroid injuries (p 337–342).
13. Understand how and when to use diagnostic imaging, including the standard radiograph, computed tomography, magnetic resonance imaging, ultrasonography, intra-abdominal pressure monitoring, and related transport considerations (p 318–321).
14. Know the signs and symptoms as well as how to manage abdominal and pelvic injuries, including both hollow and solid organ injuries (p 342–346).
15. Recognize the different types of fractures and know how to manage them (p 346–348, 349–350).
16. Know how to recognize, monitor, and manage compartment syndrome, crush injuries, and rhabdomyolysis (p 350–352).
17. Understand pharmacology as it relates to trauma and know the specific treatments and medications (p

352–353).

18. Understand the specific trauma considerations for special populations (p 353–354).

Advances in Trauma Care

Trauma poses a significant threat to life. Since the time EMS began to evolve in the 1960s, more emphasis has been placed on rapidly identifying injuries and transporting patients to an appropriate trauma center for definitive care. The severity of the injuries in a traumatic incident will vary from minor to life threatening. Most local community hospitals should be able to manage and treat patients with minor injuries. All trauma patients need a trauma assessment to determine if they have serious injuries. The ability of the CCTP to appropriately care for trauma patients en route will help to decrease the incidence of morbidity and mortality related to their injuries.

Identifying life-threatening illnesses and injuries as soon as possible and transporting the patient to an appropriate facility have improved patient outcomes. This is a popular topic of discussion because trauma is a leading cause of death in persons younger than 40 years. According to the Centers for Disease Control and Prevention, traumatic injuries account for more than 117,000 deaths each year in the United States. Many preventable trauma deaths occur in the prehospital environment, further emphasizing the importance of proper prehospital care.

Renewed emphasis on education has helped to focus prehospital care providers' priorities at the scene of a trauma incident. Priorities include scene safety, rapid immobilization/stabilization, and transport.

CCTPs may find themselves dealing with trauma patients in two very different situations. One instance is the scene call, usually to back up field BLS or ALS providers. In these cases, the CCTP will be working in more austere and less controlled conditions with less sophisticated assessment tools than in the interfacility transport. On a scene call, the CCTP may be called to provide care not available to the standard field responder, such as rapid sequence intubation (RSI); or to provide speed of transport to surgery or blood transfusion, such as by rotor wing.

The other instance involves the CCTP transferring critical patients, usually from smaller facilities to trauma centers. In this situation, the CCTPs will be able to avail themselves of the results of laboratory results, imaging, and other sophisticated assessment findings prior to transport. The CCTPs may also be able to enlist the aid of the transferring physician or other house staff to help with stabilization efforts prior to transport by helping secure difficult airways, inserting chest tubes, and hanging blood or other treatments that may be better performed in the referring hospital rather than in a moving transport vehicle. Diplomatically enlisting this aid and advocating for the patient are also the jobs of the CCTP, in addition to providing care.

In both types of calls, the time it takes to stabilize the patient's condition for transport must be balanced against the need to transport an unstable patient immediately for care that cannot be provided in the field, such as surgery. A top priority of the CCTP is to determine the treatment that needs to be provided before transport vs what can be done en route.

Morbidity and Mortality

Trauma systems in the United States spend considerable time and effort in researching ways to decrease morbidity and mortality rates. Morbidity and mortality are often used synonymously with disability and death, because this is ultimately what advanced trauma systems are working to prevent. **Morbidity** refers to nonfatal injury and disability, whereas **mortality** refers to deaths caused by injury and disease. This is an area of concern for all trauma systems in the United States, because trauma is the leading cause of death in the pediatric population and a leading cause of death overall. Half of all deaths in children result

from trauma, accounting for more than 14,000 deaths annually.

Prevention and quality trauma care are two major contributors to decreasing morbidity and mortality rates. Quality prevention programs keep the trauma system and its patients from suffering needlessly from life-threatening and/or lifealtering injuries related to trauma. This is significant because a vast majority of trauma deaths are related to motor vehicle crashes. These crashes are often caused by factors such as alcohol, excessive speed, lack of physical restraints, and poor judgment. Most of these factors are easily preventable with an established and efficiently functioning prevention program.

An alarming statistic relating to motor vehicle crashes is the number of individuals who actually survive the crash, but suffer a debilitating injury that leaves them incapacitated. Many of these injuries involve the head and the spinal cord, and occur at the time of injury. The CCTP must realize the importance of avoiding secondary injury caused by improper handling. Patients with long-term debilitating injuries will spend the rest of their lives dependent on others for basic everyday needs and may require advanced nursing care, resulting in a huge cost to society (more than $200 billion annually) and to the patients and their families, both financially and emotionally.

Overview of Trauma

Newton's Laws of Motion

By far one of the foremost scientific intellects of all time, Sir Isaac Newton discovered three laws of motion. We review them here.

Newton's First Law

Newton's first law of motion deals with force and velocity, both of which are well exemplified in automobile crashes. Essentially, Newton says, "A body in motion remains in motion in a straight line unless acted upon by an outside force." The CCTP must understand this concept in order to predict patterns of injuries. For example, envision that a vehicle traveling at 50 mph hits a tree head on and comes to an abrupt stop. The chain of events during the collision includes the car striking the tree, the patient's chest striking the steering wheel, and internal organs striking the rib cage. Therefore, the exchange of energy within the body causes many different types of damage. A solid understanding of Newton's first law of motion better prepares the CCTP to deliver the appropriate standard of care to patients with traumatic injuries.

Newton's Second Law

Newton's second law of motion refers to an object's behavior when an outside force is applied. According to this law, acceleration is dependent on two variables—the mass of the object and the force upon the object. Therefore, if force is increased, so is acceleration. If mass is increased, the acceleration is decreased. Essentially, an object accelerates in the direction it is pushed. If you push twice as hard, it accelerates twice as much. Conversely, if the object has twice the mass, it will accelerate at half the speed.

Newton's Third Law

Newton's third law of motion is most commonly paraphrased as, "To every action, there is an equal and opposite reaction." In other words, if an automobile strikes a wall at 70 mph, the wall pushes back at 70 mph. A solid understanding of the third law is of particular importance to the CCTP when evaluating the mechanism of injury and predictability of injuries. For example, the CCTP would have a higher index of suspicion of a chest injury from an automobile that hit a tree head on going 70 mph than one going 5 mph.

Types of Trauma

Traumatic injuries are generally classified into one of two categories: blunt or penetrating. Patients may have injuries that fit into both classifications at the same time. For example, an individual who is stabbed in the back (penetrating injury) and then falls down a flight of steps (blunt injury) could experience both types of injuries. Blunt injuries result from energy exchange between an object and the body, without intrusion through the skin **Figure 10-1**. Examples include rapid forward decelerations (collisions), rapid vertical decelerations (falls), and energy transferred from blunt instruments such as a stick or bat. Penetrating injuries refer to injuries caused by external forces in which the tissue is penetrated by an object. Examples include projectiles, such as bullets, knives, and fragments from explosions and falls upon fixed objects.

Deceleration injuries are caused by a sudden stop of the body's forward motion. These blunt injuries can result from falls, automobile crashes, or abuse such as shaken baby syndrome. Common injuries involve shearing, avulsing, or rupturing of body organs, fascia, nerves, and other soft tissue. Often these types of injuries are not visible to the CCTP; therefore, a thorough understanding of the types of mechanisms of injury and effective assessment skills is imperative.

External force injuries are caused by forces that violate the tissues of the body. These injuries can result from gunshot wounds, stabbings, and/or projectiles. Injuries depend upon the anatomic area involved, the mass, and, most importantly, the velocity of the foreign object that enters the body. The kinetic energy (KE) of an object is the energy associated with that object in motion. It reflects the relationship between the weight (mass) of the object and the velocity at which it is traveling and is expressed mathematically as the following equation (m = mass, v = velocity):

Figure 10-1 A front-end collision should clue the CCTP to suspect potential head, neck, and chest injuries.

$$KE = \tfrac{1}{2}\, mv^2$$

These injuries require the CCTP to provide excellent patient assessment skills in order to prioritize injuries and treatments. The CCTP must be cautious not to develop tunnel vision. Tunnel vision occurs when people focus all of their attention on what is immediately in front of them, ignoring their peripheral vision **Figure 10-2**. As a result, the CCTP's focus would be on a visible injury, which may or may not be life threatening, while no attention is focused on other injuries that may well be life threatening. Maintaining a calm, professional demeanor and using a systematic approach allows the CCTP to maintain a high index of suspicion and attention to detail.

Trauma Assessment

Although the CCTP has had extensive training in patient assessment during initial training, these skills must now be applied to the advanced practice environment of critical care transport.

Trauma assessment, much like medical assessment, encompasses both a physical examination and a

subjective interview (when possible). For the CCTP, the subjective information often has to come from someone other than the patient. Therefore, it must always be evaluated critically and not taken as gospel. Even on an interfacility call, the sending diagnosis is subjective and should be evaluated by the CCTP. If information can be gained directly from the patient, it may help focus the physical exam. For example, a trauma patient with a chest injury might say, "I'm having trouble catching my breath." The CCTP's physical examination could then lead to a field diagnosis and subsequent treatment of a tension pneumothorax. It is especially important to remember that patients are not static, and that conditions may become evident as time progresses.

Figure 10-2 An overwhelming injury can cause a CCTP to focus on the visual horror, rather than more serious emergencies such as severe internal blood loss.

As always, the assessment process begins with scene size-up, then primary assessment. The level of consciousness and status of ABCs can be assessed simultaneously. The CCTP should undertake manual cervical spine immobilization while introducing himself or herself to the patient. If the patient responds, the CCTP can easily obtain vital information in regard to mental, airway, and breathing status. Any response that is less than alert should immediately direct the CCTP to perform a more detailed assessment of the ABCs and begin to search for causes.

Once the initial trauma primary assessment is accomplished, the CCTP uses these findings along with the mechanism of injury to dictate whether a rapid trauma or a focused assessment is most appropriate. Examine the trauma scene for evidence of high-energy trauma. If one of the following is present, consider transport to a trauma center:

- Ejection from an automobile
- Death in the same passenger compartment
- Pedestrian thrown or run over or auto-pedestrian injury at greater than 5 mph
- High-speed automobile crash (greater than 40 mph)
- Intrusion into the passenger compartment of greater than 12″
- Major vehicle deformity of greater than 20′
- Vehicle rollover with an unrestrained passenger

- Extrication time of greater than 20 minutes
- Falls of greater than 20′
- Motorcycle crash at greater than 20 mph or with separation of rider and bike

Trauma patients who have an isolated injury require a focused examination, whereas a rapid trauma assessment is used for multisystem trauma patients. A secondary assessment allows the CCTP to focus on the patient's main problem, such as an isolated injury.

A rapid trauma assessment allows the CCTP to rapidly assess the head, neck, chest, abdomen, pelvis, and extremities to find and correct any life threats and should be completed in under 1 minute. When conducting the rapid trauma assessment, the CCTP should not only do a visual assessment, but also a palpation assessment to look for life-threatening injuries.

The secondary assessment is a more comprehensive examination to determine additional injuries that may have been overlooked in the primary assessment. It is extremely important to document all findings in the secondary assessment because it also serves as a baseline for future treatment decisions in the continuity of care. Critical patients who fall into the "load and go" category should have the secondary assessment performed during transport, whereas noncritical patients may be assessed on the scene.

When conducting a secondary assessment, the questions to ask will vary depending on the patient's specific injury. The patient's answers will lead you to other questions.

The more comprehensive secondary assessment is generally done during transport to a trauma center. This assessment is done to develop a baseline for future treatment decisions. This exam should include:

1. **Head-to-toe exam**: Inspect, auscultate, palpate, and percuss.
2. **Reassess vital signs**: This includes pulse, respirations, blood pressure, and monitors such as cardiac, capnography, and pulse oximetry.

Once the primary and secondary assessments are completed, the CCTP must determine the criticality of the patient and make a transport decision. Patients who meet the appropriate critical criteria should immediately be loaded into the critical care transport unit for transport to the appropriate trauma center. The CCTP should alert the receiving facility as soon as possible so that specialized health care providers can be awaiting the patient upon his or her arrival.

Patients who cannot be stabilized by interventions available to the CCTP at the point of pickup need to be rapidly transported. Patients who are bleeding internally need blood and surgery immediately. Delay of transport of these patients for crystalloid IVs, for example, is not in their best interest. Issues of airway, breathing, and stopping external bleeding are the only reasons to delay transport, and it should only be delayed long enough to intervene with these problems.

All multisystem trauma patients should be transported rapidly, even those who do not need immediate surgery to stop internal bleeding and those not in need of immediate transfusion. The CCTP must be alert and maintain a high index of suspicion for deterioration with all trauma patients.

Reassessment is continued during transport to the trauma center. Essentially, it is an ongoing reassessment of the patient and any interventions performed. If at any time during reassessment the patient's condition deteriorates, the CCTP should immediately reassess the primary assessment and address any negative findings that can be corrected.

The CCTP must also be prepared for special patients, such as those who are morbidly obese, those who are anatomically different than normal, elderly patients, children, and those with comorbid factors that will be exacerbated with traumatic injury. Patients with special circumstances may also require a creative approach and application of critical thinking skills by the CCTP in order to meet their needs. It is necessary to be both proficient at advanced-level procedures and to have excellent assessment and decision-making skills. Deployment of an effective assessment technique is of paramount importance in

order to provide appropriate care and treatment for the trauma patient. Remember that most patient catastrophes occur or are started during hand-offs of patient care.

Triage

Triage is a system of prioritizing patients based on injury severity. More simply put, triage is doing the greatest good for the greatest number. There are four common triage categories: immediate (red), delayed (yellow), minimal (green), and expectant (black).

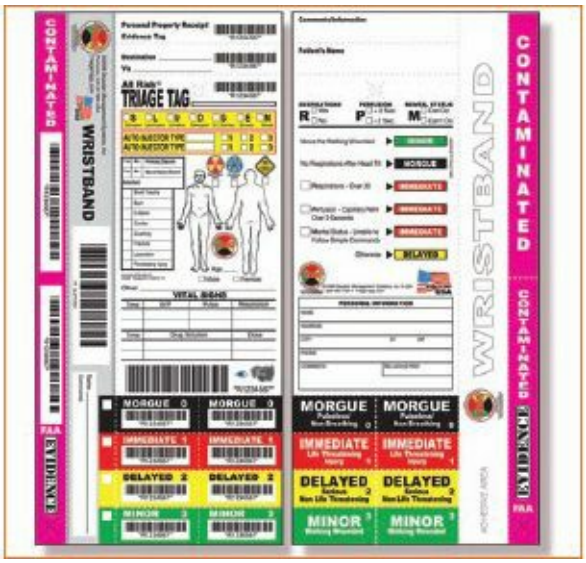

Figure 10-3 Standard triage tag.

Figure 10-3 shows a standard triage tag. Red tags denote the highest priority. Patients in this category need immediate care and transport to definitive treatment centers. Typical injures in this classification are injuries related to the ABCs, head trauma, and/or signs of inadequate tissue perfusion (shock).

Yellow tags are reserved for second- or delayed-priority patients. Patients in this category need treatment and transport, but it can be delayed. Typical injuries in this classification are serious but stable, such as orthopaedic or back injuries.

Green tags are the third priority and are often referred to as "walking wounded." Patients in this category have minor soft-tissue injuries such as contusions, abrasions, and lacerations.

Black tags are for patients for whom there is no treatment indicated: those who are dead, alive but nonsalvageable, or not injured. This may include cardiac arrest and obvious nonsurvivable injuries. The black triage category is also sometimes called expectant.

In order for triage to work, a systematic approach must be deployed that clearly defines individual roles and responsibilities of EMS providers. The triage officer must have ultimate control of the counting and prioritizing of patients. The treatment officer oversees the treatment area, the transportation officer oversees transport of patients, and the staging officer must oversee and direct the staging area in order to deploy needed resources to the appropriate treatment sectors. Individuals assigned to these positions do not take part in patient care, but rather direct the activities of their specific assignment.

START Triage

START triage is one of the easiest methods of triage. START is an acronym for simple triage and rapid treatment. The staff members at Hoag Memorial Hospital, Newport Beach, California, are responsible for developing this method of triage. It is easily mastered with practice and will give you the ability to rapidly categorize patients at a multiple casualty incident. START triage uses a limited assessment of the

patient's ability to walk, respiratory status, hemodynamic status, and neurologic status.

The first step of the START triage system is performed on arrival at the scene by calling out to the disaster site, "If you can hear my voice and are able to walk…" and then directing patients to an easily identifiable landmark. The injured persons in this group are the "walking wounded" and are considered minimal priority, or third-priority, patients.

The second step in the START process is directed toward nonwalking patients. You move to the first nonambulatory patient and assess the respiratory status. If the patient is not breathing, you should open the airway by using a simple manual maneuver. A patient who still does not begin to breathe is triaged as expectant (black). If the patient begins to breathe, tag him or her as immediate (red), place the patient in the recovery position, and move on to the next patient.

If the patient is breathing, a quick estimation of the respiratory rate should be made. A patient who is breathing faster than 30 breaths/min is triaged as an immediate priority (red). If the patient is breathing fewer than 30 breaths/min, move to the next step of the assessment.

The next step is to assess the hemodynamic status of the patient by checking for a radial pulse. An absent radial pulse implies the patient is hypotensive and should be triaged as an immediate priority. If the radial pulse is present, go to the next assessment.

The final assessment in START triage is to assess the patient's neurologic status, which simply means to assess the patient's ability to follow simple commands, such as "show me three fingers." This assessment establishes that the patient can understand and follow commands. A patient who is unconscious or cannot follow simple commands is an immediate-priority patient. A patient who complies with a simple command should be triaged in the delayed category. The START system is outlined in **Figure 10-4**.

JumpSTART Triage for Pediatric Patients

Lou Romig, MD, recognized that the START triage system does not take into account the physiologic and developmental differences of pediatric patients. She developed the **JumpSTART triage** system for pediatric patients. JumpSTART is intended for use in children younger than 8 years or who appear to weigh less than 100 lb. As in START, the JumpSTART system begins by identifying the walking wounded. Infants or children who are not developed enough to walk or follow commands (including children with special needs) should be taken as soon as possible to the treatment sector for immediate secondary triage. This action assists in getting children who cannot take care of their own basic needs into the care of someone who can. There are several differences within the respiratory status assessment compared with that in START triage. First, if you find that a pediatric patient is not breathing, immediately check the pulse. If there is no pulse, label the patient as expectant (black). If the patient is not breathing but has a pulse, open the airway with a manual maneuver. If the patient does not begin to breathe, give five rescue breaths and check respirations again. A child who does not begin to breathe should be labeled expectant (black). The primary reason for this difference is that the most common cause of cardiac arrest in children is respiratory arrest.

The next step of the JumpSTART process is to assess the approximate rate of respirations. A patient who is breathing less than 15 breaths/min or more than 45 breaths/min is tagged as immediate priority, and you move on to the next patient. If the respirations are within the range of 15 to 45 breaths/min, the patient is assessed further.

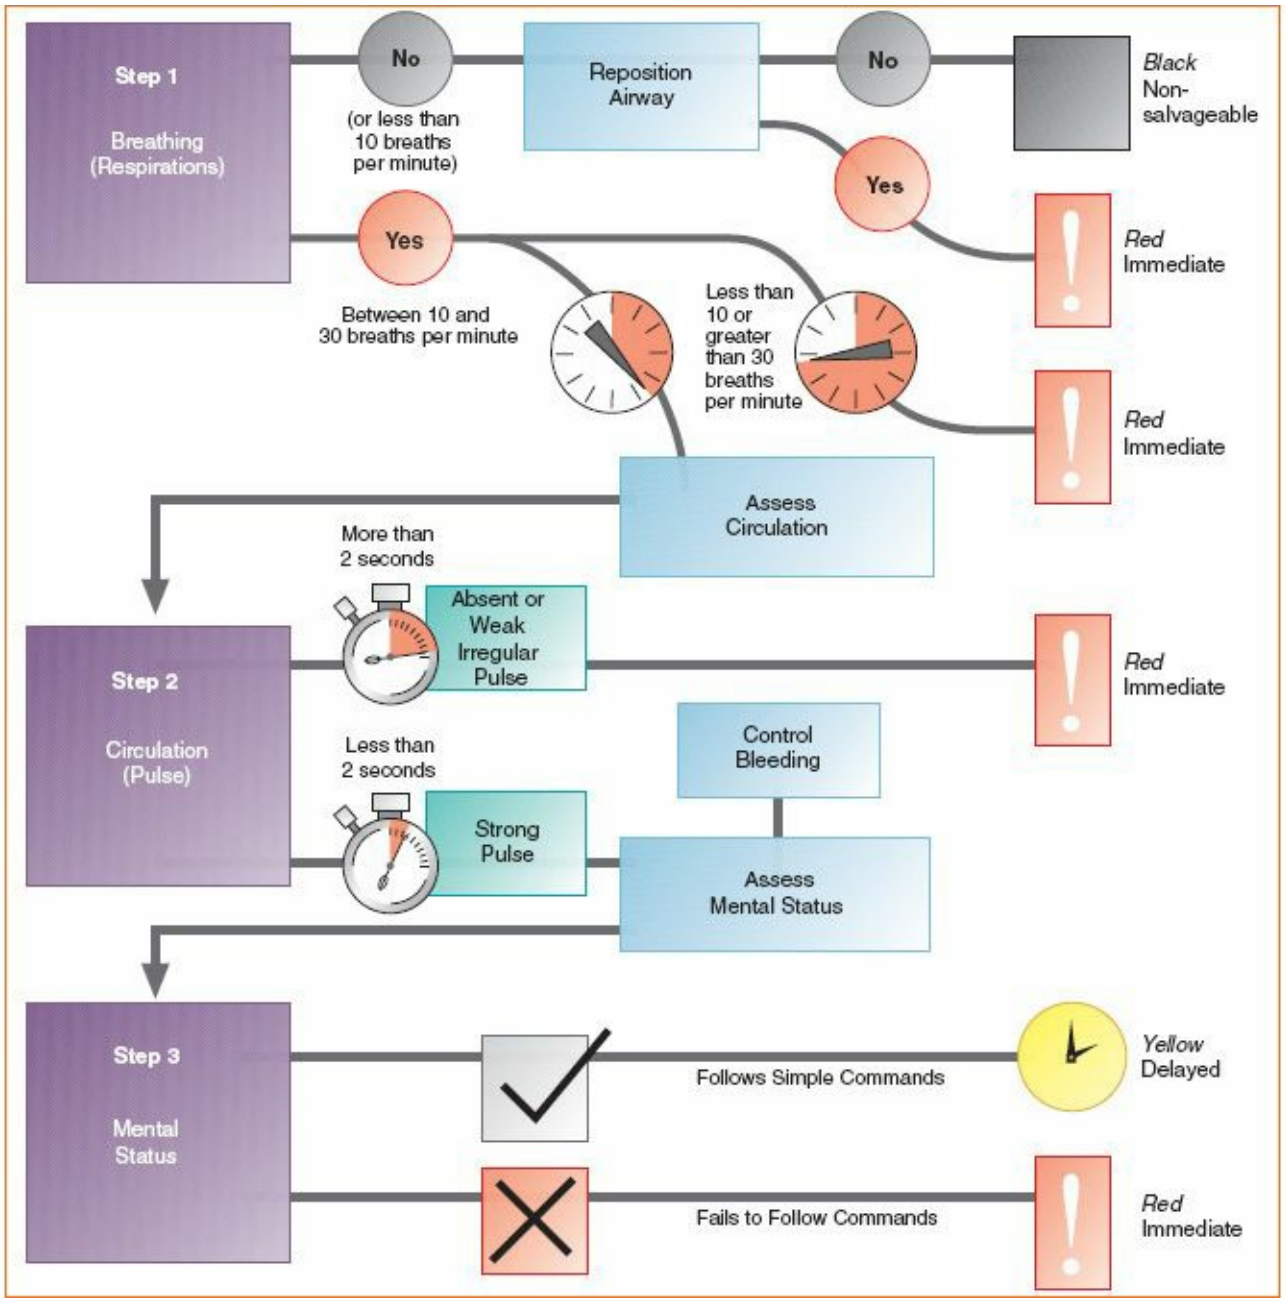

Figure 10-4 The START algorithm.

The next assessment in JumpSTART triage evaluates the hemodynamic status of the patient. As in START, you are checking for a distal pulse. This does not need to be the brachial pulse; assess the pulse that you are comfortable checking. If there is an absence of a distal pulse, label the child as an immediate priority and move to the next patient. If the child has a distal pulse, move on to the next assessment.

The final assessment is neurologic status. Responses vary in children because of their developmental differences. For JumpSTART, a modified AVPU (A, alert; V, responding to voice; P, responding to pain; U, unconscious) score is used. A child who is unresponsive or responds to pain by posturing or with incomprehensible sounds or is unable to localize pain is considered an immediate priority and tagged as such. A child who responds to pain by localizing it or withdrawing from it or is alert is considered a delayed priority patient. The JumpSTART system is described in **Figure 10-5**.

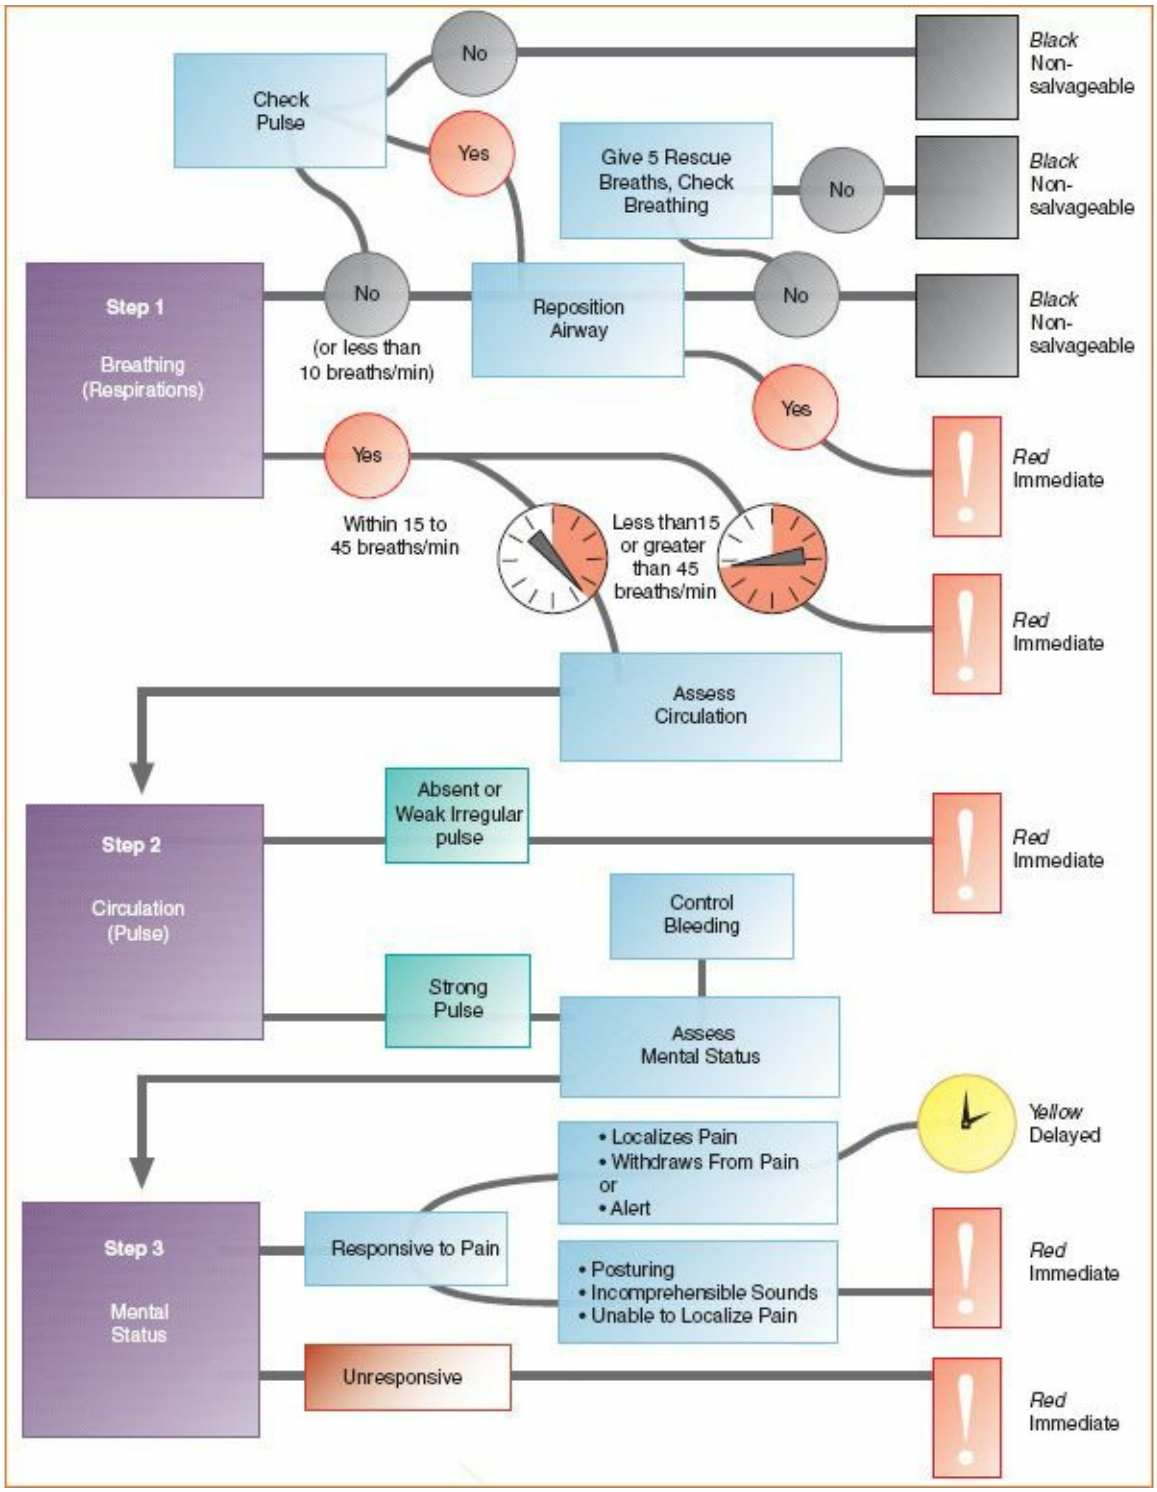

Figure 10-5 The JumpSTART algorithm.

Trauma Scoring Systems

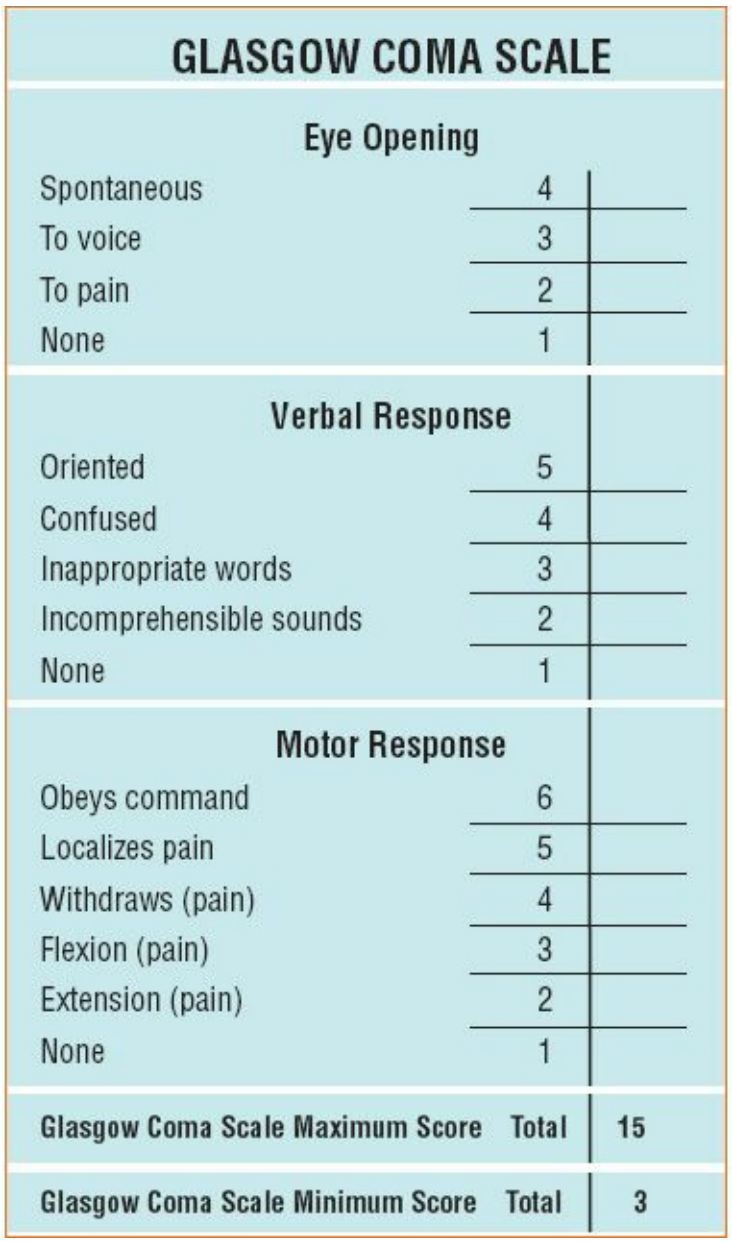
Several trauma scoring systems are used in the critical care transport environment. These provide assessment information and indicators of patient survivability. Trauma scoring systems are an important tool for regional trauma centers that use them in conjunction with their quality assurance program.

Glasgow Coma Scale

The **Glasgow Coma Scale (GCS)** is a tool that many health care professionals use to assess the neurologic function of their patients. This scoring system is used to determine a patient's level of consciousness by measuring and assigning point values, or scores, for eye opening, verbal response, and

motor response. The highest score is 15; the lowest score is 3. The GCS chart in **Figure 10-6** shows how the numerical values are determined.

Although the GCS score is often used when caring for trauma patients, it is also a great assessment tool for patients with medical conditions. Medical emergencies, such as a drug overdose, metabolic disorders, and hypercapnia, benefit from frequent patient evaluation using the GCS. Ongoing assessments assist CCTPs in rapidly identifying treatable conditions.



GLASGOW COMA SCALE

Eye Opening		
Spontaneous	4	
To voice	3	
To pain	2	
None	1	
Verbal Response		
Oriented	5	
Confused	4	
Inappropriate words	3	
Incomprehensible sounds	2	
None	1	
Motor Response		
Obeys command	6	
Localizes pain	5	
Withdraws (pain)	4	
Flexion (pain)	3	
Extension (pain)	2	
None	1	
Glasgow Coma Scale Maximum Score	**Total**	**15**
Glasgow Coma Scale Minimum Score	**Total**	**3**

Figure 10-6 Glasgow Coma Scale scores are used to assess a patient's level of consciousness, for example, in patients with head injuries. The lower the score, the more severe the extent of brain injury.

Special Populations

It is just as important to obtain an accurate neurologic exam in the pediatric population as in the adult population, although doing so may be more difficult with pediatric patients. Depending on the age of the child, modifications may need to be made in order to accurately identify any neurologic deficits.

A poor GCS score usually indicates that the patient requires some type of immediate intervention, such as airway control or aggressive resuscitation. Chapter 23 discusses the pediatric GCS and its application in the management of children.

Patients who present with GCS scores of less than 8 require intubation or another form of advanced airway intervention because they are experiencing significant neurologic impairment. Remember, the GCS score is one of the most accurate means of objectively assessing the central nervous system when invasive monitoring devices are not available. Even in an intubated patient, the GCS score provides accurate, useful information; the CCTP merely needs to note when a patient's inability to verbalize is the result of the device in his or her airway, rather than a decrease in neurologic function.

Always give detailed explanations of abnormal GCS findings in the narrative section of your patient care record. In many situations, successful management of the unresponsive patient with a head injury depends on ongoing examinations. Neurologic changes can occur in a matter of minutes, which necessitates obtaining a GCS score as often as every 5 minutes. Ongoing GCS assessment scores must always be compared to the baseline score. It is important to look for changes that signal deterioration as well as improvement. Any changes must be reported to the receiving facility.

Trauma Score

The **trauma score** is a predictor of the likelihood of patient survival. The score ranges from 1 to 16, with 16 being the best possible score, and takes into account the GCS score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill. The trauma score, however, does not accurately predict survivability in patients with severe head injuries. Therefore, the revised trauma score, discussed next, replaced the trauma score.

Special Populations

The pediatric trauma score takes into account the child's weight, systolic blood pressure, airway status, central nervous system status, whether or not he or she has an open wound, and whether there is musculoskeletal trauma. Chapter 23 discusses the pediatric trauma score and its application in the management of children.

Revised Trauma Score

The numeric scoring of trauma patients for determining the severity of their injury is common practice. There are several different trauma scoring systems, but the one that is the most commonly used is the **revised trauma score**.

The revised trauma score is a system that measures the following three physiologic parameters: respiratory rate, systolic blood pressure, and GCS score **Table 10-1**. The total score will range from 0 to 13, with the more debilitated patient receiving a lower score. The score can also be weighted, giving the three physiologic parameters different weights; the result then ranges from 1.0 to 7.8408. When the scores are weighted, the GCS score is given more weight to account for a patient's compensatory mechanisms that could prevent vital signs from accurately reflecting patient condition. The weighted score is not practical for use in the field, but is a useful research tool when studying mortality among trauma patients. In the field of trauma, it is important to understand that much time and effort is spent researching ways to decrease morbidity and mortality in trauma patients. Extensive research has proven that there is a correlation between a low revised trauma score and a high mortality rate. This simply states and proves the effectiveness of the various trauma scores **Figure 10-7**.

The revised trauma score does not readily identify the small percentage of severely injured trauma patients whose vital signs, because of compensatory mechanisms, do not accurately represent patient condition. For example, a patient with severe trauma who is in the early stages of shock may not pre-sent

with abnormal vital signs (eg, low systolic blood pressure and increased respiratory rate) because the body is compensating for the blood loss. The body's ability to compensate for this blood loss may only last for a brief period. When the patient begins to decompensate, the vital signs will begin to deteriorate. Aggressive resuscitation should begin, however, before the patient's vital signs deteriorate. Regardless of the score, the CCTP needs to be prepared for each trauma patient's condition to deteriorate with time, once the body's ability to compensate for the injury ends. For patients with a revised trauma score of less than 11, the American College of Surgeons recommends transfer to a Level I or II trauma center. A high index of suspicion should be maintained in all trauma patients.

Abbreviated Injury Scale

Developed in 1969, the **Abbreviated Injury Scale (AIS)** is an anatomic scoring system that is designed to provide a reasonably accurate means of ranking the severity of injury. This scale categorizes injuries into six body regions and assigns an individual score to each injury. The body regions include the head, neck, thorax, abdomen, spine, and extremities. Injuries are ranked on a scale of 1 to 6, with 1 being a minor injury and 6 being an injury that has the highest risk of mortality. The following list indicates the categories and the corresponding AIS scores:

- Minor injury: 1
- Moderate injury: 2
- Serious injury: 3
- Severe injury: 4
- Critical condition: 5
- Unsurvivable: 6

Modified from *Survival Probability* by Revised Trauma Score. © Trauma.org.

The AIS allows for the determination of the severity of an individual injury but does not take into account multisystem injuries.

TABLE 10-1 Components of the Revised Trauma Score

Revised Trauma Score	Components
4	GCS: 13–15 Systolic blood pressure: > 89 mm Hg Respiratory rate: 10–29 breaths/min
3	GCS: 9–12 Systolic blood pressure: 76–89 mm Hg Respiratory rate: > 29 breaths/min
2	GCS: 6–8 Systolic blood pressure: 50–75 mm Hg Respiratory rate: 6–9 breaths/min
1	GCS: 4–5 Systolic blood pressure: 1–49 mm Hg Respiratory rate: 1–5 breaths/min
	GCS: 3

0	Systolic blood pressure: 0 mm Hg Respiratory rate: 0 breaths/min

Abbreviation: GCS, Glasgow Coma Scale.

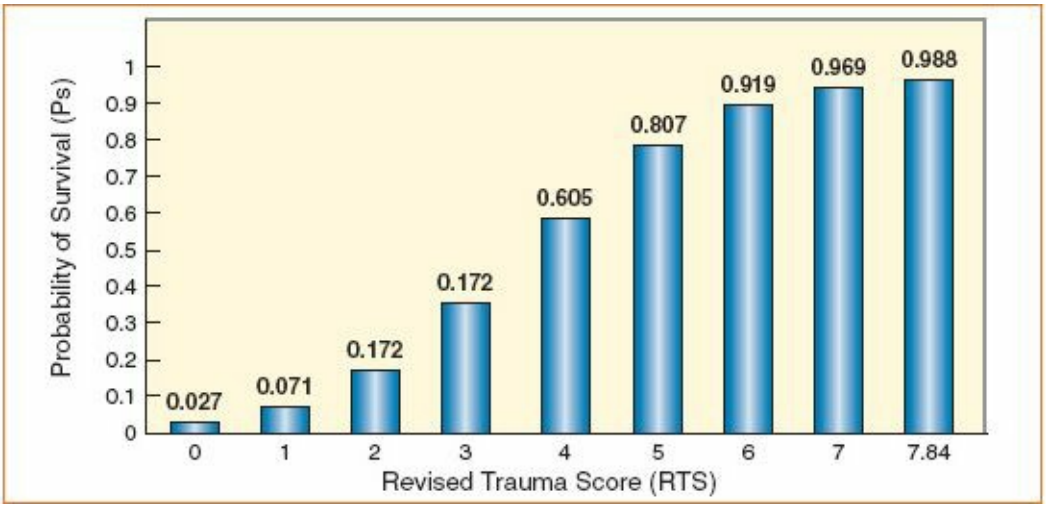

Figure 10-7 Survival probability by revised trauma score. Modified from *Survival Probability* by Revised Trauma Score. © Trauma.org.

TABLE 10-2 Sample ISS Calculation

ISS Region	Injury	AIS	Square of the Top Three AIS Scores*
Head and neck	No injury	0	
Face	Unstable facial fracture	4	16
Chest	Flail chest	5	25
Abdomen	Liver laceration	4	16
Extremity	No injury	0	
External	Abrasion to right upper quadrant of abdomen	3	

Abbreviations: AIS, Abbreviated Injury Score; ISS, Injury Severity Score.
*The ISS in this example is 57.
Reproduced from Injury Severity Score. © Trauma.org

Injury Severity Score

The **Injury Severity Score (ISS)** is an anatomic scoring system that provides an overall score for patients with multiple injuries. The ISS quantifies multisystem injuries with the use of AIS scores. The ISS is determined by adding the highest AIS scores squared in the three most severely injured body systems. The ISS is a number between 1 and 75, with 1 being a minor injury and 75 being an injury with a high mortality rate. Any ISS body region that is assigned an AIS of 6 (unsurvivable) equates to an ISS score of 75. An example of the ISS calculation is shown in **Table 10-2**.

Throughout the trauma system community, a patient with an ISS greater than 15 is frequently considered a major trauma patient who requires immediate attention and in most cases transfer to a Level I facility.

The ISS determined by health care providers is often used by trauma registry personnel for data

collection and research purposes. Once data such as ISS scores are collected, some variances can occur with this scoring system. For example, any error that is calculated with AIS scoring will increase the likelihood of errors with the ISS. Remember that you must always refer back to your triage skills in the field for determining the destination of your patient. The various trauma scoring systems are not as useful as your triage skills because a full description of the patient injuries is not known.

Trauma Injury Severity Score

The **trauma injury severity score** is another scoring system that calculates the survival probability of the critically ill or injured patient. This scoring system uses the results of the ISS and the revised trauma score along with the patient's age, which incorporate the patient's physiologic and anatomic indicators. This score is rarely used in the transport setting.

Trauma Systems

Levels of Trauma Care

The CCTP is often summoned to accident scenes and/or outlying facilities to transport critically ill trauma patients to more definitive care. For this reason, it is important to be familiar with how the American College of Surgeons' Committee on Trauma classifies trauma care. Trauma centers are classified into Levels I through IV, with Level I having the most resources followed by Levels II, III, and IV, respectively.

A Level I facility is a regional resource center and generally serves large cities or heavily populated areas. Level I facilities must be capable of providing every aspect of trauma care from prevention through rehabilitation; therefore, the facility must have adequate personnel and resources. Because of the extensive requirements, most Level I facilities are university-based teaching hospitals.

A Level II facility is typically located in less densely populated areas. Level II centers are expected to provide initial definitive care, regardless of injury severity. These facilities can be academic institutions or public/private community facilities. Because of location and resources, the Level II trauma center may not be able to provide the same comprehensive care as a Level I trauma center.

Level III facilities serve communities that do not have access to Level I or II facilities. Level III facilities provide assessment, resuscitation, emergency care, and stabilization. Level III facilities must have transfer agreements with a Level I or II trauma center, and must have protocols in place to transfer patients whose needs exceed the facility's resources.

Level IV facilities are typically found in remote, outlying areas where no higher level of care is available. These facilities provide advanced trauma life support prior to transfer. Such a facility may be a clinic or urgent care facility, with or without a physician.

Although an inclusive trauma system should leave no facility without a direct link to a Level I or II facility, all facilities are expected to provide the same high quality of initial care regardless of the classification level.

Trauma centers are categorized as either adult trauma centers or pediatric trauma centers, not necessarily both. Pediatric trauma centers are not nearly as common as adult trauma centers. When transporting a pediatric trauma patient, you must be certain to transport to the closest appropriate facility —a pediatric trauma center if that is closest.

The American College of Surgeons' Committee on Trauma also provides criteria for Level I trauma patient classification. When one or more of the following criteria listed below are present in the trauma patient, he or she is classified as a Level I trauma patient.

- Confirmed blood pressure less than 90 mm Hg at any time in adults, and age-specific hypotension

in children

- Respiratory compromise, obstruction, and/or intubation (with the exception that a patient with an unmanageable airway should go to the closest hospital)
- Transfer patients from other hospitals receiving blood to maintain vital signs
- Emergency physician's discretion

TABLE 10-3 American College of Surgeons Recommendations for a Level II Patient

Patient characteristic/condition indicators	1. Glasgow Coma Scale score of < 14 when associated with trauma 2. Respiratory rate of < 10 or > 29 breaths/min (< 20 breaths/min in an infant younger than 1 year) when associated with trauma 3. Penetrating wounds (other than gunshot wounds) to the head, neck, torso, and extremities proximal to the elbow and knee 4. Flail chest 5. Combination of trauma with burns 6. Two or more proximal long bone fractures 7. Pelvic fractures 8. Limb paralysis and/or spinal cord injury 9. Amputation proximal to the wrist and/or ankle
Mechanism of injury indicators	1. High-speed automobile crash • Initial speed > 40 mph • Major automobile deformity • Intrusion into the passenger compartment 2. Ejection from the automobile 3. Death in same passenger compartment 4. Extrication time > 20 minutes 5. Falls > 20′ or significant falls in children or elderly 6. Automobile rollover 7. Automobile vs pedestrian or automobile vs bicycle impact > 5 mph 8. All-terrain vehicle or motorcycle crash > 20 mph or separation of rider from vehicle
Consider Level II classification with these preexisting conditions	1. Age younger than 5 years or older than 55 years 2. Cardiac or respiratory disease 3. Insulin-dependent diabetes mellitus, cirrhosis of the liver, or morbid obesity 4. Pregnancy 5. Immunosuppressed patients 6. Patients with a bleeding disorder or receiving anticoagulants

- GCS score of 8 or less, with mechanism attributed to trauma
- Gunshot wound to the abdomen, neck, or chest

Although the American College of Surgeons does not cite required criteria for a Level II patient, they do provide recommendations, which are listed in **Table 10-3**.

General Trauma Management

Paramedics are already well schooled in prehospital management of trauma. Interfacility management of the trauma patient will often involve patients who are very ill and in need of close assessment and continued monitoring. Some patients may undergo damage-control surgery prior to transfer. This treatment involves surgical correction of life-threatening injuries followed by transfer to a critical care unit or tertiary hospital for correction of acidosis, hypothermia, or coagulopathies. Definitive surgery is performed after the patient's condition has been stabilized. In some patients, injuries may be managed without surgery. Regardless of the approach, management following arrival at a hospital follows Advanced Trauma Life Support guidelines. As in the prehospital setting, immediate attention is directed at the ABCs.

Immediately assess the placement of the endotracheal tube, presence of breath sounds, and capnography waveform. If any doubt exists as to proper placement of the endotracheal tube, perform direct laryngoscopy to confirm tube location. Cardiovascular status should be assessed, including the patency of all vascular access devices and the total volume of fluids infused since the patient presented at the receiving facility. A thorough neurologic exam should be performed and documented. Although it may seem duplicative, it is imperative to assess the patient from head to toe for external injuries. Previously unseen injuries can prove fatal during interfacility transport if they are not discovered and addressed prior to departure.

Elicit as much medical history as possible from the patient or hospital staff. Consider drug or alcohol intoxication; up to one third of all trauma patients are drug or alcohol dependent. Repeated head-to-toe assessments decrease the possibility of missed injuries, which occur more often in multisystem trauma patients. The CCTP must also be prepared to detect and treat complications on initial evaluation and treatment, including fluid overload, transfusion reactions, contrast-induced renal issues, abdominal compartment syndrome, bleeding, and shock.

Hypothermia in Trauma

Hypothermia is still a commonly encountered problem that the CCTP must address. Hypothermia in trauma can be attributed to environment, the injury itself, or the treatment provided. The CCTP must address hypothermia by attempting to reverse it, or prevent the onset.

Multiple studies have shown that the incidence of hypothermia in trauma can be as high as 50%. These studies also indicate that hypothermia in trauma can result in mortality rates that approach 100%. Although hypothermia does benefit select patients, it has a profound detrimental effect on trauma patients **Table 10-4**. Coagulopathy is the most profound effect of hypothermia.

Hypothermia in trauma can result from the patient being exposed to the environment, such as cold weather during a prolonged extrication. Even on a warm day, blood loss and thermoregulation loss in trauma can result in hypothermia. Hypothermia can also be induced or exacerbated by the CCTP by exposing the patient for an exam, failing to increase ambient temperature in patient care areas, and infusing fluids.

Nonwarmed infusions require the body to warm up the fluid internally, which can result in further

decreases in core temperature, expend needed energy, and stress thermoregulation mechanisms.

TABLE 10-4 Effects of Hypothermia on Trauma Patients

Impaired cardiorespiratory function
Cardiac depression Myocardial ischemia Arrhythmias Peripheral vasoconstriction Impaired tissue oxygen delivery Elevated oxygen consumption during rewarming Blunted response to catecholamines Increased blood viscosity Metabolic acidosis
Bleeding diathesis
Decreased kinetics of coagulation factors Reduced platelet function
Reduced clearance of drugs
Decreased hepatic blood flow Decreased hepatic metabolism Decreased renal blood flow
Increased risk of infection
Decreased white blood cell number and function Impaired cellular immune response Wound infection • Thermoregulatory vasoconstriction • Decreased subcutaneous oxygen tension • Impaired oxidative killing by neutrophils • Decreased collagen deposition Pneumonia Sepsis
Insulin resistance with hyperglycemia
Adapted from: Smith CE. Prevention and treatment of hypothermia in trauma patients. TraumaCare International ITACCS. Available at: http://www.itaccs.com/traumacare/archive/04_01_Spring_2004/prevention.pdf. Accessed April 23, 2009.

Treatment should focus on prevention or reduction in present hypothermia. Limit exposure of the patient as much as possible. Increase ambient temperature by using warm blankets and increasing patient compartment temperatures. This increase in temperature may be needed even on a warm day. Use of only warmed fluids is also indicated. Oxygen may be warmed and humidified as well if possible. The CCTP

should also be cognizant of the multiple other side effects of hypothermia, such reduced drug clearance. The trauma center will also employ multiple invasive and noninvasive techniques.

Diagnostic Imaging for Trauma

Obtaining and understanding imaging studies related to trauma is an integral component of the trauma care paradigm for the CCTP. The use of diagnostic imaging aids helps manage and direct further care for the trauma patient. Diagnostic imaging also confirms previous care that has been delivered, such as endotracheal tube placement and invasive catheters.

Types of diagnostic imaging were introduced in Chapter 8. There have been many exciting advances and new procedures in diagnostic imaging. We will briefly cover those that are related to the practice of the CCTP in trauma care.

Standard Radiographs

Standard radiographs, used in a stationary or portable environment, provide a beneficial starting point in most paradigms of trauma care. As mentioned in Chapter 8, standard radiographs can provide confirmation of endotracheal tube placement, cervical fractures, chest injuries, and most major bone fractures. Examples of normal and abnormal radiographs are shown in **Figure 10-8** and **Figure 10-9**.

Plain radiographs are limited in their use by access to the area to be imaged, such as obtaining all seven cervical vertebrae, and are not typically useful for advanced imaging.

Typical interpretation involves:

- Structure and landmark verification
- Proper size and placement of anatomic structure or devices Symmetry of structure
- Foreign object identification

Computed Tomography

Computed tomography is another imaging study that is of essential use for the trauma patient. For trauma patients, it is typically used for head injury identification **Figure 10-10**, identification of bleeding, and complex fractures. Typical studies will scan the head, c-spine, chest, and abdominal-pelvic regions. Interpretation is similar to that of plain radiographs because the contrast of different structures still applies.

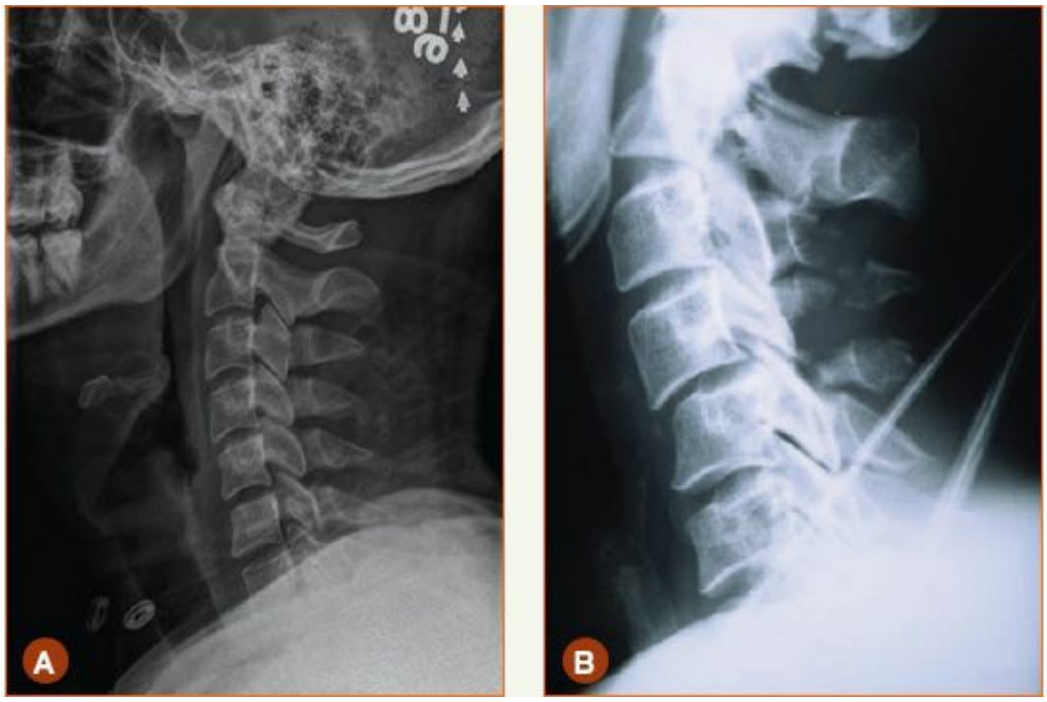

Figure 10-8 **A.** Normal cervical radiograph. **B.** Abnormal cervical radiograph.

Figure 10-9 **A.** Normal long-bone radiograph. **B.** Abnormal long-bone radiograph.

Magnetic Resonance Imaging

Once again, the contrast differences of magnetic resonance imaging (MRI) are used for identification of abnormalities in trauma **Figure 10-11**. MRI, however, may be of limited use in the major trauma patient as a result of availability and the time required to obtain images.

FAST Ultrasonography

One of the recent advances in trauma care is the **FAST** ultrasound. FAST is an acronym for Focused

Assessment with Sonography for Trauma. FAST is an ultrasound exam directed at identifying the presence of free intraperitoneal or pericardial fluids. It is typically performed in the emergency department or trauma room by trained staff. It has replaced diagnostic peritoneal lavage (DPL) and has decreased the need for laparotomy, or the exploration of the abdomen for blood by incision. However, if the FAST ultrasound is equivocal, then diagnostic peritoneal lavage or laparotomy may be performed. FAST has been adopted by some transport services as well as for use in the prehospital setting, using smaller and portable equipment **Figure 10-12**. It is showing much promise in the early identification of abdominal bleeding in trauma. Studies have also shown that the E-FAST or extended FAST exam can reliably identify chest injuries such as pneumothorax and hemothorax.

The FAST is performed by imaging four distinct areas of the abdomen. Training standards to perform this procedure vary, but at a minimum usually require some credentialing and experience.

Intra-abdominal Pressure Monitoring

Intra-abdominal pressure (IAP) is the static pressure inside the abdominal compartment. Normally, IAP is approximately 5 mm Hg with variations caused by respirations. Nonpathologic increases in IAP can occur with obesity. Recent studies of IAP in critically ill medical and surgical patients have found elevated pressures to be relatively common. The deleterious effects of intra-abdominal hypertension (IAH) can lead to **abdominal compartment syndrome (ACS)** and death if untreated. ACS is thought to play a significant role in end-organ damage and multisystem organ failure during critical illness.

IAP can be measured with a variety of commercial devices or with user-assembled equipment. The current reference standard uses a transducer connected to an indwelling urinary drainage catheter located within the bladder. IAP is expressed in mm Hg and measured at end expiration with the patient supine and the pressure transducer at the midaxillary line. The recommended technique uses a pressure transducer connected by tubing at or near the aspiration port of the urinary catheter drainage tubing. The following steps are performed.

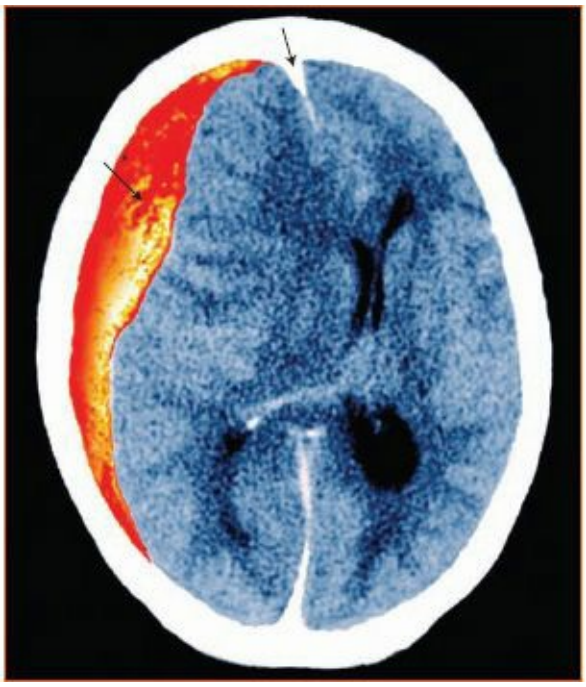

Figure 10-10 A computed tomography scan showing a head bleed with a midline shift.

Figure 10-11 Magnetic resonance image showing abnormalities of the spinal cord.

Figure 10-12 A portable FAST (Focused Assessment with Sonography for Trauma) unit.

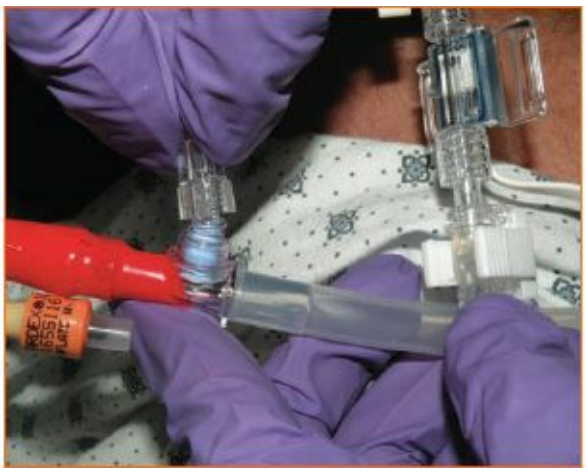

Figure 10-13 The CCTP may be asked to obtain intra-abdominal pressure measurements during transport.

1. Clamp the tubing distal to the connection.

2. Instill 50 mL or less of sterile room temperature saline through the pressure measurement system into the bladder.
3. Record the measured pressure after a 30- to 60-second stabilization period **Figure 10-13**.

IAH is defined as a sustained IAP of greater than 12 mm Hg. ACS is defined as a sustained IAP of greater than 20 mm Hg and is often associated with new-onset single- or multiorgan system failure.

There are multiple causes of IAH and not all are associated with trauma or surgical procedures to the abdomen. ACS is classified into three types:

1. Primary: Resulting from surgical interventions or injuries to the abdominal-pelvic region. Examples include damage-control exploratory laparotomy, massive retroperitoneal hematomas, liver transplantation, and failed nonoperative management of injury or disease.
2. Secondary: Develops as a result of conditions outside the abdomen, such as sepsis, burns, and capillary leakage resulting from massive fluid resuscitation.
3. Recurrent: Recurrence of ACS following initially successful surgical or medical treatment of primary or secondary ACS.

Although definitive treatment for acute ACS is surgical decompression (often with the abdomen left open until swelling is decreased), prevention through careful monitoring and targeted medical management is highly encouraged. Interventions to reduce the risk of IAH and/or to prevent IAH from progressing to ACS include neuromuscular blockade, drainage of free fluid in the abdominal cavity (paracentesis), decompression of the gastrointestinal tract using gastric tubes, prokinetic drugs (to stimulate intestinal motility), and close attention to prevention of fluid volume overload.

The CCTP may observe IAP monitoring equipment being used in the ICU or emergency department (ED) setting and may be asked to obtain IAP measurements during transport. Familiarity with the equipment in use is necessary to accurately obtain measurements.

Transport Considerations

With the rapid care of a trauma patient, not all available studies may have been performed. The CCTP should have and maintain some proficiency in interpreting imaging for obvious abnormalities. Reviewing imaging that has been performed serves to limit liability, confirm suspicions in diagnostics, and document accurate placement or performance of certain procedures. Various methods of training are available to the CCTP, and most services provide internal training as well.

Even with technology and the electronic transmission of imaging, it is still important to always ask for and ensure that all copies of the imaging studies are with patient records. Some may be as small as a disk, so care is needed not to misplace or lose them.

Thoracic Trauma

The Centers for Disease Control and Prevention reports that thoracic trauma injuries cause more than 700,000 ED visits and more than 18,000 deaths per year in the United States. Of all trauma deaths, one in four (25%) are directly associated with thoracic injuries. Given these alarming statistics, it is imperative for the CCTP to have a complex understanding of the anatomy and physiology of the thoracic cavity. However, only 15% to 20% of these potentially catastrophic injuries require open chest surgery. The majority can be managed with relatively simple interventions within the scope of the CCTP.

The thorax is essentially a bony cage consisting of 12 pairs of ribs that join anteriorly with the sternum and posteriorly with the thoracic spine **Figure 10-14**.

The chest consists of two thoracic cavities, each containing one lung. The mediastinum, which contains the heart, superior and inferior vena cava, aorta, bronchi, trachea, and esophagus, is located between the two cavities. The diaphragm inserts into the thoracic cage below the fifth rib and separates the chest and abdominal cavities. The primary function of the thorax is to allow for adequate oxygenation and circulation. Therefore, injuries to the chest must be promptly found and managed. Injuries to the thoracic region can result from either blunt or penetrating injuries; therefore, it is important for the CCTP to conduct a thorough assessment in order to avoid missing life-threatening injuries. The chest is normally a closed box with a single opening; the changes in pressure necessary for ventilation are dependent on the ribs, diaphragm, and pleural membrane all being intact and working properly. Half of all chest injuries involve the chest wall. Recent research has emphasized the importance of this relationship and normal interthoracic pressures for adequate circulation and ventilation. Especially in hypotension, excessive interthoracic pressure can interfere with blood returning to the heart. Therefore, care must be taken in trauma patients to ensure adequate positive pressure ventilations without allowing interthoracic pressure to rise too high. This may also become an issue during flight. The atmospheric pressure declines as the aircraft goes higher and gas volume expands in a closed space. This may make a small tension pneumothorax larger, and less gas will be needed to ventilate a patient using a gas-powered ventilator.

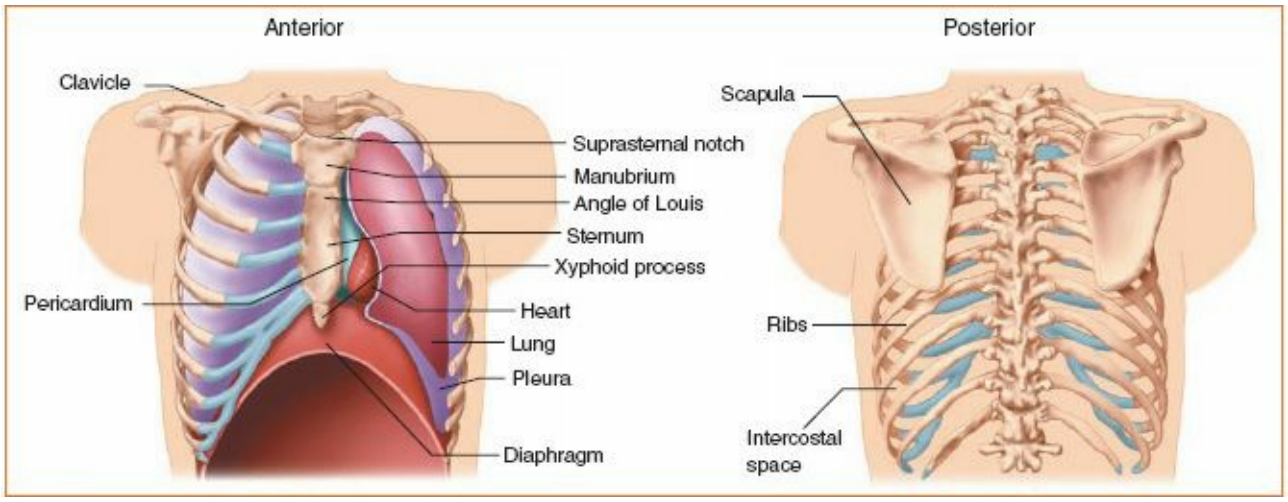

Figure 10-14 The thorax, front and back views.

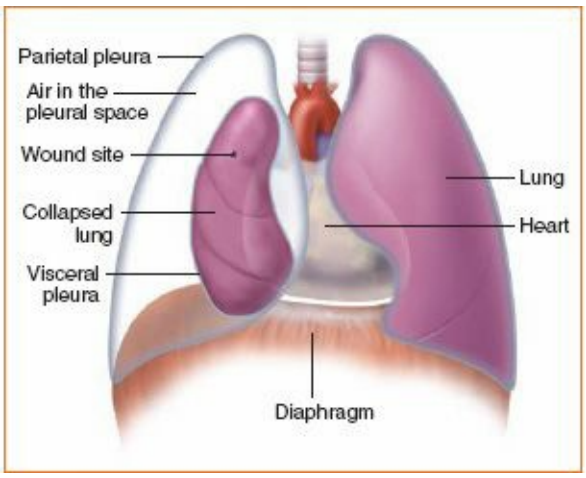

Figure 10-15 A pneumothorax occurs when air leaks into the space between the pleural surfaces from an opening in the chest or the surface of the lung. The lung collapses as air fills the pleural space.

Pneumothorax

A pneumothorax can be either open or closed **Figure 10-15** and is reported to be present in 15% to 50% of chest injuries. An open pneumothorax (also known as a communicating pneumothorax) is commonly called a sucking chest wound **Figure 10-16**, even though it does not always make a sucking noise. A tension pneumothorax occurs when a defect in the chest wall allows air to enter the thoracic space, breaking the normal adherence between the pleura (think of the suction between a wet glass and the counter top), which allows the lung to collapse **Figure 10-17**. This is often a result of a penetrating injury to the outer chest, such as a stab wound, or it can occur internally from a sharp broken rib end.

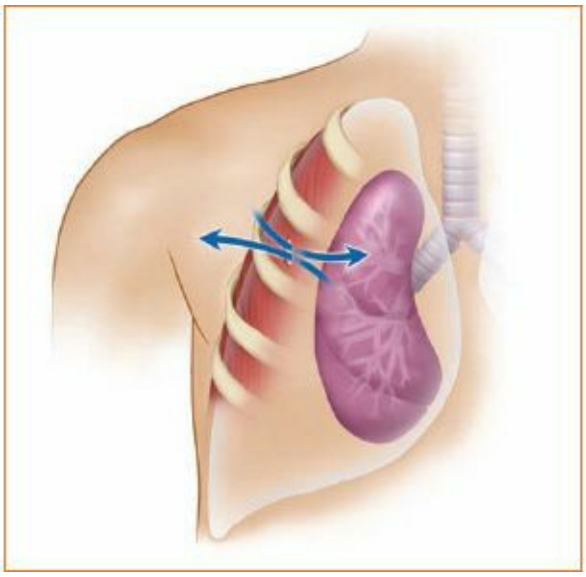

Figure 10-16 With a sucking chest wound, air passes from the outside into the pleural space and back out with each breath. The size of the defect does not need to be large to compromise ventilation.

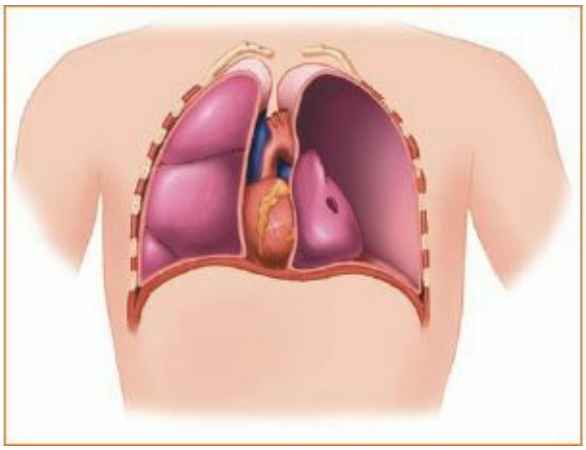

Figure 10-17 In a tension pneumothorax, air accumulates in the pleural space, eventually causing compression of the heart and great vessels.

These types of injuries cause air to be drawn into the thoracic cavity with each breath. The air enters the dead space in the pleural cavity instead of the lung; therefore, it does not oxygenate blood and it causes hypoxia. A collapse as small as 10% can be life threatening if there are other comorbidities, although a pneumothorax this small may be hard to appreciate by auscultation.

The differential diagnosis for respiratory distress in chest trauma includes the following:

- Simple pneumothorax
- Tension pneumothorax
- Flail chest

- Hemothorax
- Tracheobronchial injury
- Pulmonary contusion

Open Pneumothorax

In order to promote adequate oxygenation and ventilation, it is critical that the CCTP recognize and treat an open pneumothorax as soon as possible.

Equipment needed for managing an open pneumothorax includes the following:

- Body substance isolation equipment
- Occlusive dressing
- Medical tape

Indications include:

- Emergency relief of dyspnea secondary to open pneumothorax

Contraindications include:

- Tension pneumothorax

Complications of sealing a sucking chest wound include a tension pneumothorax. This can occur if air is still able to enter the pleural cavity from the lung side of the wound and builds up, or if the seal is incomplete. If this happens, the seal should be "burped" by releasing an edge. Many techniques of sealing sucking chest wounds attempt to address these issues, but pressure build-up or an ineffective seal may still occur. Once a seal is applied, constant surveillance is necessary to guard against either possibility. Assisted ventilation and/or needle decompression may be necessary.

Signs and Symptoms

Open Pneumothorax

- Penetrating chest trauma with a sucking sound ("sucking chest wound")
- Dyspnea
- Tachypnea

Transport Management

Open Pneumothorax

- Maintain an open airway and administer high-flow oxygen.
- Immediately close the chest wound, initially with a gloved hand.
- Apply an occlusive dressing, taped down on three sides so that a flutter value is created.
- Initiate a large-bore IV.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Watch for the development of a tension pneumothorax or an inadequate seal and the need for needle decompression or assisted ventilation.
- Consider inserting a chest tube if protocol allows.
- Monitor the chest tube drainage system during transport.

Skill Drill 10-1 illustrates the clinical procedure for managing an open pneumothorax, which is described below:

1. Maintain an open airway and administer high-flow oxygen **Step 1**.
2. Immediately close the chest wound **Step 2**. This can be initially accomplished by the use of a gloved hand. However, to reduce the risk of a tension pneumothorax, apply an occlusive dressing, taped down on three sides so that a flutter valve is created **Step 3**. Adequate overlap on the open edge is required to create a good seal. Aluminum foil does not seal on inhalation; a soft air-occlusive dressing is preferable. Several commercial devices are also available.
3. Initiate a large-bore IV to maintain peripheral perfusion **Step 4**.
4. Monitor oxygen saturation, vital signs, and the cardiac monitor **Step 5**.
5. Watch for development of a tension pneumothorax or an inadequate seal, and the need for needle decompression or assisted ventilation.
6. Transport to an appropriate facility.

Possible complications include converting an open pneumothorax to a tension pneumothorax. The CCTP should watch for increasing difficulty in breathing, peak inspiratory pressure (PIP), tracheal tugging or deviation, and jugular vein distention (JVD) as late signs.

Simple Pneumothorax

A simple pneumothorax is most often associated with a closed chest injury, such as from a fractured rib being driven inward into the lung or a collapsed lung that results from a medical cause, which is sometimes called a spontaneous pneumothorax. Loss of the negative pressure holding the two layers of the pleura together allows the lung to collapse like an empty balloon. The term actually refers to any pneumothorax that is not a tension pneumothorax and, therefore, may be used to refer to an open and a closed pneumothorax as long as there is no build-up of pressure in the pleural cavity outside the lung.

Tension Pneumothorax

A tension pneumothorax is a life-threatening injury that results from a continual influx of air into the pleural space. It may occur secondary to a closed simple pneumothorax or after sealing an open pneumothorax, which increases interthoracic pressure, hampers the body's ability to oxygenate blood or eliminate carbon dioxide from blood, and eventually collapses the affected lung. The collapse in the lung causes a shift in the mediastinum away from the injured side, resulting in ventilatory and circulatory compromise from the collapsed lung. The great vessels and the heart become deformed under the pressure. Failure to treat tension pneumothorax will cause the patient to progress to pulseless electrical activity and cardiopulmonary arrest.

Skill Drill 10-1

Managing an Open Pneumothorax

1 Maintain an open airway and administer high-flow oxygen.

2 Immediately close the chest wound, initially with a gloved hand.

3 Apply an occlusive dressing, taped down on three sides so that a flutter valve is created.

4 Initiate a large-bore IV.

5 Monitor oxygen saturation, vital signs, and the cardiac monitor. Watch for development of a tension pneumothorax or an inadequate seal, and the need for needle decompression or assisted ventilation.

Clinical signs and symptoms of a tension pneumothorax include dyspnea, anxiety, JVD (although this may be absent due to hypovolemia), tachypnea, and **tracheal deviation** (tracheal deviation is a late sign not often observed in the prehospital setting). Tracheal tugging during inspiration, a much more subtle sign, is observed much earlier in the process, but the CCTP should actively look for this sign. The most important signs, however, are increasing dyspnea or decreasing ventilatory compliance to bagging and increasing PIP or peak airway pressure, depending on settings if the patient is receiving ventilation. Auscultation of lung sounds will reveal diminished or absent breath sounds (which are difficult to appreciate in aircraft and on noisy scenes) on the affected side if the pneumothorax is large enough. Pulsus paradoxus (a pulse that disappears on inspiration that also can be associated with a drop in systolic blood pressure), electrical alternans (an alternating large QRS complex with a small QRS complex), and elevated central venous pressure (CVP) may also be present. PIP will go up despite an open airway. Management of tension pneumothorax is performed by immediate needle decompression.

Equipment for managing a tension pneumothorax includes the following:

- Body substance isolation equipment, including sterile gloves
- 14-gauge or larger IV catheter (2.5″ to 3″ is not a standard IV needle length and requires special stocking)
- 10-mL syringe with 1 to 2 mL of sterile saline in it in order to see bubbling air escaping because it is too difficult to hear in many cases
- 2% Chlorhexidine
- Flutter valve (Heimlich or nonlubricated condom or glove finger) optional
- Sterile dressings

Indications include:

- Emergency relief of tension pneumothorax

Contraindications include:

- Patient without signs of a tension pneumothorax

Skill Drill 10-2 demonstrates the clinical procedure for managing a tension pneumothorax, which is described below:

1. Assess the patient to ensure that the presentation matches that of a tension pneumothorax **Step 1**.

- Difficult ventilation despite an open airway (decreasing compliance or increasing PIP or peak airway pressure)
- JVD (may not be present with associated hemorrhage)
- Absent or decreased breath sounds on the affected side
- Hyperresonance to percussion on the affected side
- Tracheal deviation away from the affected side (this late sign is not always present)
- Electrical alternans and pulsus paradoxus
- Elevated CVP
- Signs of impending cardiovascular collapse

2. Prepare and assemble the necessary equipment **Step 2**.
   - Large-bore IV catheter, preferably 10- to 14-gauge and at least 2″ long on a syringe filled with 1 to 2 mL of sterile saline
   - Alcohol or 2% chlorhexidine
   - Adhesive tape
3. Select the appropriate site **Step 3**: midclavicular, second intercostal space, above the third rib **Figure 10-18**; or, less commonly, the midaxillary, above the fifth or sixth rib. Go over the rib to avoid the neurovascular bundle under each rib.
4. Select the largest available needle. It is optional to attach it to a syringe with a few milliliters of saline so the bubbles are visible.
5. Cleanse the site with an appropriate aseptic technique **Step 4**.
6. Make a flutter valve by inserting the needle through the end of a condom or use a commercial device such as the Asherman Chest Seal (not necessary in extremis) **Step 5**.
7. Insert the needle at a 90° angle over the rib **Step 6**.
8. Remove the needle and listen for a rush of air or look for bubbles in the syringe **Step 7**.
9. Advance the catheter over the needle and secure it in place **Step 8**.
10. Dispose of the needle in a sharps container.
11. Closely monitor vital signs, oxygen saturation, and lung compliance.
12. Be prepared to repeat decompression if necessary.

Complications include improper placement, which could lead to injury to the intercostal vessels and significant hemorrhage. Also, passing the needle into the chest may injure the lung parenchyma.

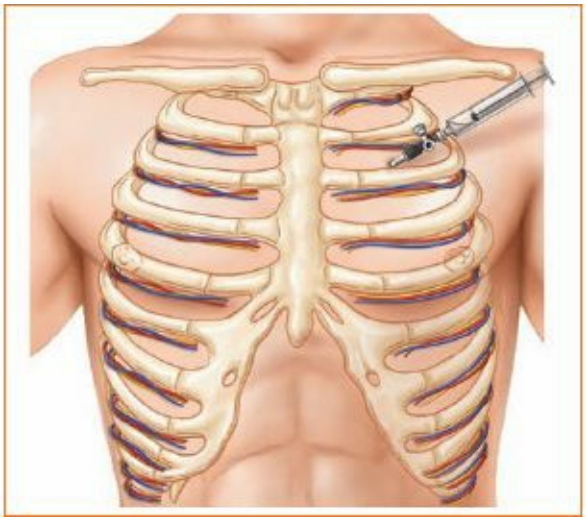

Figure 10-18 Correct placement for needle decompression. The position of nerves, arteries, and veins is shown in relation to the ribs.

Signs and Symptoms

Tension Pneumothorax

- Dyspnea
- Anxiety
- JVD
- Tachypnea
- Tracheal deviation
- Tracheal tugging during inspiration
- Decreasing ventilatory compliance to bagging
- Increasing PIP or peak airway pressure, if the patient is on a ventilator
- Diminished or absent breath sounds on the affected side, if the pneumothorax is large enough
- Pulsus paradoxus
- Electrical alternans
- Elevated CVP

Transport Management

Tension Pneumothorax

- Perform immediate needle decompression.
- Consider inserting a chest tube if protocol allows.
- Maintain the chest tube on suction during transport.

Hemothorax

Blood in the pleural space is called a hemothorax **Figure 10-19**. Each of the body's thoracic cavities can accumulate up to 3,000 mL of blood. A massive hemothorax occurs when at least 1,500 mL of blood accumulates in a thoracic cavity. A torn intercostal artery can bleed at a rate of 50 mL/min. The obvious threat from a hemothorax is hypovolemic shock, although a large amount of blood in the pleural cavity can interfere with lung function. Hemothorax can be caused by blunt trauma; however, it is more commonly a result of penetrating trauma. Medical causes include a tumor eroding through great vessels.

Skill Drill 10-2

Needle Decompression (Thoracentesis) of a Tension Pneumothorax

1 Assess the patient.

2 Prepare and assemble all necessary equipment.

3 Locate the appropriate site between the second and third rib.

4 Cleanse the appropriate area using an aseptic technique.

5 Make a one-way or flutter valve (optional).

6 Insert the needle at a 90° angle.

7 Remove the needle and listen for release of air or look for bubbling in the syringe. Properly dispose of the needle in a sharps container.

8 Secure the catheter in place. Monitor the patient closely for recurrence of the tension pneumothorax.

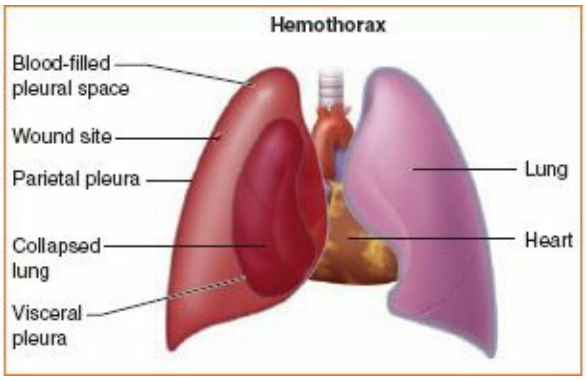

Figure 10-19 A hemothorax is a collection of blood in the pleural space produced by bleeding within the chest.

Clinical signs and symptoms of a hemothorax include hypoxia, agitation, hypotension, tachycardia, tachypnea, decreased breath sounds on the affected side, dullness to percussion on the affected side, hemoptysis, worsening shock, and falling CVP. A patient with a hemothorax rarely presents with JVD or tracheal deviation. Management of a hemothorax is supportive and is conducted as follows:

1. Maintain an open airway and apply high-flow oxygen.
2. Load and go if in the field.
3. Initiate IV fluids to maintain peripheral perfusion; however, raising blood pressure above 90 mm Hg systolic or 65 mm Hg mean arterial pressure (MAP) may increase blood loss or dislodge a clot and restart bleeding.
4. Be alert for development of a tension pneumothorax.

Management: Chest Tube Insertion

Patients with a pneumothorax, a tension pneumothorax, a hemothorax, a hemopneumothorax (combination of a pneumothorax and hemothorax) **Figure 10-20**, or an empyema ultimately may need a chest tube inserted. A chest tube is a flexible plastic tube that is inserted through the side of the chest into the pleural space **Figure 10-21**. It was traditionally attached to an underwater seal to create a one-way system allowing for air or fluid to drain from the chest with each exhalation, reestablishing the interpleural negative pressure and reinflating the lung. Modern systems no longer use a water chamber, but they have the same effect. They are used to remove air, fluid, or pus from the pleural cavity. In some systems, the CCTP may place chest tubes, but in every critical care transport system the CCTP will care for and transport patients with chest tubes in place.

Signs and Symptoms

Hemothorax

- Hypoxia
- Agitation
- Hypotension
- Tachycardia
- Tachypnea
- Decreased breath sounds on the affected side

- Dullness to percussion on the affected side
- Hemoptysis
- Worsening shock
- Falling CVP

Transport Management

Hemothorax

- Maintain an open airway; apply high-flow oxygen.
- Load and go if in the field.
- Initiate IV fluids.
- Be alert for the development of a tension pneumothorax.
- Consider inserting a chest tube if protocol allows.
- Maintain the chest tube on suction during transport.

Controversies

Use of fluids for uncontrolled internal bleeding is controversial. Although raising the blood pressure too high may increase blood loss or dislodge a clot, an adequate blood pressure of 90 mm Hg systolic or an MAP of 65 mm Hg must be maintained to perfuse the heart and brain. The ideal fluid for use is one that carries oxygen, such as blood.

The procedure for insertion of a chest tube begins with collecting the needed equipment (often packaged as a "tray"):

- Body substance isolation equipment, including sterile gloves
- Scalpel
- Chest tube: 36F to 40F

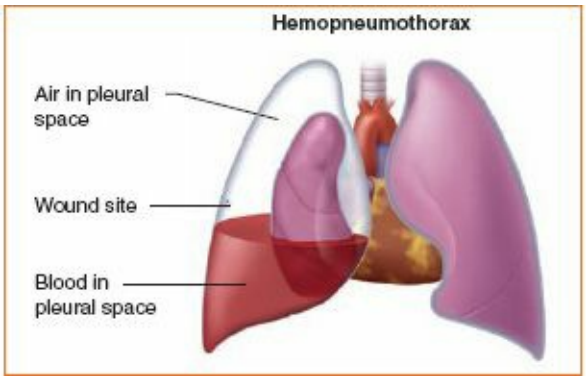

Figure 10-20 In a hemopneumothorax, both blood and air are present.

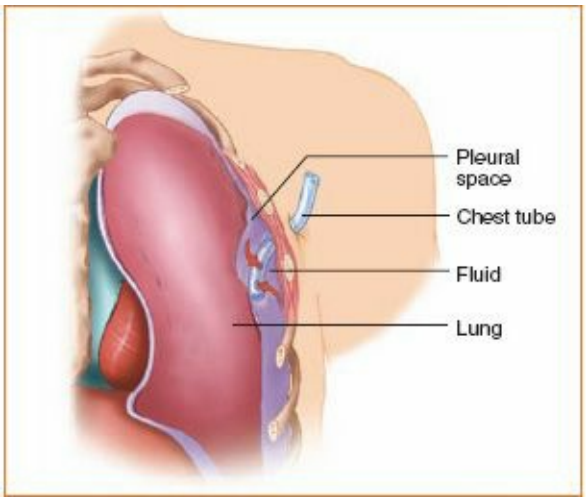

Figure 10-21 A chest tube is inserted through the side of the chest into the pleural space.

- Kelly clamps (curved and straight)
- Sterile occlusive dressing
- Suturing material
- 2% Chlorhexidine
- A local anesthetic if the patient is awake
- A fluid collection device with a one-way valve that allows air, fluid, or pus to flow out of the chest. If not available, an indwelling catheter bag with a one-way valve may be used
- Tape
- Mechanical suction device (not always used)

Indications include:

- Pneumothorax
- Hemopneumothorax
- Empyema

Complications include:

- Recurrent pneumothoraces
- Accidental removal Broken collection chamber
- Parenchymal injury
- Laceration of intercostal vessels
- Creation of a hemothorax or bleeding
- Misplacement below the diaphragm
- Infection

Skill Drill 10-3 shows the clinical procedure for inserting a chest tube, which is described below:

1. Select the appropriate site: midaxillary over the fifth rib **Step 1**.
2. Connect the indwelling catheter bag or the collection device to the distal end of the one-way valve with a rubber band **Step 2**. Be certain that the arrow on the valve is facing away from the patient.
3. Cleanse the site with an appropriate aseptic technique **Step 3**.

4. Anesthetize the area, including the pleura and periosteum, over the fifth rib **Step 4**, if the patient is conscious and time permits. If possible, place the patient in a 30° reverse Trendelenburg (head up) position so blood drains to the low end of the lung.
5. Mark the tube for the desired length of insertion **Step 5**.
6. Clamp the distal end of the tube with a large clamp (such as a Kelly clamp) and the proximal end of the tube with a curved clamp.
7. Make a transverse incision over the fifth rib in the midaxillary line **Step 6**. If the patient has fractured ribs, use the midclavicular line (between the midaxillary line and the nipple line).
8. Tunnel over the fifth rib with a large curved clamp, push through the pleura, spread the clamp, and leave it in place **Step 7**.
9. Grasp the clamp attached to the end of the chest tube and advance it through the space created by the first clamp, directing it posteriorly and downward toward the diaphragm **Step 8**.
10. Remove the clamps and advance the tube to the predetermined mark indicated on the tube, at least 5 cm beyond the last hole **Step 9**.
11. Connect the collection device **Step 10**.
12. Remove the distal clamp **Step 11**.
13. Suture the tube in place and close the wound **Step 12**.
14. Note the depth of the tube at the skin (marked on the tube) and mark with a felt-tip pen.
15. Cover the insertion site with an occlusive dressing and reinforce all connections with tape **Step 13**.
16. Upon arrival at the receiving facility, obtain a chest radiograph to confirm placement.
17. Document the procedure, including the size of the chest tube inserted, the amount of return of air/fluid after insertion of the tube, and any changes in patient condition (including oxygen saturation).

Skill Drill 10-3

Chest Tube Insertion

1 Select the appropriate site.

2 Connect the collection device to the distal end of the one-way valve with a rubber band.

3 Cleanse the site with an appropriate aseptic technique.

4 Anesthetize the area, including the pleura and periosteum, over the fifth rib.

5 Mark the tube for the desired length of insertion. Clamp the distal end of the tube with a large clamp and the proximal end of tube with a curved clamp.

6 Make a transverse incision over the fifth rib at the midaxillary line. If the patient has fractured ribs, use the midclavicular line (between the midaxillary line and the nipple line).

7 Tunnel over the fifth rib with a large curved clamp, push through the pleura, spread the clamp, and leave it in place.

8 Grasp the clamp attached to the end of the chest tube and advance it through the space created by the first clamp.

9 Remove the clamps and advance the tube to the predetermined mark indicated on the tube.

10 Connect the collection device with the one-way valve.

11 Remove the distal clamp.

12 Suture the tube in place and close the wound.

13 Cover the insertion site with an occlusive dressing. Upon arrival at the receiving facility, obtain a chest film to confirm placement. Document the procedure.

When transporting a patient with a chest tube in place:

- Make sure all connections are taped or banded with wire to prevent accidental separation.
- Ensure that the dressing over the insertion site is securely taped and occlusive. Use a felt-tip marker to mark the depth of the tube; if there are markings, note the depth of the tube on the transfer chart.

Make sure the tube is sutured, wired, or taped so it cannot be accidentally pulled out.

- Maintain the drainage unit below the level of the chest at all times during transport. Many units have bed hangers so that the unit can be hung on the stretcher. If there is water in the unit, keep it upright at all times. If attached to a suction device, find out if the suction can be discontinued for transport; if not, attach it to portable suction.
- Tubing should be kept coiled to prevent kinks or dependent loops.
- Access and document bubbling in the water seal (does not have to be continuous), any output in the collection chamber, and its type (eg, frank blood).
- Do not clamp tubes for transport. This is likely to cause a tension pneumothorax.
- Continuous bubbling may be a sign of tracheobronchial laceration. Large amounts of frankly bloody drainage need to be balanced by transfusion.

Management: Blood Administration

Because of the potential for massive hemorrhage from thoracic trauma, the CCTP must be familiar with the administration of blood. The steps for administering blood are covered in Chapter 9.

Flail Chest

A fracture in two or more places to two or more adjacent ribs is a flail chest or a flail segment **Figure 10-22**. Flail chest was found to be present in as many as a third of serious chest injuries in one study. Many escape detection for as long as 6 hours after hospital admission. A central flail involves the sternum. A flail segment may appear to move paradoxically relative to the chest wall but actually is stationary while the rest of the chest moves around it. This movement may be more obvious in unconscious patients who are no longer "splinting." Often, bruises to the underlying tissue can cause a pulmonary or myocardial contusion and represent the most dangerous sequelae of a flail chest. Flail segments are generally caused from blunt trauma, such as striking a steering wheel in a motor vehicle collision (MVC).

Signs and Symptoms

Flail Chest

- Dyspnea
- Severe pain
- Decreased breath sounds on the affected side
- Tenderness
- Crepitus to palpation
- Bruising over the area

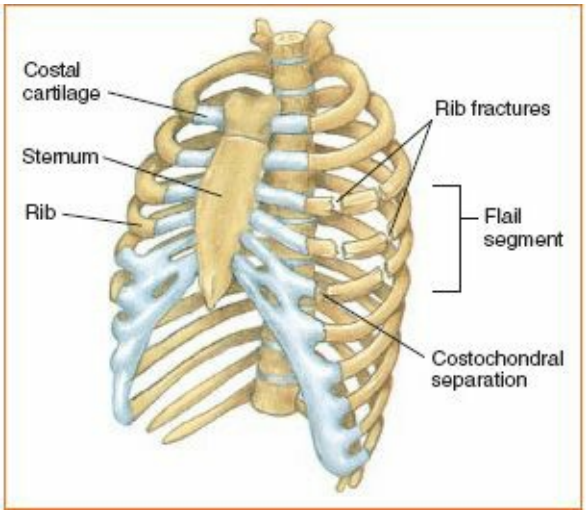

Figure 10-22 In flail chest injuries, two or more adjacent ribs are fractured in two or more places. A flail segment may move paradoxically when the patient breathes, but this is usually only present in the very young, the elderly, or other patients with underdeveloped pectoral and lattisimus muscles.

Transport Management

Flail Chest

- Maintain an open airway; apply high-flow oxygen.
- Assist ventilation with a trial of continuous positive airway pressure; be prepared to intubate.
- Load and go if the patient is a field transport.
- Initiate IV fluids.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Be alert for development of tension pneumothorax, hemothorax (shock), or respiratory failure secondary to a pulmonary contusion.

Clinical signs and symptoms of a flail chest are dyspnea, severe pain, decreased breath sounds on the affected side, tenderness, and crepitus to palpation with possible bruising over the area. Signs and symptoms are often difficult to assess as a result of the patient's efforts to splint the area and ease respiration, and may mask abdominal tenderness.

Flail segments pose a threat to the patient's ability to breathe, increase the risk for developing a hemothorax or pneumothorax, and require immediate treatment.

Management

Management of a flail chest is as follows:

1. Maintain an open airway and apply high-flow oxygen.
2. Assist ventilation with a trial of continuous positive airway pressure and be prepared to intubate.
3. Load and go if a field transport.
4. Initiate IV fluids to maintain peripheral perfusion.
5. Monitor oxygen saturation, vital signs, and the cardiac monitor. Be alert for development of tension pneumothorax, hemothorax (shock), or respiratory failure secondary to a pulmonary contusion.
6. The gold standard treatment for flail chest is mechanical ventilation (also known as internal fixation)

with a sedate, paralyzed patient who has been adequately treated for pain. It may be possible to manage some patients conservatively with pain medications and oxygen supplementation alone.

7. Use of attempts to splint (also called external fixation) or wrap the chest has been shown to be ineffective, and this practice has been abandoned.

Pericardial Tamponade

Pericardial tamponade is a life-threatening condition that requires immediate treatment. This condition is reported in 2% of penetrating injuries to the chest and upper abdomen. It is more common in stab wounds to the heart (as much as 80%) than in gunshot wounds. The pericardium normally contains a small amount of fluid that cushions and lubricates the heart as it expands and contracts. When an abundance of blood or fluid accumulates, it compresses the ventricles of the heart, thus compromising cardiac filling and output **Figure 10-23**. Abnormal amounts of fluid may result from:

- Pericarditis caused by infection and inflammation
- Trauma
- Surgery or other invasive procedures performed on the heart
- Cancer
- Myocardial infarction and congestive heart failure
- Renal failure

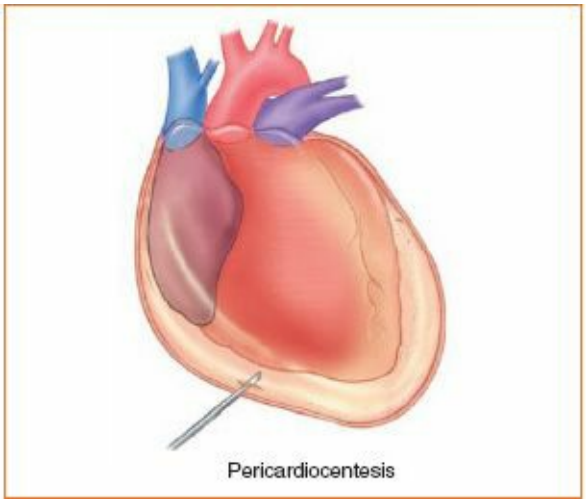

Figure 10-23 Needle aspiration in pericardial tamponade.

Signs and Symptoms

Pericardial Tamponade

- Beck's triad: narrowing pulse pressure, jugular vein distention, and muffled heart tones
- Paradoxical pulse
- Electrical alternans
- Progressive decreases of electrocardiographic (ECG) voltage
- Hypotension
- Cyanosis
- Dyspnea
- Tachycardia

- Pulseless electrical activity
- Rising CVP greater than 15 cm H_2O
- Widened mediastinum on chest radiograph

Transport Management

Pericardial Tamponade

- Provide supportive care.
- Administer a fluid bolus.
- If necessary, perform an emergency pericardiocentesis.

Classic clinical signs and symptoms of a pericardial tamponade are called **Beck's triad**: narrowing pulse pressure, JVD, and muffled heart tones. However, Beck's triad is only present 10% to 40% of the time and can be difficult to assess in the transport environment. With a low blood volume, there may be no JVD. Additionally, the patient may present with a paradoxical pulse (loss of radial pulse upon inspiration, often with a drop of 10 to 15 mm Hg systolic pressure as well), electrical alternans, progressive decreases of ECG voltage, hypotension, cyanosis, dyspnea, tachycardia, and pulseless electrical activity. A rising CVP greater than 15 cm of water may also be present (until precipitous decompensation), especially if the patient is otherwise normovolemic. Chest radiographs may show a widened mediastinum. Actual diagnosis is usually done with an ultrasound exam (FAST exam, discussed previously in this chapter), using a portable FAST unit.

Management

Most often, the prehospital management is only supportive, and a fluid bolus may buy some time; however, the CCTP may be called upon to perform or assist in an emergency **pericardiocentesis**.

The equipment needed for this procedure includes:

- Body substance isolation equipment, including sterile gloves, gown, and mask
- Cardiac monitor and defibrillator
- Pericardiocentesis kit (Mansfield catheter)
- 50-mL Luer-lock syringes
- Sterile tubes for specimen collection
- 2% Chlorhexidine
- Appropriate medications (cardiac, sedating, and numbing)
- Pigtail catheter
- Drapes
- 16- to 18-gauge by 5½″ spinal needle
- Three-way stopcock
- Sterile alligator clip
- Scalpel
- Assorted needles and syringes
- Preferably, the availability of ultrasound imaging

Indications include:

- Chest trauma with patient in extremis such as pulseless electrical activity
- FAST exam showing pericardial blood with clinical signs

Contraindications include:

- No demonstrable pericardial effusion
- Severe thrombocytopenia or noncorrectable coagulopathy
- Skin or soft-tissue infection at the proposed needle site (except in a critical patient)

Complications include:

- Malignant ventricular arrhythmias, including cardiac arrest
- Puncture of the ventricles or atria (most commonly the right ventricle)
- Laceration of the coronary arteries and lung
- Pericardial tamponade from a myocardial laceration
- Air embolism
- Acute pulmonary edema
- Puncture of the liver or stomach
- Infection

Skill Drill 10-4 illustrates the clinical procedure for pericardiocentesis, which is described below:

1. Prepare the equipment and obtain baseline vital signs, including pulse oximetry findings.
2. Place the patient into a supine position with the head of the stretcher elevated 20° to 30° as tolerated.
3. Premedicate per protocol or online medical control.
4. Don a mask, gown, hair cover, and sterile gloves.
5. Cleanse the site with an appropriate aseptic technique and drape the area **Step 1**.
6. Identify the needle entry site directly below the xiphoid—approximately 1 cm left of midline **Step 2**.
7. Infiltrate the area with 1% lidocaine into the skin and deeper tissues, if the patient is conscious **Step 3**.
8. Insert the needle-on-syringe with 2 to 3 mL of sterile saline in it at the identified entry site, at a 30° angle directed toward the left shoulder or directly cephalad. Once the needle is deeper than the skin, inject the saline to remove any skin from the needle **Step 4**.
9. Gently aspirate while inserting the needle **Step 5**. Some resistance may be felt as the needle enters the pericardial sac. *If the needle is advanced too far, the myocardium will become irritated. The needle may vibrate with the pulse. The needle should be pulled back slightly until fluid can be aspirated.*
10. If blood is withdrawn and placed in an open container, it should not clot if it comes from the pericardial sac. A sample can be placed into the collection container and transported with the patient.
11. Administer medications per protocol or online medical control.
12. Monitor for postprocedure complications.
13. Monitor vital signs and for JVD at 15-minute intervals for 1 hour, and then every hour for 4 hours.
14. The entire procedure is often done under ultrasound guidance as well.

15. In some cases, a catheter may be placed with a stopcock for periodic drainage as needed.

Aortic Dissection/Transection

Traumatic aortic rupture is the most common cause of immediate death in MVCs. The body's entire blood volume passes through the aorta; therefore, it is easy to understand how death could be immediate. Most victims die within minutes, often prior to the arrival of the CCTP. Those who do survive require surgical intervention as soon as possible.

Skill Drill 10-4

Pericardiocentesis

1 Prepare the equipment and obtain baseline vital signs, including pulse oximetry findings. Place the patient into a supine position with the head of the stretcher elevated 20° to 30° as tolerated. Premedicate per protocol or on-line medical control. Don a mask, gown, hair cover, and sterile gloves. Cleanse the site with an appropriate aseptic technique and drape the area.

2 Identify the needle entry site directly below the xiphoid.

3 Infiltrate the area with 1% lidocaine into the skin and deeper tissues.

4 Insert the needle-on-syringe at the identified entry site, at a 30° angle directed toward the left shoulder or directly cephalad.

5 Gently aspirate while inserting the needle. *If the needle is advanced too far, the myocardium will become irritated. The needle should be pulled back slightly until fluid can be aspirated.* A blood sample can be placed into the collection container and transported with the patient. Administer medications per protocol or on-line medical control. Monitor for postprocedure complications. Monitor vital signs and for JVD at 15-minute intervals for 1 hour, and then every hour for 4 hours.

The most widely accepted etiology of traumatic aortic tears is that the aorta is injured at the ligamentum arteriosum, the remnant of the fetal ductus arteriosus, as a result of decelerating injuries and sheer force. Tears in the ascending aorta are almost uniformly immediately fatal, but patients with tears on the descending side have about a 15% chance of staying alive until they reach the operating room. There is a 30% mortality rate among those who make it to the hospital. Some trauma centers are now using endovascular stenting with some success. Diagnosis of traumatic aortic tears is very difficult in the prehospital setting and is even missed in the hospital. The CCTP should closely evaluate the mechanism of injury to assess the likeliness of an aortic injury. There may be a pulse deficit or blood pressure difference from one arm to the other if the dissection is at the top of the arch of the aorta. Other signs include hypotension; decreased level of consciousness (due to decreased carotid pressure); hypertension of the upper extremities; decrease of pulse amplitude in the lower extremities; a difference in blood pressure between the two arms (if the dissection is beyond the left subclavian artery), usually greater than 15 to 20 mm Hg; chest pain; chest wall bruising; widened mediastinum on chest radiograph with blurring of the aortic knob; and fractures of the first and second ribs. Definitive diagnosis is made with computed tomography and transesophageal echocardiography.

Signs and Symptoms

Traumatic Aortic Rupture

- Pulse deficit or blood pressure difference from one arm to the other
- Hypotension
- Decreased level of consciousness
- Hypertension of the upper extremities
- Decrease of pulse amplitude in the lower extremities
- Decrease in blood pressure
- Chest pain
- Chest wall bruising
- Widened mediastinum on chest radiograph with blurring of the aortic knob
- Fractures of the first and second ribs

Transport Management

Traumatic Aortic Rupture

- Maintain an open airway; apply high-flow oxygen.
- Assist ventilation; be prepared to intubate.
- Initiate IV fluids.
- Administer beta-blockers (eg, esmolol or metoprolol) and withhold fluids to keep the MAP at 65 to 70 mm Hg.
- Load and go.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Transport to an appropriate facility with early advance notification.

Management

Potential aortic tears are managed as follows:

1. Maintain an open airway and apply high-flow oxygen.
2. Assist ventilation and be prepared to intubate.
3. Initiate IV fluids to maintain blood pressure only at 90 mm Hg systolic or 65 mm Hg MAP.
4. Medications such as beta-blockers (eg, esmolol or metoprolol) and withholding fluids may be used to keep the MAP around 65 to 70 mm Hg.
5. Load and go.
6. Monitor oxygen saturation, vital signs, and the cardiac monitor.
7. Transport to an appropriate facility with early advance notification.

Use of a pneumatic antishock garment is contraindicated.

Myocardial Contusion

A bruise to the myocardium is primarily the result of blunt trauma to the anterior chest wall. MVCs are the obvious mechanism of injury, but other blows to the front of the chest (eg, gunshot to a bulletproof vest) may also be a cause. Estimates vary widely and put the incidence of myocardial contusion at 16% to 76%

of blunt chest trauma. Several have been reported even in low-speed (20 to 35 mph) MVCs, without external chest wall bruising. The amount of damage to myocardial cells varies widely as well. A bruise is damage to small blood vessels, causing local bleeding and direct trauma to cells. The areas downstream from damaged vessels are no longer being perfused, causing damage similar to a myocardial infarction.

Assessment

The most common signs and symptoms are similar to those of an acute myocardial infarction: chest pain, palpitations, and arrhythmias. Arrhythmias may develop as late as 12 to 72 hours after injury. Arrhythmias to watch for include premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation. ST-segment elevations may be evident on the 12-lead ECG, particularly the right-sided (V_4R) leads. Bundle-branch blocks, especially on the right, and atrioventricular blocks may develop if the intraventricular septum is involved. The wider the QRS is in a bundle-branch block, the more the ventricles are out of phase, reducing the ejection fraction. Other signs include cardiac murmur, pericardial friction rub, and persistent tachycardia without other cause. Troponin I and T are very specific to cardiac injury. The creatine kinase MB is not used. If the injury is large enough, cardiogenic shock may result from reduced contractile ability of the myocardium.

Signs and Symptoms

Myocardial Contusion

- Chest pain
- Palpitations
- Arrhythmias: premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation
- ST-segment elevation on the 12-lead ECG, particularly the V_4R leads
- Bundle-branch blocks, especially on the right side
- Atrioventricular blocks
- Cardiac murmur
- Pericardial friction rub
- Persistent tachycardia without other cause
- Cardiogenic shock

Transport Management

Myocardial Contusion

- Administer oxygen.
- Provide pharmacologic treatment of arrhythmias.
- Watch closely for development of hemopericardium, leading to pericardial tamponade, myocardial rupture, or ventricular aneurysm.

Management

Treatment is similar to that of a myocardial infarction—oxygen, pharmacologic treatment of arrhythmias, and a close watch for the development of hemopericardium leading to pericardial tamponade, myocardial

rupture, or ventricular aneurysm. Aspirin and fibrinolytics are contraindicated.

Diaphragmatic Rupture

Rupture of the diaphragm may come from either blunt or penetrating trauma. Penetration inferior to the nipples or scapula may lacerate the diaphragm. These lacerations are usually small and not an acute problem, but will require eventual surgical repair. A larger problem is blunt compression of the abdomen causing a large rupture and herniation of abdominal organs into the thoracic cavity. This impinges on lung function and decreases venous return, thus both ventilatory and cardiac output are reduced. Signs and symptoms include abdominal pain, acute respiratory distress, decreased breath sounds, or abdominal sounds in the chest cavity. There may be subcutaneous emphysema or obvious penetration in the area previously noted. If enough of the abdominal organs are herniated into the chest, the abdomen may be sunken and appear empty. Management includes supporting ventilation and oxygenation. Use of a pneumatic antishock garment is contraindicated. There are controversial recommendations to limit positive-pressure ventilations and to insert a nasogastric or orogastric tube to decompress the stomach.

Signs and Symptoms

Diaphragmatic Rupture

- Abdominal pain
- Acute respiratory distress
- Decreased breath sounds
- Abdominal sounds in the chest cavity
- Subcutaneous emphysema
- Obvious penetration in the abdomen
- Sunken abdomen and/or abdomen that appears empty

Transport Management

Diaphragmatic Rupture

- Assist ventilation.
- Administer oxygen.
- Insert a nasogastric or orogastric tube to decompress the stomach (controversial).

Tracheobronchial Disruption

Tracheobronchial injuries are rare, but often life threatening. These occur in less than 3% of blunt and penetrating chest injuries, but may have up to a 30% fatality rate. More commonly caused by penetrating injury, most injuries occur within an inch and a half of the carina, but can occur anywhere along the tracheobronchial tree. The leakage of air may cause a tension pneumothorax or a tension pneumomediastinum, which will act like a cardiac tamponade. Signs and symptoms include severe respiratory distress, hypoxia, tachycardia, subcutaneous emphysema, especially in the neck, hemoptysis, JVD, and tracheal deviation. An apparent tension pneumothorax that does not improve after needle thoracostomy or one with continuous flow of air from the needle or chest tube is probably a

tracheobronchial tear. Management includes judicious use of ventilatory support. If positive-pressure ventilation makes the patient worse and no relief is obtained from needle decompression, then oxygen supplementation alone may be necessary. A chest tube may be indicated, whereas rapid sequence intubation (RSI) is contraindicated. The muscle tension of the neck may be the only thing holding the trachea in place. Paralysis of the muscles may allow retraction of the trachea into the chest.

Signs and Symptoms

Tracheobronchial Disruption

- Severe respiratory distress
- Hypoxia
- Tachycardia
- Subcutaneous emphysema, especially in the neck
- Hemoptysis
- Jugular venous distention
- Tracheal deviation

Transport Management

Tracheobronchial Disruption

- Administer oxygen.
- Provide positive-pressure ventilation, unless it worsens the patient's condition.
- Perform needle decompression, if necessary.
- Insert a chest tube, if necessary and if protocols allow.

Pulmonary Contusion

Tearing and lacerations to the lung tissue can cause bleeding and leakage of plasma into alveoli and the interstitial spaces around them **Figure 10-24**. This damage occurs when the lung hits the inside of the chest wall (such as in flail chest injury) or as a result of shearing force causing stretching and tearing between fixed and movable parts of the lung. Pressure waves from explosions also stretch and tear the lung tissue. Blood in and around the alveoli interferes with gas exchange and leads to severe hypoxemia. This bleeding may be rapid, but more often develops over hours; the patient's deterioration may be 24 hours or more. Uninjured parts of the lung undergo thickening of the alveolar capillary membranes over time as well.

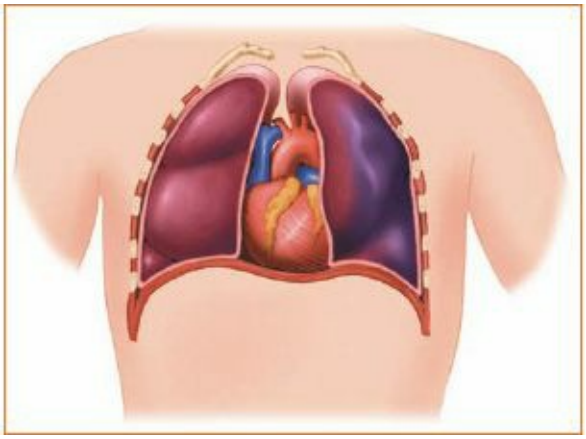

Figure 10-24 Pulmonary contusion.

Patients with flail chest or similar significant mechanisms of injury must be assumed to have a developing pulmonary contusion. Signs and symptoms may initially be absent, but over time the condition of the traumatized patient deteriorates, at which point the CCTP is called to transfer the patient to a more sophisticated medical center. The primary sign of this deterioration is increasing hypoxia. Definitive chest radiographs will show an opacity in the area of chest wall damage, but a clear chest radiograph does not rule out the pulmonary contusion. Worsening blood gases over time with a pertinent mechanism of injury are sufficient to make the diagnosis.

Signs and Symptoms

Pulmonary Contusion

- Initially absent (no signs and symptoms)
- Increasing hypoxia
- Opacity in the area of chest wall damage on chest radiograph
- Worsening blood gas levels over time

Transport Management

Pulmonary Contusion

- Provide ventilatory support: either (1) intermittent mandatory ventilation and positive end-expiratory pressure of 10 to 15 cm H_2O or (2) continuous positive airway pressure at 10 to 15 cm H_2O.
- Provide adequate analgesia.
- Give resuscitation fluids.

Treatment is to support ventilation with mechanical ventilation traditionally done with intermittent mandatory ventilation and a positive end-expiratory pressure of 10 to 15 cm H_2O. Now, more patients are successfully supported on noninvasive continuous positive airway pressure at 10 to 15 cm H_2O. In either case, especially in the presence of flail chest, adequate analgesia must be used. Some studies suggested fluid restriction for these patients, but that has largely been replaced with judicious use of necessary fluids to maintain adequate CVP or MAP. In the field, resuscitation fluids should be given as needed for

systolic pressure support.

Esophageal Perforation

Esophageal perforations are most often caused by penetrating injuries, such as from projectiles or from caustic ingestion. They can also be from a medical cause, such as cancer or gastroesophageal reflux disease erosions. Excessive vomiting may cause a Mallory-Weiss tear.

Signs and symptoms include pain, fever, dysphagia, subcutaneous air in the neck and neck stiffness, and pleuritic-type pain. Free mediastinal air or widening may be found on imaging studies. The air introduced into the mediastinum may produce a crunching sound on auscultation.

Treatment is supportive of the ABCs. A nasogastric tube insertion is usually contraindicated or should be placed with extreme care.

Signs and Symptoms

Esophageal Perforation

- Pain
- Fever
- Dysphagia
- Subcutaneous air in the neck and neck stiffness
- Pleuritic-type pain
- Free mediastinal air or widening on imaging studies
- A "crunching" sound on auscultation

Transport Management

Esophageal Perforation

- Manage the ABCs.
- If a nasogastric tube is inserted, use extreme care.

Traumatic Asphyxia

Traumatic asphyxia describes a severe, sudden crushing injury to the chest and abdomen such as a patient being caught between a truck backing up and a loading dock or a car falling off a jack. This forces blood backward out of the right side of the heart, engorging the veins of the chest, neck, and head. The deoxygenated blood makes the chest, neck, and head look blue or purple, as in extreme cyanosis, giving rise to the name asphyxia **Figure 10-25**. It is not a form of asphyxia nor is it by itself fatal, despite its undeserved reputation for high mortality. Associated injuries, if present, are far more serious. These include brain hemorrhage, possible cardiac rupture, eye injuries, flail chest, ruptured diaphragm, and pulmonary or myocardial contusions. If the patient survives the initial injury, the dramatic purple color fades after several weeks.

Specific assessment findings, besides the mechanism of injury and the purple discoloration, include JVD, conjunctival bleeding, and a sharp line of demarcation with normal skin color below. Treatment is primarily supportive with treatment for the associated injuries. If the patient is found entrapped, IVs and a

treatment plan to deal with sudden hypotension and possible release of myoglobin and potassium are necessary when the patient is released. (The patient may have crush syndrome, depending on how long he or she has been entrapped.)

Figure 10-25 Traumatic asphyxia.

Signs and Symptoms

Traumatic Asphyxia

- Blue or purple color of the chest, neck, and head
- Associated injuries
- JVD
- Conjunctival bleeding
- Sharp line of demarcation with normal skin color below

Transport Management

Traumatic Asphyxia

- Provide supportive care.
- Treat the associated injuries.
- If the patient is found entrapped, insert IVs and develop a treatment plan to deal with sudden hypotension and possible release of myoglobin and potassium when the patient is released.

Facial Trauma

Facial trauma can be life threatening and has many implications for patients socially and regarding self-image. Facial trauma can be distracting for providers as well. Facial injuries are of special significance because the patient experiences an immediate life threat as a result of airway compromise and the ability to get sensory information through sight and hearing. The CCTP must also be aware of his or her own emotional response and reactions to these injuries.

Ear Injuries

Ear injuries are generally not considered an area of concern for CCTPs because these are not life threatening nor do they involve technology for transport. They may be present in patients who have other more serious injuries, but ear injuries usually do not need much attention on either a scene call or an interfacility transport. A punctured eardrum, however, may cause vertigo and nausea, which the CCTP may need to control with medication. The patient should be protected from aircraft noise.

External Ear Injury

External ear injuries are considered a local injury with no acute systemic implications. Long-term possibility of infection or deformity (cauliflower ear) is not usually life-threatening. Standard soft-tissue injury care applies **Figure 10-26**. Blood or fluid coming from the auditory canal indicates more serious injury. A halo test for cerebrospinal fluid mixed with blood, indicating basilar skull fracture, is easily done with a piece of filter paper or a gauze pad. Do not pack the ear canal; rather, use a loose dressing instead. Chapter 11 covers neurologic emergencies in depth.

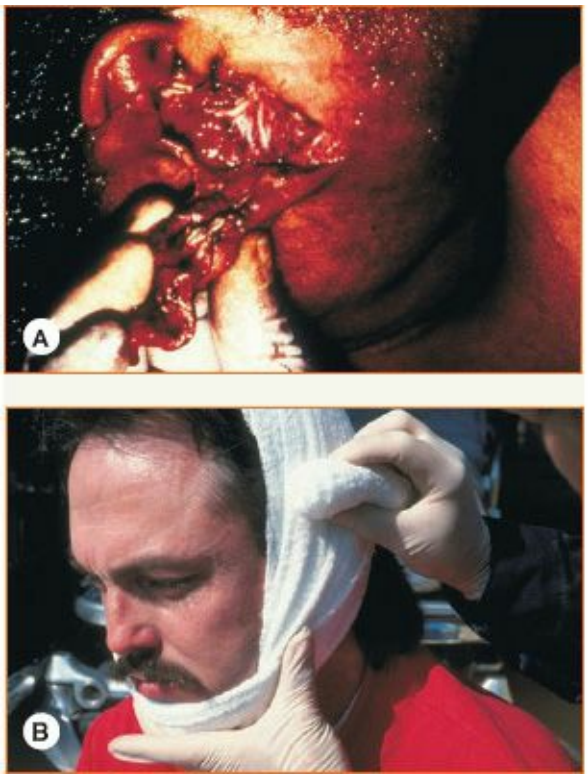

Figure 10-26 **A.** A major laceration of the ear. **B.** Place a soft, sterile pad behind the ear, between it and the scalp. Then wrap a roller gauze bandage (eg, Kling® or Kerlex®) around the head to include the entire ear.

Ruptured Tympanic Membrane

A ruptured tympanic membrane may be the result of overpressure injury, such as from an explosion or

from a direct blow to the ear. Rupture may also be the result of failure to equalize middle ear pressure during scuba diving. In the absence of infection, most will heal spontaneously and are not life threatening, but should raise the suspicion of other, much more serious overpressure injuries. Principal signs and symptoms are pain and vertigo, possibly accompanied by vomiting. There may be blood visible in the ear canal. Treatment includes external dressing to reduce the chance of infection (do not pack the ear canal), possible use of an antiemetic, and a relative contraindication to aircraft transport of the patient.

Signs and Symptoms

Ruptured Tympanic Membrane

- Pain
- Vertigo
- Vomiting
- Blood visible in the ear canal

Transport Management

Ruptured Tympanic Membrane

- Apply an external dressing (do not pack the ear canal).
- Administer an antiemetic, if necessary.
- Do not transport the patient by air, if possible.

Eye Injuries

The CCTP may transport patients with eye injuries from the field or from a local hospital to a specialty center with ophthalmologic services. Eye injuries, although often dramatic, are not life threatening. Although vision loss is serious, there is usually little for the CCTP to do other than protect the eye from further injury and transport the patient to the ophthalmology service. The major exception is chemical burns to the eye **Figure 10-27**. This is a case in which transport can actually interfere with appropriate care. Adequate washing is essential and should be performed with (preferably) sterile saline or dextrose solution for at least 10 minutes prior to transport for acid burns and at least twice as long for alkali burns. Lavage should then continue en route if possible, which may be difficult in an aircraft. Use of topical anesthesia such as tetracaine or opthane is necessary for flushing to be effective. The CCTP must be alert to the possibility of other more serious injuries that may have been overlooked and should always be treated first. There are many techniques for irrigating the eyes; the Morgan® Lens is one.

Figure 10-27 **A.** Chemical burns typically occur when an acid or alkali is splashed into the eye. **B.** A chemical burn from lye, an alkaline solution.

Eyelid Lacerations

Soft-tissue injuries to the eye and surrounding structures include lacerations and swelling. Direct pressure applied in a manner not to push on the globe (pressure directly on the globe may cause vagal stimulation) usually stops bleeding. Application of cold may reduce swelling. The CCTP should have concern for concomitant eye injuries.

Conjunctival and Corneal Injuries

The most common conjunctival and corneal injuries are abrasions and foreign bodies. More serious injuries involve shrapnel from high-speed equipment such as drills and saws. These often involve objects impaled in the eye. If possible, the eye and the object should be prevented from movement for transport. A cup or shield is generally used **Figure 10-28**. The unaffected eye may need to be patched to prevent sympathetic movement. Removal of most objects will need to be visualized with a slit lamp or ocular loupe under local anesthetic.

Hyphema

A hyphema is a collection of blood in the anterior chamber of the eye **Figure 10-29**. It may be the result of blunt trauma to the eye or a medical cause. It may be a marker of damage to other structures of the eye and, therefore, requires a full ophthalmologic examination. One of the concerns is blood clotting in the canal connecting the anterior to the posterior chamber, causing an acute rise in intraocular pressure. The patient will complain of reduced vision directly proportional to the size of the hyphema. Often the blood is visible unaided, but shining a penlight obliquely at the globe may help to visualize the blood, which will pool with gravity. If there are no other contraindications, transport should be with the patient sitting as upright as possible and both eyes patched. Pain should be managed with acetaminophen with or without codeine and aspirin; other medications with antiplatelet effects should be avoided. An anxiolytic

may facilitate transport.

Figure 10-28 An impaled object is secured with a protective barrier and a bulky dressing.

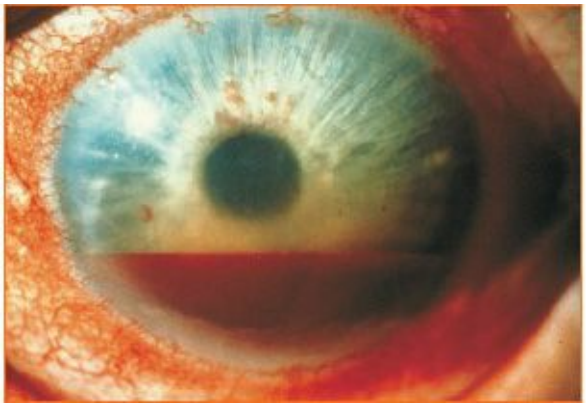

Figure 10-29 A hyphema.

Grading of the hyphema is as follows:

- **Grade 1:** Layered blood occupying less than one third of the anterior chamber
- **Grade 2:** Blood filling one third to one half of the anterior chamber
- **Grade 3:** Layered blood filling one half to less than the total anterior chamber
- **Grade 4:** Total clotted blood, often called a blackball or 8-ball hyphema

Signs and Symptoms

Hyphema

- Patient complaint of reduced vision (directly proportional to the size of the hyphema)
- Pool of blood in the eye; may be visualized either directly or by shining a penlight obliquely at the globe

Transport Management

Hyphema

- Patch both eyes.
- Transport the patient sitting as upright as possible.

- Administer analgesics; acetaminophen with or without codeine and aspirin.
- Administer an anxiolytic if necessary to facilitate transport.

Ocular Globe Rupture

Rupture of the globe with leak of vitreous humor may be the result of penetration with a foreign body or blunt trauma. Signs of an open globe include penetrating lid injury, bullous conjunctival hemorrhage, blood in the anterior chamber (hyphema), peaked or deformed pupil, lens dislocation, vitreous hemorrhage, or decreased visual acuity. Management for transport includes protecting the affected eye with a rigid eye shield or cup, not a soft patch. Antiemetics and pain medication should be given for transport. Sometimes antitussives are also used to prevent any increase in intraocular pressure as the result of coughing.

Signs and Symptoms

Ocular Globe Rupture

- Penetrating lid injury
- Bullous conjunctival hemorrhage
- Blood in the anterior chamber (hyphema)
- Peaked or deformed pupil
- Lens dislocation
- Vitreous hemorrhage
- Decreased visual acuity

Transport Management

Ocular Globe Rupture

- Protect the affected eye with a rigid eye shield or cup.
- Administer antiemetics and pain medication.
- If necessary, administer an antitussive to prevent increased intraocular pressure as the result of coughing.

Ocular Avulsion

Enucleation of the eyeball from the eye socket is possible from a trauma **Figure 10-30**. Multiple facial fractures may increase the chance of this injury. The globe may actually be hanging from the optic nerve. Despite the dramatic presentation, loss of vision is not inevitable. Proper care includes protecting the eye from further trauma in transit by using a protective cup or other rigid protective device with gauze padding.

Figure 10-30 Ocular avulsion.

Transport Management

Ocular Avulsion

- Protect the eye from further trauma with a protective cup or other rigid protective device with gauze padding.

Traumatic Retinal Detachment

In the past, retinal detachment uniformly led to blindness. Now, rapid diagnosis and surgery is truly sight saving. Retinal detachment refers to separation of the inner layers of the retina from the pigmented epithelium. There are a number of causes besides trauma. Other causes include diabetic retinopathy and sickle cell disease. Initially, the patient complains of the sensation of flashing light often accompanied by a shower of floaters and vision loss. The vision loss may be described as filmy, cloudy, irregular, curtain-like, or wavy. Patients may also complain of black spots, especially in the center of the visual field, or spiderweb-like vision. It is imperative to avoid pressure to the globe. A rigid metal eye shield should be used. Do not use soft patches. Although some types of retinal detachment are treated medically, most require surgery within 24 hours.

Signs and Symptoms

Traumatic Retinal Detachment

- Sensation of flashing light, often accompanied by a shower of floaters and vision loss
- Black spots, especially in the center of the visual field
- Spiderweb-like vision

Transport Management

Traumatic Retinal Detachment

- Avoid pressure to the globe.
- Protect the eye with a rigid metal eye shield.

Signs and Symptoms

Mandibular Fracture or Dislocation

- Crepitus
- Trismus
- Swelling
- Patient complaint that the jaw "doesn't feel right" (malocclusion)

Transport Management

Mandibular Fracture or Dislocation

- If the patient's jaw is wired shut, have wire cutters available to open the jaw in case an emergency airway is needed.
- Have nasotracheal intubation skills and equipment available.
- Be prepared to make emergency surgical access.

Mandibular Fracture and Dislocation

The mandible is the only movable bone in the skull and makes up the lower third of the face. Because of its U shape, single blows can cause multiple fractures anywhere around its length. It can also become anteriorly dislocated, causing the mouth to be locked in an open position. Signs of fracture include crepitus, trismus, swelling, and patient complaints that the jaw does not feel right (malocclusion). Treatment is usually not necessary on a scene call, but transfers to rehabilitation may involve a patient with a jaw wired shut. Provision must be made for emergency airway during such transfers. This may involve having wire cutters available to open the jaw or nasotracheal intubation skills and equipment, and being prepared for emergency surgical access.

Dental Avulsion

Avulsed teeth have a good chance of reimplantation if replaced within an hour. Until that time, the tooth or teeth must be handled carefully.

Guidelines from the American Dental Association include the following:

- Never place an avulsed tooth in anything that can dry or crush the outside of the tooth.
- Do not handle the tooth roughly. Do not rinse it off or rub, scrape, or disinfect the outside of the tooth.
- Place the tooth in a soft transport device, preferably in Hank's solution (a pH-balanced, isotonic, glucose, calcium, magnesium solution). Do not use tap water. Some recommendations suggest whole milk as a second-best solution to Hank's solution. A third choice is saline, but only for less than an hour.

Neck Injuries

The critical structures running through the neck are relatively unprotected and, therefore, susceptible to many types of injuries. In addition to critical airway and vascular structures, the possibility of unstable cervical spine and cord injury must always be considered. For scene calls, selective spinal

immobilization criteria have become standard. If a patient has a cervical collar in place at a sending facility and the sending physician is unwilling to clear the cervical spine, the CCTP must consider full reimmobilization prior to transport. Patients with neck injury should always be considered difficult airway patients. Securing the airway with endotracheal intubation should be considered prior to most transports. Deterioration of the patient's airway in the back of a transport vehicle with limited space and personnel can be disastrous. Special airway considerations in the presence of neck injury include bleeding into the airway field, expanding hematomas, and tracheal disruption.

For neck trauma resulting in hoarseness accompanied by skin lacerations, ecchymosis, tenderness, subcutaneous emphysema, and/or stridor, an immediate otolaryngology consult is recommended. This may be the reason for transport to a larger hospital. Humidified oxygen, inhaled corticosteroids, and/or nebulized epinephrine may be ordered. Wounds may need to be dressed with occlusive dressings. If the wound is to the lower neck or clavicular area, vascular access may need to be achieved in the lower extremity as the result of compromised drainage from the arms.

Laryngotracheal Injuries

Laryngotracheal injuries represent less than 1% of all traumatic injuries. Most are in the area of the cervical trachea. Direct blunt trauma is the most common. Examples include a steering wheel to the extended throat, hanging, strangulation, and "clothesline" injury during sports such as mountain biking or snowmobiling. Penetrating laryngotracheal injuries are 10% of all penetrating neck injuries. Bubbling from a neck wound and subcutaneous air, along with dysphonia, dyspnea, stridor, visible wounds, and swelling, are all signs of laryngotracheal injury. These injuries can appear stable for a time, followed by rapid and catastrophic deterioration.

The most severe cases are laryngotracheal disruptions. It is vital that paralytics and muscle relaxants not be used. The only support for the trachea may be the supporting musculature. If the patient is paralyzed, the trachea may retract into the chest, making it impossible to ventilate the patient. If the trachea is visible through the neck wall, the endotracheal tube should simply be passed through the neck into the trachea.

Signs and Symptoms

Laryngotracheal Injury

- Bubbling from a neck wound
- Subcutaneous air
- Dysphonia
- Dyspnea
- Stridor
- Visible wounds
- Swelling

Transport Management

Laryngotracheal Injury

- Airway management with careful endotracheal intubation

- Occlusive dressing for open neck wounds
- Spinal precautions
- Transport to a trauma center

Thyroid Injuries

The thyroid gland is very vascular, and direct trauma to the front of the neck can cause hematomas of sufficient size to impinge on the airway. If surgical airway management is required, the location may need to be inferior to the usual site and inferior to the thyroid gland.

There are multiple case reports of **thyrotoxicosis** (thyroid storm, an excess of thyroid hormones) after trauma, including strangulation and direct blows to the anterior neck, shock (hypotension), or surgical procedures involving the thyroid. Thyroid storm has a 20% to 30% mortality rate. Thyroid storm causes a hypermetabolic crisis, including tachycardia over 140 beats/min, hyperthermia (sometimes with a temperature >103.9°F), coma with agitation, nausea, vomiting, diarrhea, and unexplained jaundice and pulmonary edema. Definitive diagnosis usually includes an elevated thyroxine level (normal level, 5.5 to 12.5 µg/dL). Treatment may include a beta-blocker such as an esmolol drip, sedation, and cooling for transport.

Signs and Symptoms

Thyrotoxicosis (Thyroid Storm)

- Tachycardia greater than 140 beats/min
- Hyperthermia (sometimes a temperature >103.9°F)
- Coma with agitation
- Nausea
- Vomiting
- Diarrhea
- Unexplained jaundice and pulmonary edema
- Elevated thyroxine level

Differential Diagnosis

Thyrotoxicosis (Thyroid Storm)

- Head injury
- Sepsis
- Toxic ingestion

Transport Management

Thyrotoxicosis (Thyroid Storm)

- Administer a beta-blocker (eg, an esmolol drip).
- Administer a sedative.

- Implement cooling measures.

Vascular Neck Injuries

Injury to the carotid, subclavian, and vertebral arteries and external and internal jugular veins can produce rapid exsanguination, hematoma formation, or embolization of air. Vascular neck injury accounts for one fourth of all penetrating neck trauma. Mortality may be as high as half of these patients. Many of the complications of these injuries do not occur for days to weeks and involve thromboemboli causing neurologic problems. Because of the possibility of venous air embolism, direct pressure with an occlusive dressing should be applied while the patient is kept in the Trendelenburg position. Keep in mind that the Trendelenburg position may lead to respiratory compromise and that ventilatory assistance may be needed.

Transport Management

Vascular Neck Injury

- Apply direct pressure to the injury with an occlusive dressing.
- Keep the patient in the Trendelenburg position.

Abdominal Trauma

Traumatic injuries to the abdomen will be some of the most difficult injuries for the CCTP to recognize. Whether providing care at a trauma scene or transferring a critical patient from the emergency department to a trauma center, it is important to document an accurate history and physical exam for later comparison. At a sending facility, it is usually worthwhile to interview the crew that brought the patient from the field. With interfacility critical care transport calls, always try to review all studies that have been done, including labs, radiographs, ultrasound (FAST exam), computed tomography scans, and, less frequently performed, diagnostic peritoneal lavage.

The abdominal cavity is an extremely large space that is home to many different vital organs. In many instances, your patient will experience blunt or penetrating trauma to the abdominal cavity, and signs or symptoms of injury may be very difficult to observe until shock becomes obvious. Because of the size of the abdominal cavity, a significant amount of blood can collect within the cavity and go unnoticed. Unlike other vital organs in the body, those in the abdominal cavity have very little protection, which makes them that much more susceptible to injury.

The following organs, structures, and vessels are located within the abdomen, and, if injured, can cause potential harm to your patient:

- Spleen
- Liver
- Kidneys
- Aorta
- Bladder
- Gallbladder
- Small and large intestines
- Pancreas

- Stomach

Blunt or penetrating trauma to many of these organs can cause a life-threatening hemorrhage and serious organ damage. It is important for the CCTP to focus attention on the mechanism of injury, instead of the outward signs of trauma found on assessment. Injuries to any of the previously listed organs may not readily present with outward signs and symptoms. This makes it that much more important for the CCTP to perform a detailed assessment and a thorough ongoing assessment during the transport, looking for subtle changes that might indicate a progressing condition. If a significant injury is suspected or confirmed, the most definitive treatment that the CCTP can provide is rapid transport to the trauma center, so that surgical intervention can be performed if needed. Once the CCTP recognizes the need for immediate transport to the trauma center, his or her job is to stabilize and maintain the patient's hemodynamic status as efficiently as possible until arrival at the trauma center. This task will be difficult and may require the administration of a crystalloid solution, blood products, or even vaso-active medications in the more severe cases. Grey-Turner's sign **Figure 10-31** and Cullen's sign **Figure 10-32** are indications of internal abdominal bleeding.

Figure 10-31 Grey-Turner's sign.

Figure 10-32 Cullen's sign.

Abdominal trauma can be classified into two different categories: blunt and penetrating trauma. Blunt trauma occurs when any type of external force is placed on the abdominal cavity, such as a fall, automobile crash, or motorcycle crash. Penetrating trauma can involve many different objects, such as knives, guns, tree limbs, or metal rods. One of the least suspected culprits in the blunt trauma classification is the seatbelt. The seatbelt has significantly decreased the incidence of morbidity and mortality related to automobile crashes, but continues to cause less noticeable abdominal injuries. Penetrating injuries will be very difficult for the CCTP to assess because the necessary information is often not available (eg, the size of the knife, the length of the blade, and whether it was jagged or straight-

edged). In many instances, even if you know this information, it will still be very difficult to rapidly identify what structures inside the abdominal cavity were injured without the assistance of imaging studies.

When beginning the physical assessment of the patient, the CCTP should try to ascertain as much about the events leading up to the injury as possible. Gathering more information will make diagnosing and treating the problem that much quicker and oftentimes simpler. The physical exam performed to rapidly identify blood loss is the most important task. When completing the physical exam, remember to always inspect, auscultate, and palpate, in that order. The primary assessment needs to be completed at the bedside, before beginning transport. It will be very difficult to obtain an accurate assessment in the back of a moving helicopter or ambulance if you choose to wait that long. This assessment must be repeated frequently during the transport, watching for changes that require immediate intervention. The CCTP will need to monitor the patient's level of consciousness, heart rate, and blood pressure, watching for changes that would indicate a progressively worsening condition.

Patients who experience massive amounts of blood loss may compensate initially, but they will eventually begin to present with signs of shock. Signs and symptoms to be constantly looking for include:

- Altered mental status
- Tachycardia
- Absence of palpable pulses
- Pale, moist, and mottled skin
- Poor peripheral perfusion
- Hypotension

The assessment should not be limited to these symptoms; however, they are some of the most common occurrences related to hypovolemic shock. Regardless of your findings during the initial assessment, all patients suspected of having abdominal injuries should be transported on high-flow oxygen with fluid administration. A minimum of two lines (as with most critical care transport patients) should be achieved, and central lines may need to be considered. CVP and arterial pressure lines are a very good idea because of the inaccuracy of noninvasive blood pressure monitoring in transit, especially in low blood pressure states. However, permissive hypotension should also be considered, especially if an aneurysm of a great vessel is suspected. The patient's blood pressure should be maintained at 90 mm Hg systolic (±10 mm Hg) or 65 mm Hg MAP. A bolus of crystalloid should be given in 250-mL to 500-mL amounts titrated to blood pressure, MAP, or CVP. The more severe cases may need aggressive airway management and blood administration; most transport programs carry packed red blood cells (O negative) for emergency situations. To prevent hemodilution, protocols should be written that allow the administration of human blood if a large volume of fluids is deemed necessary. Many new fluids with oxygen-carrying capacity are in the final stage of research and will begin to show up on the market. Except in cases of suspected urethral injury, all patients with serious abdominal trauma will, in addition to the vascular access, need to have a Foley placed prior to transport. Completing this step prior to transport will help the CCTP evaluate shock by evaluating the amount of urine output. In addition, the presence of frank blood will indicate renal system damage. Patients should be kept warm, and open abdominal wounds should be covered with sterile dressings and then covered with an occlusive dressing to prevent evaporative cooling.

Signs and Symptoms

Abdominal Injury

- Altered mental status
- Tachycardia
- Absence of palpable pulses
- Pale, moist, and mottled skin
- Poor peripheral perfusion
- Hypotension

Transport Management

Abdominal Injury

- Administer high-flow oxygen and fluids.
- Establish at least two IV lines; consider placement of central lines.
- Keep the patient's blood pressure at 90 mm Hg systolic or 65 mm Hg MAP.
- Administer a bolus of crystalloid in 250- to 500-mL amounts titrated to blood pressure, MAP, or CVP.
- If necessary, secure the airway.
- If necessary, administer blood products.
- Except in cases of suspected urethral injury, insert an indwelling catheter prior to transport.
- Keep the patient warm.
- Cover open abdominal wounds with sterile dressings than cover with an occlusive dressing to prevent evaporative cooling.

Hollow vs Solid Organ Injury

Hollow organs primarily leak their contents when injured, whereas solid organs bleed. Treatment should be oriented toward treating shock. Solid organs include the liver in the upper right quadrant, the spleen in the upper left quadrant, and the pancreas and the kidneys in the retroperitoneal space. The hollow organs include the stomach in the upper left quadrant, the intestines in all quadrants, and the gallbladder under the liver in the upper right quadrant. Hollow organs in the midline include the urinary bladder and ureters, and the uterus and great vessels of the descending (abdominal) aorta and the inferior vena cava. The primary concern with hollow organ injury is peritonitis.

Spleen

About 5% of circulating blood filters through the spleen every minute. This organ gets direct vascular supply from the aorta, and its drainage goes directly to the inferior vena cava. The spleen is the most commonly injured organ in the abdominal cavity. It can even be injured by what seems to be minor trauma. Young adults and patients with sickle cell disease are at particular risk, as a result of the spleen being relatively larger. Located in the upper left quadrant of the abdomen, the spleen is partially protected by the lower rib cage, but lacks a strong exterior capsule. Injuries to the spleen that do not cause a disruption to the organ itself will likely only cause minimal amounts of bleeding. More significant bleeding may occur if the exterior capsule is damaged. As mentioned previously, the presence of normal vital signs does not indicate the absence of an injury. Especially with injuries involving the spleen, the patient may only complain of pain on primary assessment, and symptoms of shock may develop later. In

some cases, symptoms arise as late as 2 to 3 weeks after the original trauma. A helpful tool for recognizing a splenic injury through referred pain is called **Kehr's sign**. This sign presents as pain in the shoulder as a result of the presence of blood or other irritants in the peritoneal cavity. Pain in the left shoulder (Kehr's sign) is considered a classic symptom of a ruptured spleen, but it also may result from any free blood irritating the diaphragm. The same phenomenon also occurs on the right side with irritation to the liver or gallbladder. Failure to recognize, understand, and treat the signs and symptoms of hypovolemic shock related to internal hemorrhage will rapidly lead to death. However, many spleen injuries are often able to be managed through careful observation, because the spleen sometimes heals over time and invasive interventions are not needed.

Signs and Symptoms

Spleen Injury

- Pain in the area of the spleen
- Kehr's sign: pain in the shoulder

Transport Management

Spleen Injury

- Treat the patient for signs and symptoms of hypovolemic shock.

Liver

The largest organ in the abdominal cavity, the liver is also the most vascular organ, and receives 25% of the cardiac output. The liver does have a little more protection than the spleen, because it is surrounded by many different structures of the thorax, including ligaments that stabilize the organ and keep it from being jostled around during impact. However, the ligament in front of the liver (ligamentum teres) can slice the liver in sudden deceleration. Additionally, the liver's close proximity to the lower rib cage makes it susceptible to injury after a rib fracture occurs. Liver injuries will cause pain in the right upper quadrant, along with Kehr's sign in the right shoulder as blood accumulates around the diaphragm.

In the past, the majority of liver injuries were surgically repaired. Studies have shown that many of the less severe liver injuries can endure 1 or 2 days of observation before making a decision to surgically repair the organ. In most instances, simple observation is the only intervention that is needed, because the liver heals over time and invasive interventions are not needed. This is not the case for severe liver injuries, because surgery is likely the only intervention that will prevent death.

Large and Small Intestines

The intestines are hollow organs that occupy much of the space within the abdominal cavity. Penetrating trauma is the most common cause of injury to the intestines, because they lie very close to the surface of the abdomen. When objects such as knives or bullets penetrate the abdominal wall, injury to the hollow intestine is likely. Although penetrating trauma is the most common, blunt trauma to the abdominal wall can also cause injury to the small bowel. In this particular situation, the most common culprit is the seatbelt, because the lapbelt lies along the lower quadrant of the abdominal cavity **Figure 10-33**. The patient would likely present with an ecchymotic area across the lower portion of the abdomen (seatbelt

sign), which should necessitate assessment for internal injuries.

Figure 10-33 Seatbelt sign.

Signs and Symptoms

Intestinal Injury

- Ecchymotic area across the lower portion of the abdomen (seatbelt sign)
- Presence of pain with palpation to the abdomen
- Guarding
- Abdominal distention
- Rebound tenderness
- Vomiting

Transport Management

Intestinal Injury

- Maintain a high index of suspicion for occult injury.
- Establish two large-bore IVs.
- Consider other injuries, such as chest, neck, and lumbar spine injuries.
- Provide rapid transport.

The lack of visible injury should not be used to exclude internal injury. Once again, the CCTP will rely on his or her assessment skills to detect abnormalities. In some cases, the presence of pain, with palpation to the abdomen, might be the only indicator of injury. In addition to the pain with palpation, other indicators, such as guarding, abdominal distention, rebound tenderness, and vomiting, may be

present.

The large intestine or colon is the most frequent area to be injured by penetrating trauma. Injury to the large intestine or colon was found in 96% of penetrating traumas in one study, of which gunshots accounted for more than 90%. Ruptures of the colon or rectum are particularly prone to sepsis and peritonitis.

Stomach

Damage to the stomach from trauma is rare. The most common blunt trauma occurs when the stomach is caught against the steering wheel when full. The stomach can also be damaged in penetrating injuries.

Duodenum

The duodenum is a retroperitoneal organ and, therefore, is well protected. If ruptured because of its retroperitoneal location, it may not produce symptoms, but as a result of its close proximity to multiple organs, it is never injured by itself. This injury should be suspected in children who are thrown off a bicycle and strike their abdomen on the handlebars.

Jejunum and Ileum

The jejunum and ileum are generally victims of penetrating trauma. Approximately 80% of gunshot wounds to the abdomen and 30% of stab wounds lacerate these organs. Because the jejunum and ileum are anchored to the abdominal wall by the ligament of Trietz, the mesentery and its vasculature often is torn and causes hemorrhage.

Vascular Injuries

Unfortunately, injuries that occur to the vessels of the abdomen are usually life threatening. The abdominal aorta is a large vessel that carries blood away from the heart, supplies all the abdominal organs, and continues its distribution of blood and oxygen to the toes. Severe blunt trauma may cause disruption of these vessels, but the most common cause of vascular injury is, once again, penetrating trauma. In instances of blunt trauma, the shearing force at impact causes the vessels to break away from their branches, thus allowing blood to freely flow into the abdominal cavity. The major blood vessels in the abdomen that have the potential for being injured are:

- Aorta
- Inferior vena cava
- Renal artery
- Mesenteric artery
- Iliac artery

Management

Bleeding from an injury to any of the major abdominal vessels may occur rapidly, and signs of shock may not even be noticed. Aggressive management of these patients is required, but may not be very helpful, because arterial injuries will cause exsanguination unless immediate surgery is available. Therefore, rapid transport to a hospital capable of immediate surgery may be the best possible treatment. The abdominal cavity is also home to several large veins that will cause the body to lose large amounts of blood, but not at the rapid pace of an artery. Bleeding into the abdominal cavity may slowly occur without obvious signs or symptoms.

The treatment is similar to the other abdominal injuries. Airway patency is the key, because an altered mental status is likely with patients who are experiencing massive blood loss. Immediate steps should be taken to endotracheally intubate to secure the airway if necessary. Attention should be focused

on treating the hypovolemic shock and transporting to a center capable of trauma surgery. In the initial treatment of this patient, aggressive fluid resuscitation is the key to maintain a systolic blood pressure of at least 80 mm Hg but not higher than 90 mm Hg, with progression toward blood products as soon as possible. If the patient does survive the transport, the surgical team needs to intervene as soon as possible so they can attempt to surgically repair the disturbed vessel. Even if the patient makes it to surgery, several serious complications can occur after the surgery, such as disseminated intravascular coagulation, continued bleeding, and thrombosis formation. All of these conditions are life threatening, and will be treated as such by the team caring for the patient.

Signs and Symptoms

Abdominal Vascular Injury

- Potentially none
- Altered mental status
- Hypovolemic shock

Transport Management

Abdominal Vascular Injury

- Maintain airway patency; insert an endotracheal tube if necessary.
- Administer aggressive fluid resuscitation; maintain a systolic blood pressure of at least 80 mm Hg but not higher than 90 mm Hg.
- Administer blood products, if available.
- Transport the patient immediately to a center capable of trauma surgery.

Pelvic Trauma

Pelvic Fracture

Pelvic fractures are the result of motor vehicle trauma (approximately 60% to 70% of the time), pedestrian vs motor vehicle (12% to 18%), motorcycle crashes (5% to 10%), and falls (up to 10%). A pelvic fracture results from significant force. Because of the force involved, the presence of a pelvic fracture should alert the CCTP to the possible existence of other injuries. Mortality in one study of blunt trauma pelvic fractures was as high as 50%. Most of the threat to life comes from internal hemorrhage. The pelvis is made up of three paired bones: the ileum, ischium, and pubis. Together, they are called the innominate bones and are connected posteriorly by the sacrum and coccyx. The very rich blood supply comes from the left and right iliac arteries. The veins in the pelvis are without valves and are adhered to the pelvic wall. Because they are thin, are easily torn, and can flow in either direction, fractures can result in catastrophic hemorrhage. Subjective assessment includes a good history of the mechanism of injury, location, and radiation of pain, as well as the presence of hematuria and the possibility of pregnancy. Objective examination should include observing for the rotation or uneven height of the iliac crests and uneven length of the legs. Palpation of the posterior aspect of the pelvic ring should not elicit tenderness. Gentle lateral compression and inward compression should not result in pain, crepitus, or movement. This test should be done carefully and stopped if any instability is felt and not repeated.

The pelvis also houses the female reproductive organs and the bladder in both sexes. When full, the bladder can rise above the pelvic rim and become victim to seatbelt injury causing rupture. The uterus, ovaries, and fallopian tubes are well protected in the nonpregnant patient. Injuries to these organs are usually found later using computed tomography.

Management of pelvic injury depends on the type of fracture. Field treatment consists of splinting and treatment for shock. Soft-tissue damage to the genitalia can be managed like any other soft-tissue injury. Packaging for transport of suspected or confirmed pelvic fracture should involve immobilization on a scoop stretcher or backboard or use of a pelvic binder **Figure 10-34**.

Signs and Symptoms

Pelvic or Open-Book Fracture

- Rotation or uneven height of the iliac crests
- Uneven length of the legs
- Tenderness upon palpation of the posterior aspect of the pelvic ring
- Pain, crepitus, or movement upon gentle lateral compression and inward compression

Figure 10-34 A pelvic binder.

Transport Management

Pelvic or Open-Book Fracture

- Splint the fracture.
- Treat the patient for shock.
- Manage any soft-tissue damage to the genitalia.
- Package the patient for transport using immobilization on a scoop stretcher or backboard; alternatively, use a pelvic binder.

Open-Book Fracture

Open-book fractures, a subset of pelvic fractures, account for about 15% of pelvic fractures and involve the loss of stability of the pelvic ring. They result from anterior-posterior compressive forces separating the pelvis at the symphysis pubis. The greatest danger is from hemorrhage. Some of these fractures have gone undiscovered until the pneumatic antishock garment was deflated in the emergency department. Reduction of these fractures decreases the bleeding. Assessment and treatment are the same as for any pelvic fracture, and patients should be transported on a well-padded backboard or scoop. Pelvic binders

or even pneumatic antishock garments have also been successfully used.

Extremity Trauma

Musculoskeletal Injuries

Musculoskeletal injuries are rarely life threatening. They include fractures, sprains, strains, dislocations, muscular contusions, and compartment and crush syndromes. Often dramatic, they may be an indicator of the amount of energy transferred to the body and the likelihood of additional injury. However, the CCTP must not let dramatic fractures distract from a proper primary and secondary assessment. Initial immobilization on the scene can be accomplished by using a backboard as a whole-body splint to accelerate time off the scene for multiple trauma patients. On interfacility transports, there is usually time to make sure individual fractures are properly splinted. In both cases, adequate pain control should be used if blood pressure allows. All musculoskeletal injuries should be assessed for the six Ps—pain, pallor, pulselessness, paresthesia, paralysis, and pressure—before and after any manipulation. This should be documented on the patient's chart, and pulse locations should be marked with a felt-tip or skin marker on the patient to speed rechecking during transport.

Fractures

A break in the continuity of a bone is a fracture, and may be open or closed. Regardless of whether a fracture is open or closed, the CCTP must make prevention of further injury due to movement with pain assessment and management a priority. The CCTP should use appropriate analgesic medications as permitted in system protocols to reduce the pain and suffering of the patient.

In a closed fracture, the skin over the bone remains intact, thus reducing the probability of infection. However, closed fractures can be as dangerous as open fractures due to involvement of internal bleeding into the tissues. Depending on the anatomic area of the body where a closed fracture occurs, it could result in a large amount of blood loss before enough pressure is internally achieved to tamponade the bleeding. For example, a closed fracture of one femur could easily result in the loss of 1 L of blood, whereas bilateral femur fractures could result in the loss of 2 L of blood **Table 10-5**. Multiple fractures of trauma patients can cause massive internal hemorrhage and even death, with no external bleeding noted.

In an open fracture, the skin over the bone is broken, thus adding the potential danger of infection, which could lead to sepsis and death. Open fractures typically result from high-energy injuries, and thus have the potential for more blood loss than closed fractures.

Clinical signs and symptoms of fractures include pain, swelling, deformity, rigidity, shortening, ecchymosis, guarding, and crepitus. The patient could have one or more of the presented signs and symptoms. Management of isolated fractures is as follows:

- Maintain an open airway and apply high-flow oxygen if necessary.
- Assess pulses and motor and sensory function distal to the fracture site.
- Control bleeding with direct pressure and pressure dressings; if that is not effective after adequate time, then a tourniquet should be used. Apply a sterile dressing to any exposed bone or tissue.
- Initiate IV fluids to maintain peripheral perfusion.
- Consider the administration of analgesic medication titrated to pain relief prior to manipulating the fracture if the patient is hemodynamically stable.
- Splint in a normal anatomic position with an appropriate splint while maintaining circulation.

TABLE 10-5 Estimated Blood Loss by Fracture Type

Estimated Potential Blood Loss (mL)	Fracture Type
125 each	Rib
250–500	Radius or ulna
500–750	Humerus
500–1,000	Tibia or fibula
1,000–2,000	Femur
1,000 to massive	Pelvis

Signs and Symptoms

Extremity Fractures

- Pain
- Swelling
- Deformity
- Rigidity
- Shortening
- Ecchymosis
- Guarding
- Crepitus

Differential Diagnosis

Extremity Fractures

- Fracture
- Sprain
- Contusion
- Compartment syndrome

Transport Management

Extremity Fractures

- Maintain an open airway; apply high-flow oxygen if necessary.
- Assess pulses and motor and sensory function distal to the fracture site.
- Control bleeding with direct pressure and pressure dressings; if that is not effective after adequate time, apply a tourniquet.
- Apply a sterile dressing to any exposed bone or tissue.
- Initiate IV fluids.
- Consider administration of analgesic medication.
- Splint the extremity in its normal anatomic position with an appropriate splint while maintaining

circulation.
- Reassess pulses and motor and sensory function distal to the fracture site after application of the splint.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Splint femur fractures with a traction splint.

- Reassess pulses and motor and sensory function distal to the fracture site after application of the splint.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Femur fractures should be splinted using a traction splint, because this reduces the muscle spasms and pain and bleeding.

Femur Fracture

The femur is the largest bone in the body, surrounded by some of the strongest muscles. When the femur is broken, the muscles contract, causing sharp bone ends to override and damage soft tissue. More importantly, the slack muscle can provide a large space for the collection of blood. Generally, femur fractures should be considered to account for loss of at least 1 L of blood from circulation.

The traction splint pulls the slack muscles taut again, tamponading the bleeding. When first invented during the Crimean war, the traction splint reduced mortality from femur fracture secondary to gunshot from 80% to 20%. However, there are a number of contraindications and dangers with use of traction splints. The contraindications include hip and pelvic fractures, knee injury, and ankle damage. The dangers include damage or worsening damage to the neurovascular bundle of the thigh; this includes the sciatic and femoral nerves and the vasculature of the area.

Vertebral Fracture

Trauma is the leading cause of injury to the vertebral column. About 20,000 new spinal cord injuries occur in a year in the United States, with nearly half as a result of motor vehicle trauma, followed by intentional violence, falls, and sports injuries. Vertebral fractures can be stable or unstable. Unstable injuries can result in permanent devastating neurologic deficits. Any movement during transport can transform an unstable fracture without neurologic deficit into a life-long disability. The current practice is to fully immobilize the spine for transport. This often means placing the patient in the sending facility on a backboard again. The use of traditional rigid backboards for immobilization has been associated with the development of pain and skin breakdown when patients are confined for more than 30 minutes. Adequate padding or use of vacuum mattresses may reduce this problem. Acute spinal injury is classified as stable or unstable and by the mechanism of injury. Flexion, flexion with rotation, extension, and compression are all mechanisms of injury. Some fractures also have specific names, such as clay shoveler's fracture or hangman's fracture. Secondary injury can be the result of hypoxia, hypoglycemia, hypotension, or hyperthermia, as well as mishandling during transport. All of these conditions must be assessed for and treated if found so they do not exacerbate a cord injury secondary to vertebral fracture.

Cervical Fracture

The most devastating vertebral fractures occur in the seven cervical vertebrae. Control of the entire body, including cardiorespiratory functions, descends through the cervical vertebra. The phrenic nerve controlling the diaphragm arises from C3, C4, and C5. Damage to vertebrae in this area may compromise respiratory effort. Patients being transported from one facility to another who have not definitively had their cervical spine cleared should be completely immobilized. Advance planning for airway management

and prevention of aspiration, especially in small aircraft, must be undertaken prior to transport.

Thoracic Fracture

Thoracic fractures can lead to a loss of innervation of the intercostal muscles, leading to respiratory insufficiency. Sympathetic nervous control arises from the thoracic and high lumbar spinal cord. Although rare, a condition called "spinal shock" can affect the thoracic area or higher. In this type of shock, hypotension is accompanied by bradycardia instead of tachycardia. Pulse pressure will be normal or widened, instead of narrowed as in hypovolemia. The area above the fracture will be pale and cool, but the area below the fracture will be warm. Treatment should be fluids and pressors to maintain MAP in a range of 80 to 90 mm Hg. Transport considerations should match the stabilization precautions for cervical vertebra.

Lumbar Spine Fracture

The lumbar vertebrae are the largest vertebrae. However, they are not supported as the thoracic vertebrae are by the ribs and are, therefore, prone to injury. Jackknifing injuries, such as over a seatbelt, are frequently the mechanism of injury. Immobilization for transport is the appropriate treatment.

Humerus Fracture

The humerus, like the femur, is a vascular long bone. Blood loss from a humeral fracture may be significant. As much as 750 mL of blood may be lost from a single fracture. In addition, radial nerve injury is possible. During on-scene calls for multiple trauma patients, the humerus may simply be splinted to the body on a long board to facilitate rapid evacuation. For interfacility transports, it should be splinted carefully with attention to distal circulation and nerve function. It is a good practice to mark the location of pulses that are found prior to transport with a skin marker. This will allow for quick repeat assessment during transport. The absence of distal pulses or nerve function should receive immediate attention, which usually involves traction in anatomic alignment and manipulation.

Rib Fracture

Single rib fractures are rarely life threatening. They may cause pneumothorax, and torn intercostal arteries can lead to significant blood loss or hemothorax. Multiple rib fractures will negatively impact respiratory excursion even if there is no flail segment. To treat rib fractures, provide sufficient pain medication so that self-splinting does not interfere with respiration. Multiple rib fractures may require ventilatory assistance.

Nasal Fracture

Nasal fractures are important to the CCTP because of the concern for patency of the airway. Swelling as a result of nasal fractures can interfere with the nose as an air passage and foreclose use of this route for an artificial airway, such as nasopharyngeal or nasotracheal airways.

Dislocations

When a bone displaces from a joint, the condition is called a dislocation. When a body part exceeds its normal range of motion, a dislocation can occur. Until proven otherwise, all dislocations should be assumed to be coupled with a fracture. Although joint dislocations are not life threatening, they are true emergencies as a result of the potential for neurovascular compromise that could lead to amputation if not appropriately treated. The CCTP should use appropriate analgesic mediations as permitted in protocols in order to reduce the pain and suffering of the patient.

Clinical signs and symptoms of a dislocation include pain, swelling, distorted anatomy, shortening, ecchymosis, guarding or being "locked," and being unable to move. The patient could have one or more of

the presented signs and symptoms. Management of a dislocation is as follows:

Signs and Symptoms

Dislocations

- Pain
- Swelling
- Distorted anatomy
- Shortening
- Ecchymosis
- Guarding or being "locked"
- Inability to move

Differential Diagnosis

Dislocations

- Fracture
- Contusion

Transport Management

Dislocations

- Maintain an open airway; apply high-flow oxygen as needed.
- Initiate IV fluids.
- Assess pulses and motor and sensory function distal to the dislocation.
- Splint the dislocation in the position of comfort with an appropriate splint while maintaining circulation.
- Reassess pulses and motor and sensory function distal to the injured site after application of the splint.
- Administer analgesic medication titrated to pain relief and blood pressure.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.

- Maintain an open airway and apply high-flow oxygen as needed.
- Initiate IV fluids to maintain peripheral perfusion.
- Assess pulses and motor and sensory function distal to the dislocation.
- Splint in the position of comfort with an appropriate splint while maintaining circulation.
- Reassess pulses and motor and sensory function distal to the fracture site after application of the splint.
- Administer analgesic medication titrated to pain relief and blood pressure. This may need to be done prior to splinting to facilitate placement of the splint.

- Monitor oxygen saturation, vital signs, and the cardiac monitor.

Subluxations

A subluxation is a partial dislocation of a joint. Sometimes also called sprains, subluxations can be graded from I to IV. A grade I sprain has minimal abnormal movement, and a grade IV is a dislocation.

Amputation

An amputation is the separation of a body part from the remainder of the body. Amputations can be life threatening and are often disabling. There is potential for hemorrhage, but usually bleeding can be controlled with direct pressure to the stump. If not a tourniquet, then a band at least 2″ wide, such as a blood pressure cuff, should be used. The CCTP should make every attempt to locate the part and transport it with the patient for possible reattachment. If located, the amputated part should be put into a plastic bag and then placed in ice water and transported with the patient.

Management

General management of fractures and trauma depends on the overall state of the patient. If the patient needs immediate resuscitation, airway, ventilation, control of blood loss, and fluid resuscitation must take priority. In cases of on-scene trauma calls, the trauma patient requires immediate resuscitation about 10% of the time. The priority in these cases is resuscitation and transport to surgical capability to stop internal bleeding. In such situations, the care of fractures is limited to stopping external bleeding and stabilization by splinting on a backboard to facilitate rapid transport. For the calls that do not require critical resuscitation, the priority shifts to pain control, assurance of distal neurovascular function, and careful splinting of each fracture. On interfacility critical care transports, similar priorities apply, although for stable patients the type of immobilization may be much more sophisticated.

Splinting

Splinting a fracture is done primarily to prevent further harm from movement of the bone ends, which could cause further soft-tissue injury, bleeding, and pain. The principles of splinting involve holding the bones in an anatomically correct position and preventing any movement. To get the bones into the anatomically correct position, tension needs to be applied while gently returning the limb to alignment. This should be stopped if there is any resistance or a significant change in pain level. Traditional rigid splints must be well padded to prevent skin breakdown and pain at pressure points. Alternatively, vacuum splints have been found to be effective and comfortable, but, like older air splints, are affected by altitude changes. No matter what type of fixation splint is used, the entire bone with the adjacent joints must be held immobile in order for the splint to be effective. Distal neurovascular function should be documented before application and frequently during transport. Any reduction in function requires readjustment of the splint.

Casting

Casts made of plaster, or now more commonly fiberglass, are applied by an orthopaedic surgeon after acute swelling has gone down. This is usually at least 24 hours after the injury occurs. Swelling under a cast can cause compartment syndrome. Any patient with a cast who is transported by a CCTP should be evaluated for neurovascular function distal to the cast prior to transport and periodically during transport. It is recommended that the location where pulses are found be marked on the skin and documented in the patient care record.

Reduction/Realignment

Typically, reduction and realignment is not a priority of care in the critical patient. Resuscitation of cardiovascular status must always take priority. Usually, reductions are done by an orthopaedist as part of the resuscitation team or soon thereafter. Realignment becomes a priority if the neurovascular function distal to the injury is compromised. This is accomplished by applying gentle traction in the anatomic direction of the bone distal to the fracture while stabilizing the bone proximal to the break. Then the bone is brought into alignment or to a position in which maximal pulse is felt and then splinted in that direction.

External Fixation

External fixation of fractures has become common. Placed by an orthopaedic surgeon, external fixation uses external rods held to the bone with plates and screws. The apparatus is placed surgically. The external joints are adjusted over time as needed by the orthopaedist. The CCTP will from time to time transport patients with this device in place. Adequate padding and positioning is required for transport.

Internal Fixation

Internal fixation is the placement of rods such as Harrington rods with plates and screws in the operating room to hold fractures in place for healing. Later the rods may be removed or left in place permanently. Occasionally the rods work themselves out of position and may need surgical revision. Generally, this equipment is not of concern during transport.

Compartment Syndrome

In compartment syndrome, bleeding or swelling occurs within the nonstretchable fascia that divides each extremity into compartments and exceeds the amount of space available, thus impairing circulation and causing pain. The most common anatomic locations for compartment syndrome are the forearms and legs. However, any extremity and the buttocks can develop compartment syndrome. In one study, 69% of compartment syndrome cases were associated with fracture (half of the fractures were to the tibia), but burns, external compression from splints or bandages, and crushing injury can all lead to compartment syndrome. In the same study, 31% of patients had soft-tissue injuries without a fracture. Compartment syndrome usually develops over a period of hours.

Clinical signs and symptoms of compartment syndrome initially present as pain out of proportion for the evident injury, sometimes described as burning and paresthesia over the compartment site. Additional signs include tension of a muscle when not in use, loss of distal sensation or pulses, and extreme pain on extension or voluntary movement. The presence of pulses or Doppler blood flow does not rule out compartment syndrome. The signs are commonly referred to as the six Ps—pain, pallor, pulselessness, paresthesia, paralysis, and pressure. Sometimes a seventh P is included, poikilothermia (ie, affected extremities may be cold).

Management of compartment syndrome is as follows:

1. Maintain an open airway and apply high-flow oxygen as necessary.
2. Assess pulses and motor and sensory function.
3. Elevate the extremity above the heart.
4. Place ice packs over the extremity.
5. Initiate IV fluids to maintain peripheral perfusion.
6. Consider loosening the constrictive splint material and/or clothing.
7. Administer pain medication.
8. Monitor carefully for signs of, and be prepared to treat, rhabdomyolysis, hyperkalemia, and myoglobinuria.

For interfacility transport, there are several methods of monitoring actual compartment pressures invasively. In noncontracting muscle, the normal mean interstitial tissue pressure is close to 0 mm Hg. If this pressure becomes elevated to 30 mm Hg or more, small vessels in the tissue can become compressed, which results in reduced blood flow, ischemia, and pain. Pay close attention to compartment pressure and diastolic blood pressure **Figure 10-35**. It is considered an emergency if diastolic blood pressure drops below 30 mm Hg over compartment pressure. When compartment pressure exceeds diastolic pressure, the blood flow in the extremity is stopped. Untreated compartment syndrome–mediated ischemia of the muscles and nerves leads to eventual irreversible damage and death of the tissues within the compartment.

Figure 10-35 Compartment pressure monitoring devices.

Signs and Symptoms

Compartment Syndrome

- Pain
- Pallor
- Pulselessness
- Paresthesia
- Paralysis
- Pressure
- Poikilothermia (affected extremities may be cold)

Transport Management

Compartment Syndrome

- Maintain an open airway; apply high-flow oxygen as necessary.
- Assess pulses and motor and sensory function.
- Elevate the extremity above the heart.
- Place ice packs over the extremity.
- Initiate IV fluids to maintain peripheral perfusion.
- Consider loosening constrictive splint material and/or clothing.
- Administer pain medication.
- Monitor carefully for signs of, and be prepared to treat, rhabdomyolysis, hyperkalemia, and myoglobinuria.

Crush Injury and Rhabdomyolysis

Rhabdomyolysis is damage to the sarcolemma (muscle membrane) from any cause. This damage allows an influx of calcium and sodium, followed by water, to the cells and a release of myoglobin, aspartate transaminase, lactate, creatine kinase, potassium (K^+), uric acid, and phosphorus. The membrane damage also results in extracellular hypocalcemia and hyperkalemia. Hyperkalemia leads to cardiac arrhythmias. The release of myoglobin with hypovolemia and acidosis leads to the blockage of renal tubules, causing acute renal failure.

There are multiple etiologic causes of rhabdomyolysis, both traumatic and medically induced. The leading causes are exercise, alcohol, drugs, infections, trauma, compression, and seizures. The list of causes also includes metabolic myopathies, drugs and toxins (including cocaine and hallucinogens such as PCP and MDMA), infections, electrolyte abnormalities (including hypokalemia, hypophosphatemia, and both hypernatremia and hyponatremia), electrical current injuries, hypoxia (including carbon monoxide poisoning and sickle cell crisis), hyperthermia (including from heat stroke, neuroleptic malignant syndrome, and malignant hyperthermia), and idiopathic causes. Assessment must start with a high index of suspicion because of the many causes. Any patient who lies in one position without being able to move for several hours is at risk. Physical examination may reveal motor weakness, obvious evidence of trauma or compression, and sensory loss. All of these symptoms may be accompanied by evidence of dehydration and dark or tea-colored urine. The urine on a dipstick will show blood with only a few red blood cells on microscopic urine analysis, and a blood test will show significant creatine kinase levels of 5 times normal or higher. The upper normal level is 150 U/L. Sometimes, several hundred thousand units per liter may be present in rhabdomyolysis. Electrolytes will show hyperkalemia (> 5.5 mEq/L), with the expected ECG changes of tall pointed T waves with a narrow base that widens as K^+ increases, and then a flattening P wave. Hypocalcemia (< 4.3 mEq/L) may also be present, which will show on an ECG as a prolonged QT interval.

Signs and Symptoms

Rhabdomyolysis

- Motor weakness
- Obvious evidence of trauma or compression
- Sensory loss
- Dehydration
- Dark or tea-colored urine
- Blood with only a few red blood cells on microscopic urine analysis
- Significant elevations in creatine kinase (5 times normal or higher)
- Hyperkalemia (>5.5 mEq/L), plus ECG changes of tall, pointed T waves with a narrow base that widens as K^+ increases, and then a flattening P wave
- Hypocalcemia (>4.3 mEq/L), plus a prolonged QT interval on ECG

Transport Management

Rhabdomyolysis

- Administer 2 L (or more) of saline.
- Administer 1 mEq/kg of sodium bicarbonate.

- Place the patient on a heart monitor.
- If signs of elevated K^+ are seen, give calcium as often as every 4 minutes as a slow IV push.
- If IV or intraosseous access cannot be obtained, apply a tourniquet proximal to the entrapment.
- Insert an indwelling catheter, and give enough fluids to maintain output of 200 to 300 mL/h.
- Give enough bicarbonate to keep urine pH greater than 6.5, by adding 1 to 2 amps per 1 L saline given.
- Administer mannitol.
- On interfacility transfers, monitor electrolytes.

Management

When a CCTP is called to a scene for prolonged (longer than 4 hours) entrapment of a large muscle area, it is imperative that evaluation and treatment be started prior to the release of the entrapped patient. Crush syndrome is known as the smiling death. This is because extricated patients are shown happy and smiling until the released K^+ reaches the heart and sudden death ensues. Immediately prior to rescue, 2 L or more of saline (not potassium-containing lactated Ringer's solution) should be infused and 1 mEq/kg of sodium bicarbonate should be given. The patient should be on a heart monitor when released and if signs of elevated K^+ are seen, then calcium should also be given as often as every 5 minutes as a slow IV push. If IV or intraosseous access cannot be obtained, a tourniquet should be applied proximal to the entrapment to prevent the release of myoglobin and K^+ and the entry of fluid into the muscle mass. Once an indwelling catheter is placed, fluids should be given to maintain output of 200 to 300 mL/hr. Bicarbonate should be given to keep urine pH greater than 6.5. This can be done by adding 3 amps to a liter of 5% dextrose in water to maintain an isotonic solution. Mannitol is the diuretic of choice. It is both an osmotic diuretic, reducing swelling of the damaged muscle, while serving as an intravascular volume expander. It also dilates and flushes the renal tubules. Mannitol also is a free radical scavenger that reduces direct damage. Loop diuretics (furosemide) should be avoided because they acidify the urine. On interfacility transfers, the previously mentioned therapies should be guided by following electrolytes carefully. This includes a set immediately prior to transfer and, if available, use of bedside electrolyte monitoring during transport, such as with an I-STAT device **Figure 10-36**.

Figure 10-36 An I-STAT bedside electrolyte monitoring device for use during transport.

Pulseless Extremity

Although a traumatized pulseless extremity may be repositioned successfully to reestablish circulation, there are inherent dangers to this maneuver. It should be done with manual traction in anatomic alignment with the long bone. Traction should reduce and not cause pain if it is done in the correct anatomic direction. If the injury is a dislocation rather than a fracture, analgesia and benzodiazepines may help

relax the muscles to facilitate the repositioning. Position the extremity to maximize the strength of the pulse and splint in position. Mark the skin where pulses are obtained to make reassessment faster.

Pharmacologic Management

Nonsteroidal Anti-Inflammatory Drugs

Although nonsteroidal anti-inflammatory drugs are used in stable patients to control pain and reduce inflammation, during the acute phase of resuscitation and transport of critical patients, opiates such as fentanyl should be used. Ketorolac can be used for moderate pain if there is no bleeding and if hypovolemia is not an issue.

Opiate Analgesics

During critical care transport, opiates are the mainstay of pain control. Proper amelioration of pain should be a primary concern of the CCTP. All opiates have side effects. The most serious in the short term can be respiratory depression. Hypotension and nausea or vomiting can also be side effects of opiates as a result of the release of histamine. Fentanyl is rapidly becoming the most widely used opiate for critical care use because it does not release histamine. These side effects can be controlled even with use of traditional morphine if it is given slowly and with enough fluids.

Antibiotics

Early use of antibiotics is common practice with trauma. Especially in patients with open fractures and body cavity wounds, it has become common practice to start IV antibiotics during the resuscitation phase of care. The CCTP will often transport patients from one facility to another with an antibiotic hanging. In most cases, the CCTP will simply need to be aware of any drug interactions and be alert for signs of an allergic reaction. If the patient is intubated, watch the capnography wave form for signs of bronchospasm.

Muscle Relaxants

The muscles around a fracture will undergo spasms to hold the bone ends in place. This self-splinting causes pain. Muscle relaxants can be used to control this pain in more stable patients. These medications are usually not used in the transport of the critical care patient. Occasionally, benzodiazepines are used both as anxiolytics and as muscle relaxants for critical care transport. Other muscle relaxants include cyclobenzaprine (Flexeril) and carisoprodol (Soma). These drugs potentiate opiates.

Anticoagulants

Anticoagulants represent another group of medications that the CCTP must be very comfortable with. The CCTP will transport many patients who will be on anticoagulants; most will be cardiac patients. During the critical care phase of the trauma, use of anticoagulants must be very carefully balanced against the risk of further bleeding. Anticoagulants are used in trauma to prevent deep venous thrombosis (DVT) and disseminated intravascular coagulation (DIC). DVT can result from damage to the blood vessel walls due to tissue debris or stasis of blood during low-pressure states and patient immobilization. Heparin has been the main preventive measure against DVT but is being replaced by low-molecular-weight heparin as a result of lower risk and less need to follow coagulation studies as closely. DIC can result from multiple blood transfusions, hypothermia, and damage to various organs, including the liver. There is a high risk in pregnant patients in particular. Treatment is complex and varied, but may include use of anticoagulants along with transfusion of various blood products.

Sedatives/Hypnotics

Anxiety and agitation impact negatively on patient care. In addition to the psychologic and physiologic impact, the agitated patient can endanger himself or herself as well as the transport crew. Adequate control of anxiety and agitation is an important part of safe and humane critical care transport, second only to cardiorespiratory stability and pain control. Benzodiazepines such as lorazepam and sedatives such as propofol are examples of medications used by many critical care transport units. It may be necessary to use etomidate and a long-acting paralytic such as vecuronium to provide for safe transport of the patient and to minimize his or her pain.

Trauma to Special Populations

Geriatric trauma and trauma to pregnant patients are covered here. Pediatric trauma is covered in Chapter 23.

Geriatric Trauma

Some 34 million Americans (12%) are older than 65 years, the age we call geriatric; but when it comes to trauma, mortality rates start to climb after the age of 30 years. The incidence of complicating comorbid conditions also increases after 30 years of age. These coexisting medical conditions cause lesser traumas, which then have a higher mortality. By the year 2030, 20% of the US population will be older than 65 years. Although patients older than 65 years account for only 11% of pedestrian accidents, they account for 25% of the fatalities. A driver older than 65 years is five times more likely to be fatally injured in an MVC than a younger driver. The 1-year mortality rate for hip fractures in the over-65 population is 20% and the 2-year rate is 33%. One in five burn center admissions is a patient older than 65 years. This is about 1,500 people a year, with a fatality rate seven times that of younger patients.

Assessment of the airway needs to include the presence of dentures or other dental devices that can become dislodged. Removing dentures may make intubation easier, but without having them in place, getting a mask seal is more difficult. Broken teeth are at an increased risk of becoming a foreign body in older patients. Kyphosis can cause problems for both spinal immobilization and airway management. Extra padding to fill the void under the head and additional personnel to assist with immobilization may be necessary. Because of a reduced cough reflex and an increased risk of aspiration, additional attention to suctioning may be necessary. The nasal tissues are more fragile and, if the patient is on anticoagulants, the risk of bleeding may render the use of both basic and advanced nasal airways problematic. Respiratory assessment must take into account reduced vital capacity and decreased ability for chest excursion, even prior to injury. Reduced tidal volume and lower minute volume can lead to significant reduction in oxygen and carbon dioxide exchange as a baseline. Progressive hypoxia can result from even minor chest injury. Increased PIP may be necessary as a result of chest wall stiffness. Older patients are often more dependent on diaphragmatic excursion, and any restriction of the abdomen may interfere with this respiratory movement. Assessment for shock and perfusion may be difficult in the elderly. Capillary refill may be normally delayed. Furthermore, a cardiovascular assessment of the geriatric patient may be complicated by medications such as beta-blockers or other antihypertensives. These medications may interfere with compensatory mechanisms of shock, holding the heart rate artificially low in the face of hypovolemia. Patients with pacemakers also will be unable to compensate by raising their heart rate. Preexisting hypertension means that decompensated shock may present as what appears to be a normal blood pressure to the observer. A slow or absent vasoactive response means that the patient is more dependent on preload. Although fluid resuscitation is still the mainstay of traumatic shock resuscitation for the elderly, caution must be exercised to prevent fluid overload from the inability of the

cardiovascular system to adjust to rapid changes in fluid volumes. Slow responses to questions or a lack of orientation to a location or date may not be a sign of head trauma but part of a retired and elderly person's lack of concern with dates and the slower processing of a normal older patient. Therefore, if the patient is conscious, history taking may require more patience when waiting for answers. The use of open-ended questions is recommended. Management considerations, in addition to those previously listed, include extra care to maintain temperature control and extra padding between splints or backboards as a result of the reduced subcutaneous fat.

Trauma During Pregnancy

Abdominal Injuries to Pregnant Patients

Injuries to pregnant patients are complicated by the multiple physiologic changes to the patient and the fact that the CCTP is now responsible for two lives. The primary cause of fetal demise in the traumatized mother is maternal shock and death. Therefore, the best treatment for the fetus is to resuscitate the mother. Trauma occurs in 8% of pregnancies but is the leading cause of death in pregnancy, accounting for 45% of maternal deaths. The most common cause of trauma during pregnancy is MVCs, followed by assault. About 8% of women between 15 and 40 years of age presenting to trauma centers do not even know they are pregnant. For the physiologic changes in pregnancy, see Chapter 21.

Some of the changes in pregnancy can mimic shock. In the first trimester, blood pressure drops about 5 mm Hg systolic and 15 mm Hg diastolic. The pregnant patient's heart rate increases as much as 20 beats/min. Other changes may hide shock as well. Blood volume increases by about 50% in mid-pregnancy, and a relative anemia results from hemodilution. The traumatized patient may lose as much as 40% of blood volume before the signs of shock are obvious. Because of the increase of coagulation factors and fibrinogen, the risk of DVT, pulmonary embolus, and DIC increases. This is especially true in patients with an ISS greater than 8.

Because of the increase in blood flow to the uterus to over 0.5 L/min with venous congestion of the pelvic vessels, the risk of massive blood loss is considerably increased with trauma to the bony pelvis.

Any pregnant patient who suffers from a pelvic injury most certainly has a bladder and/or uterine injury. At term, the uterus/placenta is perfused with approximately 600 to 800 mL of blood *per minute*! There should be a high rate of suspicion for these injuries, because these patients may exsanguinate rapidly.

Abruptio Placenta

In blunt trauma, as much as 70% of fetal demise is the result of abruptio placenta. Sudden deformation of the uterine wall can shear the placenta from the site of implantation. There may be no external signs of this occurrence. Signs of abruption include vaginal bleeding (only about 37% of the time), abdominal cramping, and symptoms of maternal hypovolemia. The most important sign is fetal distress. Ultrasounds are less than 50% accurate in finding an abruption. Women with an abruption are at an extremely high (54 times) risk for DIC as a result of release of thromboplastin from the placenta.

Signs and Symptoms

Abruptio Placenta

- Vaginal bleeding
- Abdominal pain
- Back pain

- Uterine tenderness
- Signs of shock
- Lack of fetal heart sounds

Differential Diagnosis

Abruptio Placenta

- Ectopic pregnancy
- Placenta previa
- Preterm labor
- Spontaneous abortion

Transport Management

Abruptio Placenta

- If the patient is beyond 20 weeks' gestation, tilt her left laterally at least 15° to prevent vena cava syndrome.
- Provide bleeding control.
- Maintain the patient's airway; provide maximum oxygenation.
- Initiate early IV access and implement aggressive fluid resuscitation (eg, with warmed lactated Ringer's solution).
- Provide rapid transport.

Management

Fetal resuscitation focuses on maternal resuscitation, and maternal resuscitation starts with the ABCs. With a higher risk of aspiration and the increase in gastric acidity, isolating the patient's airway is of vital importance. Because of increased oxygen consumption and reduced reserve, all mothers should receive maximum oxygenation. Hypoxia alone can cause a 30% reduction in uterine blood flow. Increased tidal volume and respiratory alkalosis as a baseline must be taken into account with ventilators and end-tidal carbon dioxide ($ETCO_2$) monitoring. The target for $ETCO_2$ should be 30, not 40 mm Hg. Early IV access with aggressive fluid resuscitation should be initiated before signs of shock. Warmed lactated Ringer's solution has been shown to restore fetal oxygenation better than other crystalloids. Beyond 20 weeks of gestation, the patient should be tilted left laterally at least 15° to prevent vena cava syndrome. CVP is helpful in guiding fluids, but remember that CVP normally trends down to as low as 3 mm Hg as pregnancy progresses.

Flight Considerations

The principles presented in this chapter apply to both ground and air critical care transport; however, as a result of the critical nature of their injuries, patients with severe trauma are more likely to be transported by air, especially in situations in which ground transport time could take considerably longer than air.

Summary

Caring for patients with traumatic injuries requires the CCTP to have a solid understanding of the trauma system in the United States. Knowledge and application of commonly used trauma scoring systems and triage are essential parts of daily work as a CCTP. The CCTP must apply this knowledge and the appropriate assessment skills to assess, triage, treat, and transport patients with traumatic injuries to the most appropriate facility. It is imperative that the CCTP is competent in clinical skills, understands why certain injuries occur, and has knowledge of which emergency procedures need to be performed to decrease morbidity and mortality. In mastering these skills, the CCTP becomes an integral part of the overall trauma care and management process, which in turn maximizes the patient's acute care, rehabilitation, and recovery.

Case Study

YOU ARE WORKING THE DAY SHIFT with a nurse-medic–staffed helicopter. You have been dispatched to a scene. You receive a report from your communication center that you are going to a farm site where an older man has been kicked by a bull. The patient is currently alert and his vital signs are stable, as reported by the paramedics on the scene. The closest Level 1 trauma center from the scene is a 30-minute flight.

Upon landing, you and your partner approach the scene, which is in the pasture of a beef cattle farm. You survey the scene to ensure your safety. You receive a report from the local paramedics. The patient, a 68-year-old man, was assisting in feeding cattle when one of the bulls attacked him, first striking him in the chest with his head (horns removed) and then kicking him in the chest. The medic states that the patient is complaining of shortness of breath and severe chest pain, but otherwise he is alert and oriented and his vital signs remain stable.

Your assessment reveals a well-developed man who appears to be extremely short of breath. He is wearing a nonrebreathing mask and is receiving oxygen at 15 L/min; his oxygen saturation is 90%. In looking at his chest wall, you see a significant defect on the left side of the chest, with paradoxical chest wall motion. The patient is alert and oriented, with a GCS score of 15. He states his breaths are becoming progressively shorter. The patient has two large-bore IVs in place and has already received 1,000 mL of normal saline. His vital signs include a blood pressure of 110/70 mm Hg, a pulse rate of 118 beats/min, a respiratory rate of 32 breaths/min, and an oxygen saturation of 90%.

You and your partner discuss the patient's need for pain medication. You administer 1 μg/kg IV of fentanyl. His heart rate slows down to approximately 100 beats/min, but his respiratory status does not improve. You and your partner discuss managing this patient's airway/ventilator status and elect to intubate the patient orally before leaving the scene. Using your local protocol, you administer etomidate, 0.3 mg/kg IV, and succinylcholine, 2.0 mg/kg IV. Cricoid pressure is applied and c-spine stabilization is maintained. The intubation is performed without difficulty. After intubation, you hear bilateral breath sounds but crackles in the left base. You apply capnography and monitor his $ETCO_2$. His initial reading after intubation was 60 mm Hg. You finish packaging the patient and begin transport.

In flight, you administer long-term paralytics and, additional sedation agents, and continue to treat the patient's pain. His vital signs remain stable, with a blood pressure of 98/70 mm Hg, a pulse rate of 90 beats/min, and ventilations at 16 breaths/min with 97% saturation. His $ETCO_2$ reading is 40 mm Hg, which shows that he is adequately ventilated. You and your partner discuss IV flow rates and elect to keep open both his IV lines. The patient is admitted to the Level 1 trauma center and a report is given to the attending staff.

1. Why did you elect to intubate this person when the standard of care for flail chest is to keep the

patient off mechanical ventilation if it all possible?

2. Why did you decide to continue the patient's fluids in-flight?

Analysis

For cases of flail chest the patient's pain is treated aggressively. With the pain under control, many times the patient is then able to ventilate adequately on his or her own. In this patient there were two concerns that needed to be considered. First, the patient was dyspneic and was not breathing adequately, as shown by his poor SaO_2, despite high-flow oxygen. Even after his pain was treated and his heart rate slowed down, his oxygen saturations were borderline at best. Second, the patient has a 30-minute flight, and the chance that his condition would continue to deteriorate seems high. In the treatment of flail chest, mechanical ventilation should be reserved for patients who have persistent respiratory insufficiency or failure, after adequate pain control. This patient met that standard; therefore, intubation is appropriate, and RSI should be performed. Follow local protocol for appropriate medication use. In this patient, it is imperative that you continue to treat his pain after administration of long-term paralytics and sedation. C-spine stabilization also needs to be maintained during intubation and the flight. Patient monitoring after intubation should include continuous capnography. A capnography reading is an excellent indicator of adequate ventilation in flight.

Many services are carrying continuous positive airway pressure devices on the helicopter. This patient would have been a candidate for continuous positive airway pressure in flight, thus avoiding mechanical ventilation. The CCTP would have to be astute in ongoing pulmonary assessment to realize when the patient's condition is failing and would need to provide mechanical ventilation.

With chest trauma that is significant enough to break multiple ribs, there is a higher associated risk of underlying parenchymal injury to the lung. Aggressive fluid resuscitation only worsens the interstitial fluid leak, which leads to ventilation-perfusion mismatch and, thus, worsening pulmonary contusion. This patient had already received 1,000 mL of fluid, which probably worsened his lung condition.

The patient's mean arterial blood pressure should be maintained at or above 65 mm Hg. His current reading is approximately 79 mm Hg, which is adequate for end-organ perfusion. This patient's IV fluids should be restricted. If his blood pressure dictates, titrate the patient's fluids according to his MAP.

Prep Kit

Ready for Review

- A paradigm shift in the care of critically injured trauma patients has resulted in an emphasis on rapidly identifying and treating those patients who need immediate transport to an appropriate trauma center.
- The ability of the CCTP to rapidly identify life-threatening injuries while recognizing the need for transport to a trauma center will help to decrease the incidence of morbidity and mortality related to these traumatic injuries.
- CCTPs may encounter trauma patients during a scene call, when they are called to back up field BLS or ALS providers. In these cases, the CCTP will be working in more austere and less controlled conditions with less sophisticated assessment tools than in an interfacility transport.
- CCTPs may also aid in transferring critical patients with trauma, usually from smaller facilities to trauma centers. In this situation, the CCTP may have access to the results of any assessment findings identified prior to transport and may be able to enlist the aid of the sending physician or other house staff to help with stabilization efforts prior to transport.

- The balance of treatment before transport vs what can be done en route should always be a top priority in the CCTP's decision-making process.
- Trauma is a major cause of death in persons younger than 40 years, and is the leading cause of death in children.
- Many people survive a motor vehicle crash, only to suffer a debilitating injury that leaves them incapacitated. Providers must appreciate the importance of avoiding secondary injury caused by improper handling of these patients.
- Trauma scoring systems are used in the critical care transport environment to provide assessment information and indicators of patient survivability.
- The Glasgow Coma Scale (GCS) is a neurologic assessment tool that assigns a numerical value to the patient's condition based on three body functions: best eye-opening response, best verbal response, and best motor response.
- The GCS should be used regardless of the cause of central nervous system alteration. It is predominantly used and reported during the care of critically ill and injured patients when their current level of consciousness is pertinent to their acuity level.
- Patients who present with GCS scores of less than 8 require intubation or another form of advanced airway intervention.
- The trauma score takes into account the GCS score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill rate. The score, which ranges from 1 to 16 (the best possible score), reflects the likelihood of patient survival.
- The revised trauma score measures three physiologic parameters: respiratory rate, systolic blood pressure, and GCS score. The total score ranges from 0 (the most severely debilitated patient) to 13 or, when a weighted system is used, from 1.0 to 7.8408.
- The revised trauma score is considered flawed because it measures the body's physiologic response to the injury and will not identify a small percentage of severely injured trauma patients.
- The AIS is an anatomic scoring system that provides a reasonably accurate means of ranking the severity of the injury by categorizing injuries into six body regions. Scores for each region range from 1 (minor injury) to 6 (unsurvivable), but do not take into account multisystem injuries.
- The ISS is an anatomic scoring system that provides an overall score for patients with multiple injuries. Scores range from 1 (minor injury) to 75 (high mortality).
- A patient with an ISS of greater than 15 is frequently considered a major trauma patient who requires immediate attention and, in most cases, transfer to a Level I facility.
- The trauma injury severity score is used to determine the survival probability of the critically ill and/or injured patient. It takes into account the ISS, the revised trauma score, and the patient's age, which collectively summarize the patient's physiologic and anatomic indicators.
- Understanding Newton's first law of motion—"A body in motion remains in motion in a straight line unless acted upon by an outside force"—enables the CCTP to predict patterns of injuries in trauma incidents and deliver the appropriate standard of care.
- Traumatic injuries are generally classified into one of two categories: blunt or penetrating.
- Blunt injuries result from energy exchange between an object and the body, without intrusion through the skin—for example, rapid forward decelerations (collisions), rapid vertical decelerations (falls), and energy transferred from blunt instruments.

- Penetrating injuries refer to injuries caused by external forces in which the tissue is penetrated by an object—for example, injuries caused by projectiles such as bullets, knives, fragments from explosions, and falls upon fixed objects.
- Deceleration injuries are caused by a sudden stop of the body's forward motion. Because they may not be visible to the CCTP, an excellent understanding of the types of mechanisms of injury and effective assessment skills are imperative for detecting them.
- External force injuries are caused by forces that violate the tissues of the body. Their severity depends on the anatomic area involved, the mass, and the velocity of the foreign object that enters the body.
- The CCTP must not develop tunnel vision; that is, he or she must not focus on a visible injury, which may or may not be life threatening, while paying little or no attention to other, life-threatening injuries.
- Maintaining a calm, professional demeanor allows the CCTP to maintain a high index of suspicion and attention to detail.
- Trauma assessment begins with scene size-up, which encompasses scene safety, body substance isolation, number of patients, determination of whether additional resources are needed, and mechanism of injury (ie, what happened or how the patient was injured).
- Trauma assessment encompasses both a physical examination and a subjective interview (when possible); the latter information often has to come from someone other than the patient.
- The primary assessment should take no longer than 1 minute and includes the general impression of the patient, level of consciousness, and assessment of the ABCs.
- If the initial trauma primary assessment reveals no major injury, the CCTP should move on to either a rapid trauma exam or a focused exam. Trauma patients who have an isolated injury require a focused examination; a rapid trauma assessment is used for patients with multisystem injuries.
- A rapid trauma assessment allows the CCTP to rapidly assess the head, neck, chest, abdomen, pelvis, and extremities to find and correct any life threats and should be completed in less than 1 minute.
- When conducting a focused exam, the questions to ask will vary depending on the patient's specific injury.
- A more comprehensive secondary assessment is generally done during transport to a trauma center. The secondary assessment is a more comprehensive examination to determine additional injuries that may have been overlooked in the primary assessment; its findings serve as a baseline for future treatment decisions in the continuity of care.
- Critical patients who fall into the "load-and-go" category should have the secondary assessment performed during transport; noncritical patients may be assessed on the scene.
- Once the primary and secondary assessments are completed, the CCTP must determine the criticality of the patient and make a transport decision. Patients who meet critical care criteria should immediately be loaded into the critical care transport unit and taken to the appropriate trauma center.
- Issues related to airway, breathing, and external bleeding are the only reasons to delay transport, and it should only be delayed long enough to intervene with these problems.
- Continual reassessment of the patient and interventions performed should occur during the transport. If the patient's condition deteriorates, the CCTP should immediately reassess the primary assessment and address any negative findings, if possible.
- Triage is a system of sorting patients based on injury severity, with the goal being to use the limited resources for those patients who need them the most ("doing the greatest good for the greatest number").

- Immediate (red) triage tags denote the highest-priority cases. Patients in this category need immediate care and transport to definitive treatment centers.
- Delayed (yellow) triage tags are reserved for second- or delayed-priority patients. Patients in this category need treatment and transport, but those measures can be delayed.
- Minimal (green) triage tags are given to third-priority patients—the "walking wounded," who have minor soft-tissue injuries.
- Expectant (black) triage tags are used for patients for whom no treatment is indicated—those who are dead, those who are alive but nonsalvageable, and those who are not injured.
- The triage officer has ultimate control of the counting and prioritizing of patients; the treatment officer oversees the treatment area; the transportation officer oversees transport of patients; and the staging officer oversees and directs the staging area to deploy needed resources to the appropriate treatment sectors.
- START (simple triage and rapid treatment) triage is one of the easiest methods of triage and entails a limited assessment of the patient's ability to walk, respiratory status, hemodynamic status, and neurologic status.
- The JumpSTART triage system is used for prioritizing care of children younger than 8 years or who appear to weigh less than 100 lb. It includes the same parameters as the START system, albeit tailored to pediatric patients.
- Trauma centers are classified into Levels I through IV, with Level I (regional centers that provide every aspect of trauma care) having the most resources, followed by Level II (facilities that provide initial definitive care), Level III (facilities that provide assessment, resuscitation, emergency care, and stabilization, and then transfer patients to higher-level centers), and Level IV (clinics that provided advanced trauma life support prior to patient transfer).
- Patients with severe trauma (Level I patients) are more likely to be transported by air, especially in situations in which ground transport time could take longer than air transport.
- Of all trauma deaths, 25% are directly associated with thoracic injuries.
- For trauma patients, computed tomography scanning is typically used for head injury identification, identification of bleeding, and complex fractures. Typical studies will scan the head, chest, and abdominal-pelvic regions.
- Magnetic resonance imaging provides much greater contrast that is useful for identification of abnormalities in trauma.
- Focused Assessment with Sonography for Trauma (FAST) ultrasound is used to identify the presence of free intraperitoneal or pericardial fluids, and has replaced diagnostic peritoneal lavage and laparotomy for this indication.
- Intra-abdominal pressure (IAP) is the static pressure inside the abdominal compartment. Deleterious effects of intra-abdominal hypertension (IAH) can lead to abdominal compartment syndrome (ACS) and death if untreated. Definitive treatment is surgical decompression, but there are many interventions that can help prevent IAH and ACS. Also, the CCTP may be asked to obtain IAP measurements during transport.
- When transporting trauma patients, CCTPs should always ask for and ensure that all copies of any imaging studies are included as part of the patient record.
- The primary function of the thorax is to allow for adequate oxygenation and circulation. Therefore, injuries to the chest must be promptly found and managed.

- Care must be taken in traumatized patients to ensure adequate positive-pressure ventilations without allowing interthoracic pressure to rise too high; this may become an issue during flight.
- Pneumothorax injuries cause air to be drawn into the thoracic cavity with each breath. A collapse as small as 10% can be life threatening if there are other comorbid issues.
- Complications of sealing a sucking chest wound can cause a tension pneumothorax if air is still able to enter the pleural cavity from the lung side of the wound and builds up or if the seal is ineffective.
- A simple pneumothorax is most often associated with a closed chest injury, such as from a fractured rib being driven inward into the lung or from a medical cause of a collapse of the lung.
- A tension pneumothorax is a life-threatening injury that results from a continual influx of air into the pleural space. It may occur secondary to a closed simple pneumothorax or after sealing an open pneumothorax.
- Management of a tension pneumothorax is performed by immediate needle decompression.
- Hemothorax can be caused by blunt or penetrating trauma, as well as a tumor eroding through the great vessels. It may potentially lead to hypovolemic shock or, if a large amount of blood accumulates in the pleural cavity, it can interfere with lung function.
- Patients with a pneumothorax, hemothorax, hemopneumothorax, or empyema ultimately may need a chest tube insertion. In addition, CCTPs routinely care for and transport patients with chest tubes in place.
- Because of the potential for massive hemorrhage from thoracic trauma, the CCTP must be familiar with the administration of blood.
- A flail chest (flail segment) consists of a fracture in two or more places to two or more adjacent ribs. Bruises to the underlying tissue causing a pulmonary or myocardial contusion are the most dangerous sequelae of a flail chest.
- Flail segments pose a threat to the patient's ability to breathe, increase the risk for developing a hemothorax or pneumothorax, and require immediate treatment.
- The hallmark treatment for flail chest is mechanical ventilation with a sedate, paralyzed patient who has been adequately treated for pain. Some patients may be managed conservatively with pain medications and oxygen supplementation alone.
- Pericardial tamponade is a life-threatening condition that requires immediate treatment. It occurs in 2% of penetrating injuries to the chest and upper abdomen, and is more common in stab wounds to the heart than in gunshot wounds.
- Most often, prehospital management of pericardial tamponade is only supportive; sometimes, however, the CCTP may need to perform or assist in an emergency pericardiocentesis.
- Traumatic aortic rupture is the most common cause of immediate death in motor vehicle collisions.
- Tears in the ascending aorta are almost uniformly immediately fatal, but patients with tears on the descending side have a 15% chance of making it to the operating room. However, there is a 30% mortality rate among those patients who make it to the hospital.
- Myocardial contusion (bruise to the myocardium) is primarily the result of blunt trauma to the anterior chest wall, such as trauma that occurs during motor vehicle collisions or with other blows to the front of the chest (eg, gunshot to a bulletproof vest).
- With myocardial contusion, damage to small blood vessels may cause local bleeding and direct trauma to cells. Because the areas downstream from the damaged vessels are no longer perfused, the damage

may resemble that associated with myocardial infarction.

- If blunt compression of the abdomen occurs (eg, from blunt or penetrating trauma), it may cause diaphragmatic rupture and herniation of abdominal organs into the thoracic cavity. This impinges on lung function and decreases venous return, resulting in decreased ventilatory and cardiac output.
- Tracheobronchial injuries are rare, but often life threatening. The leakage of air with such damage may cause tension pneumothorax or tension pneumomediastinum, which will act like a cardiac tamponade.
- Management of tracheobronchial disruption includes judicious use of ventilatory support. CCTPs must be aware that paralysis of the muscles may allow retraction of the trachea into the chest.
- Tearing and lacerations to the lung tissue (pulmonary contusion) can cause bleeding and leakage of plasma into alveoli and the interstitial spaces around them. This damage interferes with gas exchange and leads to severe hypoxemia.
- Patients with pulmonary contusion may be managed with noninvasive, continuous positive airway pressure and resuscitation fluids.
- Esophageal perforations are most often caused by penetrating injuries, such as from projectiles or from caustic ingestion, but can also be caused by a medical issue, such as cancer, gastroesophageal reflux disease erosions, or excessive vomiting.
- Traumatic asphyxia (a severe sudden crushing injury to the chest and abdomen) is not a form of asphyxia nor is it by itself fatal. Associated injuries, if present, tend to be far more serious.
- Facial trauma can be life threatening as a result of airway compromise and the threat to the patient's ability to get sensory information through sight and hearing; it also has many social and self-image implications for the patient and can be distracting for caregivers.
- A punctured eardrum may cause vertigo and nausea, which the CCTP may need to control with medication. The patient should be protected from aircraft noise.
- Blood or fluid coming from the auditory canal indicates a more serious injury and should be assessed with the halo test.
- A ruptured tympanic membrane is not life threatening, but should raise the suspicion of other, much more serious overpressure injuries.
- Eye injuries, although often dramatic, are not life threatening. Care typically consists of protecting the eye from further injury and transporting the patient to the ophthalmology service.
- In chemical burns to the eye, adequate washing is essential and should be performed for at least 10 minutes prior to transport for acid burns and at least twice as long for alkali burns.
- If an object is impaled in the eye, both the eye and the object should be prevented from movement, if possible, for transport.
- Hyphema (a collection of blood in the anterior chamber of the eye) may be a marker of damage to other structures of the eye and requires a full ophthalmologic examination.
- Rupture of the ocular globe with leak of vitreous humor may be the result of penetration by a foreign body or blunt trauma.
- Despite the dramatic presentation of enucleation of the eyeball from the eye socket, loss of vision is not inevitable. Proper care includes protecting the eye from further trauma in transit by using a protective cup or other rigid protective device with gauze padding.
- Retinal detachment (separation of the inner layers of the retina from the pigmented epithelium) may be caused by trauma, diabetic retinopathy, and sickle cell disease. With rapid diagnosis and surgery,

blindness may sometimes be avoided in such cases.

- Treatment is usually not necessary on a scene call for mandibular fracture or dislocation, but provision must be made for an emergency airway during the transfer of any patient whose jaw is wired shut.
- Avulsed teeth have a good chance of reimplantation if replaced within an hour.
- The critical airway and vascular structures running through the neck are relatively unprotected during trauma events. In addition, the possibility of unstable cervical spine and cord injury must always be considered and protected against.
- Securing the airway with endotracheal intubation should be considered prior to transporting any patient with a neck injury. Deterioration of the patient's airway in the back of a transport vehicle with limited space and personnel can be disastrous.
- Most laryngotracheal injuries occur in the area of the cervical trachea and are most frequently caused by direct blunt trauma. These injuries can appear stable for a time, but then be followed by rapid and catastrophic deterioration.
- In case of laryngotracheal disruptions, paralytics and muscle relaxants are absolutely contraindicated.
- Direct trauma to the front of the neck (including the thyroid gland) can cause hematomas of sufficient size to impinge on the airway. Thyrotoxicosis (thyroid storm) has a 20% to 30% mortality rate.
- Injury to the carotid, subclavian, and vertebral arteries, and to the external and internal jugular veins, can produce rapid exsanguination, hematoma formation, or embolization of air, with lethal outcomes.
- If the patient has experienced blunt or penetrating trauma to the abdominal cavity, signs or symptoms of injury may be very difficult to identify until shock becomes obvious. Because of the size of the abdominal cavity, a significant amount of blood can collect within the cavity and go unnoticed.
- With abdominal injuries, it is important for the CCTP to focus attention on the mechanism of injury, instead of the outward signs of trauma found on assessment.
- If a significant abdominal injury is suspected or confirmed, the most definitive treatment that the CCTP can provide is rapid transport to the trauma center, while stabilizing and maintaining the patient's hemodynamic status as effectively as possible, so that surgical intervention can be performed if needed.
- The seatbelt has significantly decreased the incidence of morbidity and mortality related to automobile crashes, but continues to cause less noticeable abdominal injuries.
- Penetrating injuries may be very difficult for the CCTP to assess because the necessary information about the penetrating object is often not available. Even when this information is available, it is difficult to rapidly identify which structures inside the abdominal cavity were injured without the assistance of imaging studies.
- In case of abdominal injury, the physical exam performed by the CCTP to rapidly identify the presence of blood loss is the most important task.
- The primary assessment of a patient with abdominal injury should be completed before beginning transport, and repeated frequently during transport, watching for changes that require immediate intervention.
- All patients suspected of having abdominal injuries should be transported on high-flow oxygen with fluid administration. The more severe cases may need aggressive airway management and blood administration.
- The primary concern with hollow-organ injury is the potential for peritonitis to develop.

- The spleen is the most commonly injured organ in the abdominal cavity. Young adults and patients with sickle cell disease are at particular risk for spleen injury.
- Failure to recognize, understand, and treat the signs and symptoms of hypovolemic shock related to internal hemorrhage will rapidly lead to the patient's death.
- The ligament in front of the liver can slice the liver in sudden deceleration. The liver's close proximity to the lower rib cage also makes it susceptible to injury after a rib fracture occurs.
- Although penetrating trauma is the most common source of injury to the intestines, blunt trauma to the abdominal wall—often caused by a seatbelt—can also damage the small bowel.
- Approximately 80% of gunshot wounds to the abdomen and 30% of stab wounds lacerate the jejunum and ileum.
- Injuries that occur to the vessels of the abdomen are usually life threatening. Severe blunt trauma may cause disruption of these vessels, but the most common cause of vascular injury is penetrating trauma.
- Rapid transport of patients with an injury to any of the major abdominal vessels to a hospital capable of immediate surgery is the best possible treatment.
- The presence of a pelvic fracture should alert the CCTP to the possible existence of other injuries, given the force that must be exerted to cause pelvic fracture; the potential for (possibly fatal) internal hemorrhage is high.
- Subjective assessment for pelvic fracture includes identification of the mechanism of injury, location and radiation of pain, presence of hematuria, and possibility of pregnancy. Objective examination should include observing for the rotation or uneven height of the iliac crests and uneven length of the legs, palpating the posterior aspect of the pelvic ring, and exerting gentle lateral compression and inward compression.
- Musculoskeletal injuries, although often dramatic, may distract the CCTP from more serious injuries. Nevertheless, their presence may be an indicator of the amount of energy transferred to the body and may suggest the likelihood of additional injury.
- All musculoskeletal injuries should be assessed for the six Ps (pain, pallor, pulselessness, paresthesia, paralysis, and pressure) before and after any manipulation.
- Regardless of whether a fracture is open or closed, the CCTP must make prevention of further injury as a result of movement, with pain assessment and management, a priority.
- Closed fractures can be as dangerous as open fractures because of the internal bleeding into the tissues involved.
- In an open fracture, the skin over the bone is broken, adding the potential danger of infection, which could lead to sepsis and death.
- Femur fractures should be considered to account for the loss of at least 1 L of blood from circulation.
- Any movement during transport of a patient with a vertebral fracture can transform an unstable fracture without neurologic deficit into a life-long disability. Accordingly, the current practice is to fully immobilize the spine for transport.
- The most devastating vertebral fractures can occur in the seven cervical vertebrae. Planning for airway management and prevention of aspiration (especially in small aircraft) must be made prior to transport of any patient with such an injury.
- Thoracic fractures can lead to a loss of innervation of the intercostal muscles, leading to respiratory insufficiency. Spinal shock, in which hypotension is accompanied by bradycardia instead of

tachycardia, can affect the thoracic area or higher.

- Humerus fractures may result in significant blood loss. Absence of distal pulses or nerve function should receive immediate attention, usually in the form of traction in anatomic alignment and manipulation.
- Until proven otherwise, all dislocations should be assumed to be coupled with a fracture. Joint dislocations are true emergencies as a result of the potential for neurovascular compromise that could lead to amputation if the injury is not treated appropriately.
- Amputations can be life threatening and are often disabling. There is potential for hemorrhage, although bleeding can usually be controlled with direct pressure to the stump.
- General management of fractures and trauma depends on the overall state of the patient. If the patient needs immediate resuscitation, then airway, ventilation, stopping blood loss, and fluid resuscitation must take priority.
- For fracture and trauma scene calls that do not require critical resuscitation, the priority for care is pain control, assurance of distal neurovascular function, and careful splinting of each fracture.
- No matter which type of fixation splint is used, the entire bone with the adjacent joints must be held immobile for the splint to be effective.
- Swelling under a cast can cause compartment syndrome. The most common anatomic locations for compartment syndrome are the forearms and legs.
- If diastolic blood pressure drops below 30 mm Hg over compartment pressure, it is considered an emergency. When compartment pressure exceeds diastolic pressure, the blood flow in the extremity is stopped.
- Rhabdomyolysis (damage to the sarcolemma) initiates a cascade of events that ultimately results in cardiac arrhythmias and acute renal failure. The leading causes of rhabdomyolysis are exercise, alcohol, drugs, infections, trauma, compression, and seizures.
- When a CCTP is called to a scene involving a patient with prolonged entrapment of a large muscle area, it is imperative that evaluation and treatment be started prior to the release of the entrapped patient to avoid the mortality associated with crush syndrome.
- Although a traumatized, pulseless extremity may be repositioned successfully to reestablish circulation, there are dangers in doing so. If attempted, repositioning should be done with manual traction in anatomic alignment with the long bone.
- A primary concern of the CCTP is to properly ameliorate pain by using nonsteroidal anti-inflammatory drugs in stable patients and opiates in acute-care and critical patients.
- The most serious side effect of opiates in the short term is respiratory depression. Hypotension and nausea or vomiting can also be side effects of these drugs.
- Especially in patients with open fractures and body cavity wounds, it has become common practice to start IV antibiotics during the resuscitation phase of care. Before doing so, be aware of any drug interactions and stay alert for signs of allergic reaction.
- Many patients the CCTP will transport will be on anticoagulants, and most will be cardiac patients. In trauma patients, use of anticoagulants in the critical care phase must be very carefully balanced against the risk of further bleeding.
- The agitated patient can endanger himself or herself as well as the transport crew. For this reason, adequate control of anxiety and agitation is an important part of safe and humane critical care transport.

- Considerations when treating geriatric patients with trauma include several aging-related issues: presence of dentures or other dental devices, kyphosis, reduced cough reflex and increased risk of aspiration, fragility of the nasal tissues, increased risk for bleeding, reduced vital capacity and decreased ability for chest excursion, chest wall stiffness, difficulty of assessment for shock and perfusion, preexisting cardiovascular abnormalities or use of cardiovascular medications, tendency toward fluid overload, slower mental processing, and difficulties in thermoregulation.
- The primary cause of fetal demise in the traumatized pregnant patient is maternal shock and death. Therefore, the best treatment for the fetus is to resuscitate the mother.
- Some of the changes in pregnancy can mimic shock, which makes it difficult to diagnose true shock in a pregnant trauma patient.
- The risk of massive blood loss is considerably increased with trauma to the bony pelvis of a pregnant patient. Any pregnant patient who suffers from a pelvic injury most certainly has a bladder and/or uterine injury.
- Fetal resuscitation centers on maternal resuscitation, and maternal resuscitation starts with the ABCs.

Vital Vocabulary

Abbreviated Injury Scale (AIS) A trauma scoring system that ranks injury severity by assigning an individual injury score of 1 to 6 to six body regions, with 1 being a minor injury and 6 being an injury with a high mortality rate; does not account for multisystem injuries.

abdominal compartment syndrome (ACS) A condition that can result from intra-abdominal hypertension, and that includes a range of deleterious effects, including decreased end-organ perfusion; if untreated, it can lead to death.

Beck's triad The combination of a narrowed pulse pressure, muffled heart tones, and jugular vein distention associated with cardiac tamponade; usually resulting from penetrating chest trauma.

FAST An ultrasound examination directed at identifying the presence of free intraperitoneal or pericardial fluids, performed by transducing four distinct areas of the abdomen; stands for Focused Assessment with Sonography for Trauma.

Glasgow Coma Scale (GCS) An evaluation tool used to determine level of consciousness, which evaluates and assigns point values (scores) for eye opening, verbal response, and motor response, which are then totaled; effective in helping predict patient outcomes.

Injury Severity Score (ISS) A trauma scoring system that adds the squares of the three highest abbreviated injury scale scores to create a score between 1 and 75 that accounts for multiple injuries, with 1 being a minor injury and 75 being an injury with a high mortality rate.

JumpSTART triage A sorting system for pediatric patients younger than 8 years or weighing less than 100 lb. There is a minor adaptation for infants because they cannot ambulate on their own.

Kehr's sign Left shoulder pain that may indicate a ruptured spleen. Right shoulder pain may indicate trauma to the liver.

morbidity The number of nonfatally injured or disabled people. Usually expressed as a rate, meaning the number of nonfatal injuries in a certain population in a given time period divided by the size of the population.

mortality Deaths caused by injury and disease. Usually expressed as a rate, meaning the number of deaths in a certain population in a given time period divided by the size of the population.

pericardial tamponade Impairment of diastolic filling of the right ventricle as a result of significant amounts of fluid in the pericardial sac surrounding the heart, leading to a decrease in the cardiac output.

pericardiocentesis A procedure in which a needle or angiocath is introduced into the pericardial sac to relieve cardiac tamponade.

revised trauma score A trauma scoring system that rates injury severity by comparing the Glasgow Coma Scale score, the systolic blood pressure, and the respiratory rate and assigning a score between 1 and 13 based on these three values; in some cases the parameters are weighted, resulting in a score of between 1.0 and 7.8408.

rhabdomyolysis Damage to the sarcolemma (muscle membrane) from any cause, leading to a release of potassium and myoglobin.

START triage A patient sorting process that stands for simple triage and rapid treatment and uses a limited assessment of the patient's ability to walk, respiratory status, hemodynamic status, and neurologic status.

thyrotoxicosis An excess of thyroid hormones resulting in a hypermetabolic crisis, including tachycardia over 140 beats/min; hyperthermia (sometimes greater than 103.9°F); coma with agitation, nausea, vomiting, diarrhea, and unexplained jaundice; and pulmonary edema; marked by an elevated thyroxine level; also called thyroid storm.

tracheal deviation The late sign of a tension pneumothorax in which the trachea is tugged to one side of the neck, usually opposite the side of the pneumothorax.

trauma injury severity score A calculated scoring system that uses the results of the injury severity score, the revised trauma score, and the patient's age to determine survivability rate; rarely used in the transport setting.

trauma score A score from 1 to 16 that takes into account the Glasgow Coma Scale score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill, and relates to the likelihood of patient survival; not accurate for patients with severe head injuries.

traumatic asphyxia A condition resulting from severe, sudden crushing injury to the chest and abdomen, forcing blood backward out of the right side of the heart; engorging the veins of the chest, neck, and head; and giving the chest, neck, and head an extremely cyanotic appearance.

Neurologic Emergencies

Authors

Attila J. Hertelendy, PhD(c), MS, MHSM, NREMT-P, CCEMT-P

J. Michael Brewer

Kenneth C. Hancock, BSME, MSIE, CCEMT-P

Scott P. Sherry, MS, PA-C

Objectives

1. Describe the major anatomic structures of the nervous system and their physiology as is pertinent to the CCTP (p 366–380).
2. Describe how to perform a neurologic assessment, including the following specific assessments: mini-mental exam; assessment of speech abnormalities, cranial nerves, eyes, motor function, and sensory function, reflex testing, and evaluation of meningeal irritation (p 381–395).
3. Discuss the pathophysiology of traumatic brain injury, including primary and secondary brain injury (p 395–396).
4. Explain the significance of cerebral perfusion pressure and mean arterial pressure (p 396).
5. Discuss the pathophysiology of specific neurologic injuries, including scalp injuries, skull fractures, facial fractures, epidural hematoma, subdural hematoma, and diffuse axonal injury (p 396–404).
6. Discuss lab values relevant to neurologic emergencies and their interpretation (p 424).
7. Define intracranial pressure (ICP) and explain its pathophysiology (p 405).
8. Discuss clinical manifestations of increased ICP, including brain herniation (p 407).
9. Discuss the concept of ICP monitoring, including indications, contraindications, methods, devices, waveforms, complications, procedures, adverse reactions and interventions, and post-procedure care (p 408).
10. Discuss management of ICP during transport (p 412).
11. Describe spinal injuries, including primary spinal cord injury and secondary spinal cord injury, and their assessment, management, and complications (p 416–421).
12. Discuss types of stroke, their assessment, transport management, and thrombolytic and fibrinolytic therapy (p 421).
13. Describe the pathophysiology of subarachnoid hemorrhage, its assessment, and its management, including neurologic diagnostics (p 423).
14. Discuss seizures and epilepsy, including transport management (p 424).
15. Discuss transport considerations for patients with neurologic injuries (p 425).
16. Discuss considerations for managing neurologic emergencies in flight (p 426).

Introduction

Critical care patients with neurologic complications present a variety of assessment and management challenges during transport for the critical care professional. The CCTP will find that an understanding of

the underlying principles of neurologic structure, function, and dysfunction will provide the basis for critical care management. Patients with neurologic illness and injury require skilled care that includes a thorough history and physical examination as well as a variety of specialized interventions.

A majority of neurologic patients who require transport will have traumatic brain injury (TBI). An in-depth understanding of the types of injuries, their pathophysiology, and current (evidenced-based) management trends is fundamental to managing these patients in a way that ensures the best possible outcome.

Anatomy and Physiology

The human nervous system is a truly remarkable arrangement of fibers running throughout the body that allows the body to interact with and adapt to differing environments by regulating the activities of virtually every other body system. An intimate understanding of the anatomy and physiology of the nervous system is essential to the delivery of competent medical care—and especially assessment—by the CCTP. This chapter reviews the structures and functions of certain components of the nervous system that are most pertinent.

Nervous System Organization

The nervous system is perhaps the most diverse and highly organized organ system in the human body. Its various components are classified in terms of location or function.

When classifying the parts in terms of their location, the nervous system is divided into the central nervous system (CNS), which consists of the brain and spinal cord, and the peripheral nervous system (PNS), which consists of the spinal and **cranial nerves**.

The parts of the PNS are also differentiated on the basis of the information that is transmitted on certain fibers. Most activities mediated by the nervous system occur as a result of sensory stimulation sensed by special receptors, such as visual, auditory, or tactile receptors. **Afferent pathways** (ascending pathways) carry sensory impulses toward the CNS. **Efferent pathways** (descending pathways) carry impulses away from the CNS to effector organs, such as muscles (smooth and skeletal) or glands **Figure 11-1**.

Physiologically, the nervous system consists of voluntary and involuntary divisions. The **voluntary (somatic) nervous system** is composed of nervous system fibers that connect the structures of the CNS with skeletal muscles and the integument. The **involuntary (autonomic) nervous system** is divided into the sympathetic and parasympathetic branches. Both of these branches are composed of nervous system fibers that connect the structures of the CNS with smooth muscle, cardiac muscle, and glands, which allow the system to regulate the body's internal environment by controlling organ systems. For example, the sympathetic nervous system is responsible for sweating, pupil dilation, ejaculation, and temperature regulation, as well as the shunting of blood from the periphery to the core—the "flight or fight" responses.

Central Nervous System

The CNS consists of the brain and the spinal cord, both of which are encased in and protected by bone. The brain, located within the cranial cavity, is the largest component of the CNS. It contains billions of neurons that serve a variety of vital functions.

Cranial Anatomy and Physiology

The brain is a very delicate, gelatinous-like substance that requires the protection afforded by the skull. Although primarily protective, excessive forces can cause a fracture to the adult skull and force bone

fragments into vulnerable brain tissue. The skull, or cranium, consists of the **neurocranium** (brain box) and the **viscerocranium** (the 14 bones that make up the facial skeleton).

The neurocranium is the part of the skull that encloses the brain and provides a protective vault for this vital organ **Figure 11-2**. It has a domelike roof—the calvaria (skullcap)—and a cranial base. The neurocranium includes eight bones: the frontal bone, paired parietal bones, paired temporal bones, an occipital bone, a sphenoid bone, and an ethmoid bone.

When the skull is observed from the inside, the superior surfaces form a smooth inner wall. In contrast, the basilar skull contains many ridges and folds with sharp edges that normally provide structure for the support of many parts of the brain **Figure 11-3**. When the head comes into contact with significant forces, the brain may shift over this base and become lacerated or contused by the sharp edges. This mechanism is a common culprit in many of the brain injuries encountered by the CCTP.

The base of the skull is also the location for openings, or foramina, which allow cranial nerves and blood vessels to enter and exit the cranial cavity. These openings also weaken the area, leaving it susceptible to fracture.

Special Populations

Children have extremely pliable skull bones and often have not healed their suture lines or closed their fontanelle prior to the age of 8 years. Excessive forces can cause a fracture in the adult skull, but in a child they are more likely to result in brain injury without skull fracture.

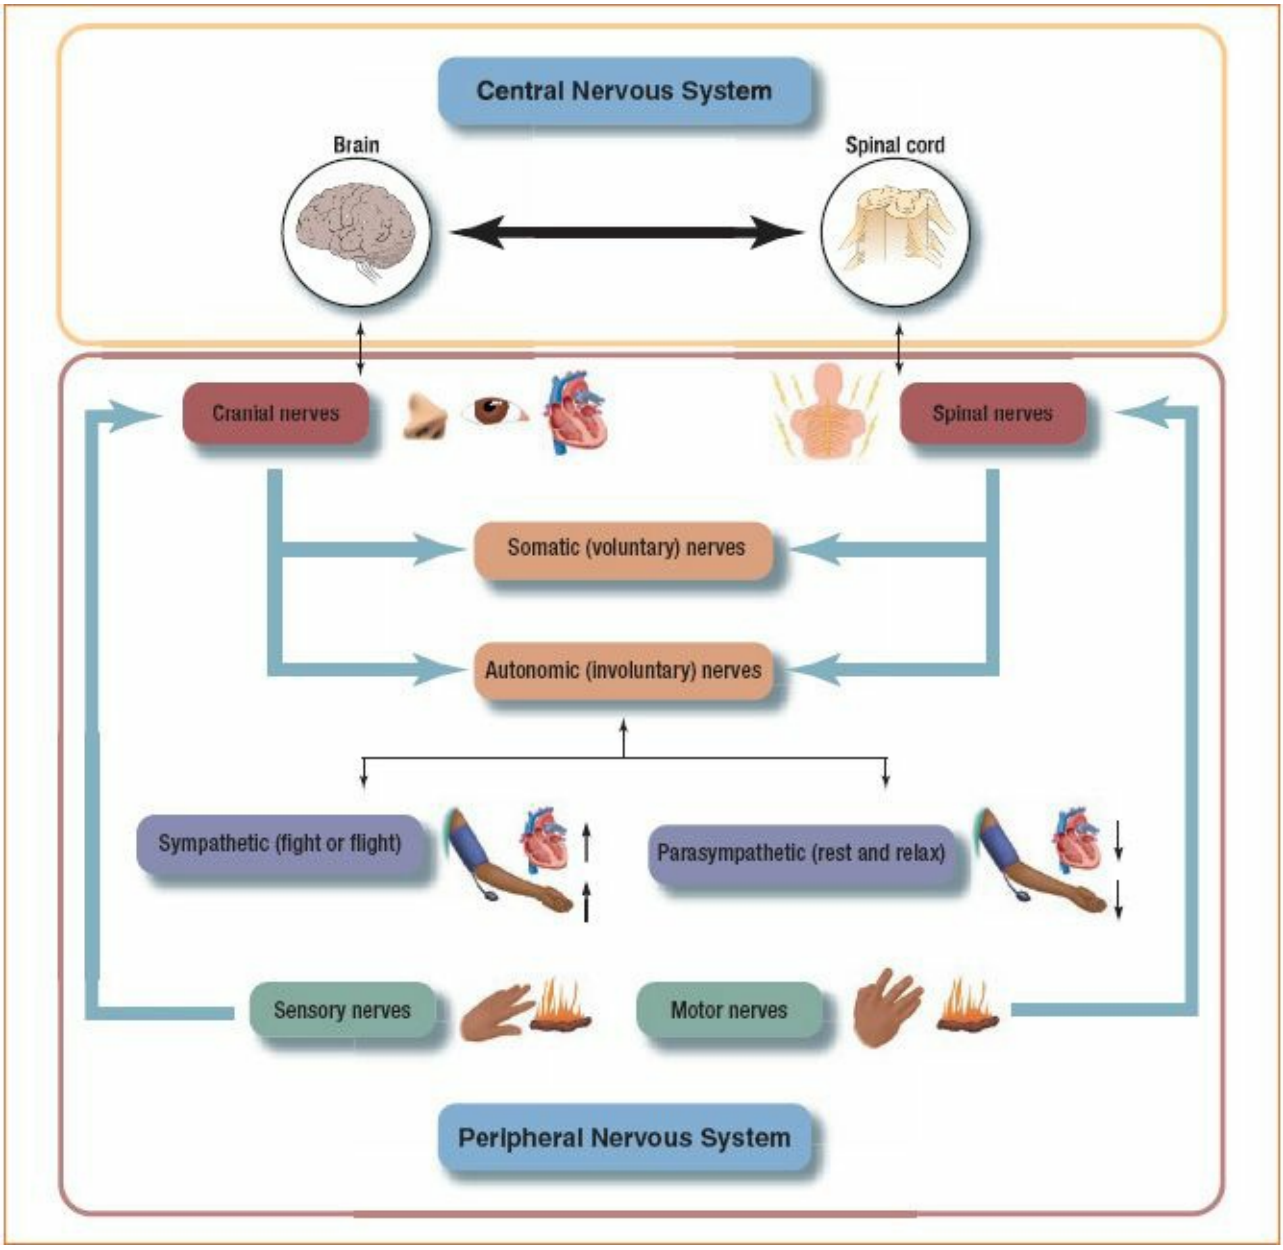

Figure 11-1 Organization of the nervous system.

Meningeal Anatomy and Physiology

The entire CNS is enclosed by a set of three membranes collectively known as the meninges **Figure 11-4**. The cranial meninges—internal to the neurocranium—protect the brain and form the supporting framework for arteries, veins, and venous sinuses. The cranial meninges consist of three layers: (1) the **dura mater**, an external thick, dense fibrous membrane; (2) the **arachnoid mater**, an intermediate, delicate membrane; and (3) the **pia mater**, an internal delicate, vascular membrane.

The dura mater is adherent to the internal surface of the cranium and is actually a two-layered membrane. The outer layer comprises the periosteum for the cranial bones and is the layer that actually adheres to the internal surface of the calvaria. The inner meningeal layer of the dura extends into the cranial space and is continuous at the foramen magnum with the dura covering the spinal cord. Except for those sites in which the two dural layers separate to form a dural venous sinus, the two layers are fused. The four extensions or folds of the dura mater are the falx cerebri, the tentorium cerebelli, the falx cerebelli, and the diaphragma sellae.

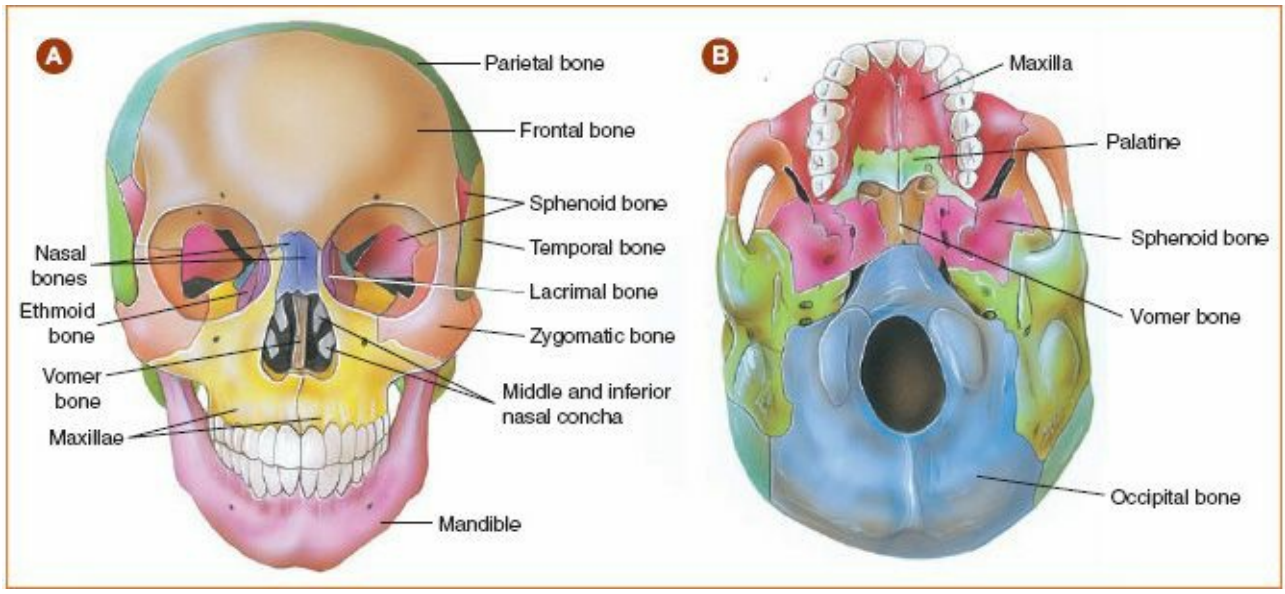

Figure 11-2 The skull and its components. **A.** Front view. **B.** Bottom view.

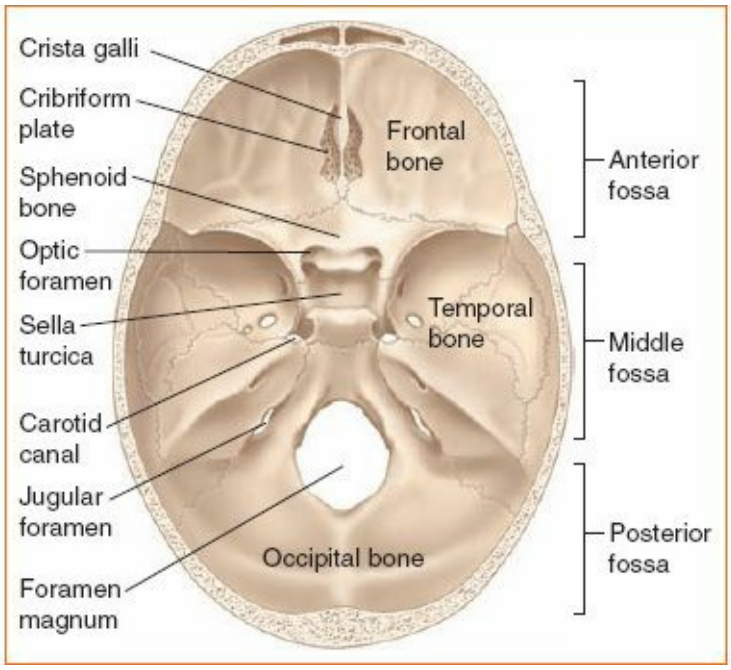

Figure 11-3 The floor of the cranial vault and its anatomy.

The **falx cerebri** is a double fold of dura mater that divides the cerebrum into right and left hemispheres by descending vertically into the longitudinal fissure that extends from the frontal lobe to the occipital lobe. The falx cerebri is the structure that is observed to *shift* on computed tomographic (CT) scan during times of brain swelling. It extends posteriorly by becoming continuous with the tentorium cerebelli.

The falx cerebri attaches to the **tentorium cerebelli** in the midline and holds it up, giving it a tent-like appearance. The tentorium cerebelli separates the occipital lobes of the cerebrum from the cerebellum and brain stem. This fold of the dura mater divides the brain into an upper compartment (supratentorial) and a lower compartment (infratentorial). The tentorium cerebelli is noted for its role in brain swelling, as it is the location where the **uncus** (the medially curved anterior part of the hippocampal gyrus) of the temporal lobe slips off of the tentorium and compresses cranial nerve (CN) III, which lies underneath the dural structure. This process causes a unilateral fixed and dilated pupil, characteristic of uncal herniation.

The **falx cerebelli** forms the division between the two lateral lobes of the cerebellum. The final extension of the dura mater, the **diaphragma sellae**, forms a roof over the sella turica, which contains the pituitary gland.

Further dural separations form the **dural venous sinuses**, which are endothelial-lined spaces between the periosteal and meningeal layers of the dura mater. Large veins from the surface of the brain empty into these sinuses, and all blood from the brain ultimately drains through them into the internal jugular veins. It is in these dural sinuses that arachnoid granulations—tufted prolongations of the arachnoid mater that protrude through the meningeal layer of the dura into the venous sinuses and transfer cerebrospinal fluid (CSF) to the venous system—are found.

The arachnoid mater is an extremely thin and delicate layer that loosely encloses the brain. It is closely applied to the meningeal layer of the dura mater by the pressure of the circulating CSF beneath the arachnoid layer. Web-like arachnoid trabeculae (small protrusions of connective tissue) pass between the arachnoid and pia, connecting the two layers and forming the subarachnoid space, which contains CSF and a variety of cerebral arteries and veins. Although it is commonly stated that the brain *floats* in CSF, the brain is actually suspended in the CSF-filled subarachnoid space by the arachnoid trabeculae. In essence, the meninges and CSF form a fluid-filled cushion that protects the brain and spinal cord.

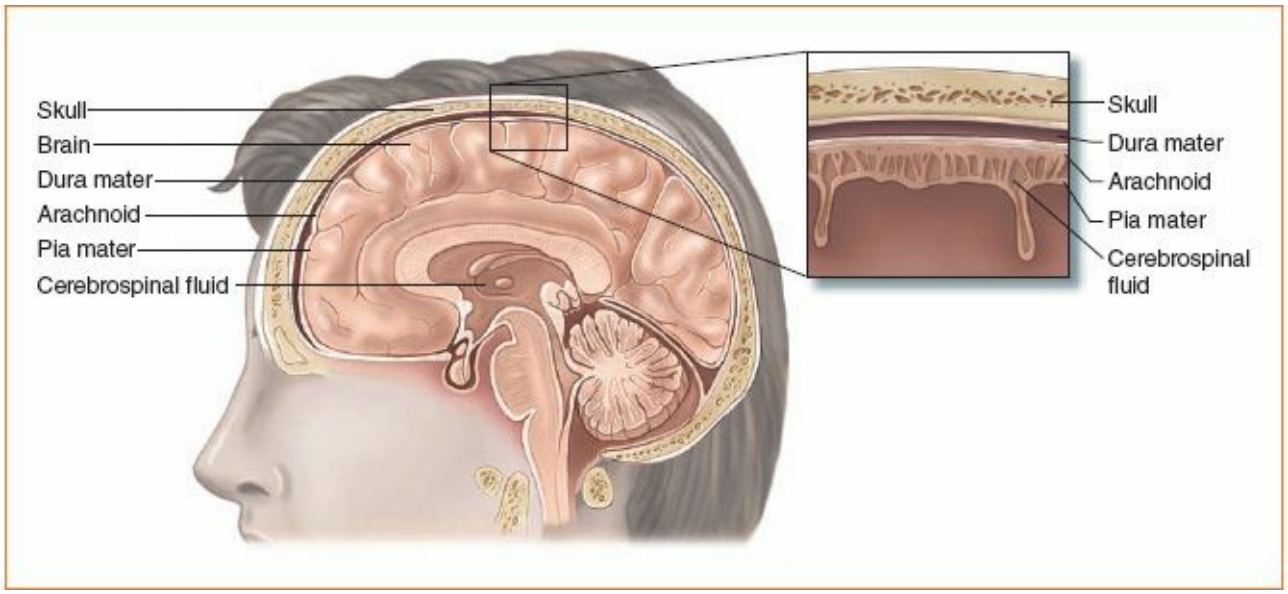

Figure 11-4 The meninges.

The pia mater is a vascular membrane that adheres to the surface of the brain and follows its contours. It is rich in small blood vessels that supply a large volume of arterial blood to cerebral tissues. In fact, when the cerebral arteries penetrate the cerebral cortex, the pia follows them for a short distance, forming a pial coat and creating a periarterial space. Tufts or folds of the pia mater in the lateral, third, and fourth ventricles form a portion of the choroid plexus, which is responsible for the production of CSF.

Three meningeal spaces are related to the cranial meninges. The **extradural space** or epidural space is normally not an actual space but only a potential one between the cranial bones and the periosteal layer of the dura. It becomes a real space only when blood from torn vessels pushes the periosteum from the cranium and accumulates. The dura–arachnoid junction, also called the **subdural space**, is normally only a potential space but may develop into a real one after a blow to the head causes a loss of blood into the area. The subarachnoid space between the arachnoid and the pia is actually a space that contains CSF, trabeculae, arteries, and veins.

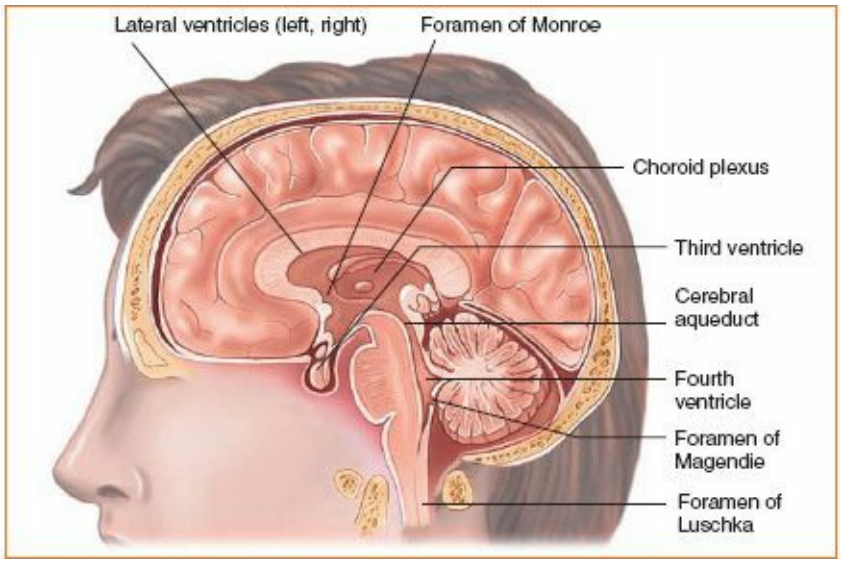

Figure 11-5 The ventricles of the brain and the cerebral aqueduct.

Ventricular System and CSF

The ventricular system is the central CSF-filled core of the brain. It consists mainly of two lateral ventricles (the largest ventricles) and midline third and fourth ventricles connected by the cerebral aqueduct **Figure 11-5**.

One lateral ventricle lies in each of the cerebral hemispheres. The lateral ventricles extend from the frontal lobe to the occipital lobe and have horns that extend from the main ventricular chamber. They are named for the respective area of the cerebrum in which they are contained. The lateral ventricles are important structures for **intracranial pressure (ICP)** monitoring, CSF drainage, or placement of a CSF shunt.

The **foramen of Monro** connects the two lateral ventricles with the third ventricle, a central cavity. Situated directly above the midbrain, the third ventricle lies between the structures of the thalamus in the diencephalon.

The **cerebral aqueduct**, the narrowest portion of the ventricular system, provides communication with the fourth ventricle, which lies between the brain stem and the cerebellum. Because of its small size, it is vulnerable to obstruction. At the base of the fourth ventricle, two openings—the **foramen of Luschka** and the **foramen of Magendie**—open the ventricular system into the subarachnoid space and are essential for the normal flow of CSF.

The **choroid plexus** of the lateral and the third and fourth ventricles produces more than 70% (approximately 500 mL/d) of the CSF by active transport and diffusion. Microscopically, the choroid plexus has the appearance of a delicate sponge with a collection of blood vessels covered by a thin coating of cells. CSF is constantly secreted from these surfaces. The remaining 30% of the CSF is produced from other sites within the ventricular system, including the ependymal cells lining the ventricles and blood vessels of the meninges and the blood vessels of the brain and spinal cord.

CSF fills the ventricular system and surrounds the brain and spinal cord in the subarachnoid space. This fluid provides a protective mechanism for the CNS by acting as a *shock absorber* for minor acceleration and deceleration and participates in the removal of waste products from cerebral tissue. CSF is normally clear, colorless, and odorless with a total volume of approximately 150 mL, of which only 23 mL is in the ventricles. The remaining 127 mL fills the subarachnoid space surrounding the brain and spinal cord. Under normal conditions, CSF is virtually cell free and low in proteins, glucose, potassium ions, and calcium ions relative to plasma. It is high, however, in magnesium, sodium, and chloride ions as compared to plasma. The normal composition of CSF is detailed in **Table 11-1**.

The CSF also has a slightly lower osmolality (289 mOsm/L) compared with serum (290 to 300 mOsm/L), which explains the transport of small molecules, metabolic products, and drugs from the surrounding brain tissue into the CSF.

No feedback mechanisms exist for the regulation of the rate or volume of CSF production. That is, the choroid plexus continues to produce CSF even if the ventricles and subarachnoid spaces are filled and the pressure is high. Consequently, any obstruction to the normal flow—either in the ventricular system or at the level of the arachnoid granulations—may produce high CSF pressure and lead to brain damage.

Once the CSF is formed in the ventricles, it flows within the closed system. Fluid formed in the two lateral ventricles passes into the third ventricle by way of the two foramina of Monro. The fluid then flows through the cerebral aqueduct into the fourth ventricle. The CSF exits the fourth ventricle by taking one of two paths. In the first path, fluid exits medially through the foramen of Magendie, where it is then directed to the subarachnoid space of the spinal cord. In the second path, fluid exits the fourth ventricle laterally through the two foramina of Luschka, where it is directed to the subarachnoid space surrounding the brain.

TABLE 11-1 CSF Composition

Property (Substance)	Value (Normal Range)
pH	7.35-7.45
Specific gravity	1.007
Glucose	50-75 mg/dL
Protein	5-25 g/dL
Pressure	70-200 mm H_2O (lumbar puncture) 3-15 mm Hg (brain ventricle)
Potassium	2.8-3.2 mEq/L
Sodium	147-151 mEq/L
Chloride	118-132 mEq/L
Calcium	1.05-1.35 mg/dL
Magnesium	0.78-1.26 mEq/L
Carbon dioxide	22.9 mEq/L

On entering the subarachnoid space, CSF moves over the surface of the spinal cord and brain to ultimately leave the subarachnoid space and enter the dural venous sinuses via the arachnoid villi. The arachnoid villi are very permeable oneway valves that allow CSF to exit easily from the subarachnoid space into the venous sinuses, but do not allow blood to enter the subarachnoid space.

Blockage of the movement of CSF into the dural venous sinuses leads to a condition known as communicating hydrocephalus. If CSF cannot leave the ventricular system, the condition is called noncommunicating hydrocephalus.

Anatomy and Physiology of the Brain

The brain gives members of the human species the ability to reason, function intellectually, express

personality and mood, and interact with their environment. The brain weighs approximately three pounds —a meager 2% of body weight—yet consumes 20% of the total cardiac output. The three major areas of the brain are the cerebrum, the brain stem, and the cerebellum.

Cerebrum

The cerebrum is, by mass, the largest part of the brain, accounting for 80% of its weight. It consists of two cerebral hemispheres that are incompletely separated by the longitudinal cerebral fissure. The cerebral hemispheres are connected at the base of the longitudinal cerebral fissure by the corpus callosum. The **corpus callosum** is a large tract of transverse fibers that provides a communication link between the two cerebral hemispheres. The hemispheres are further separated from the underlying brain stem and cerebellum by the transverse cerebral fissure. Both fissures contain meninges and thick folds of dura—specifically, the falx cerebri and the tentorium cerebelli.

The surface of the cerebrum is characterized by numerous convolutions called **gyri**. The gyri functionally increase the cortical surface area. Grooves between adjacent gyri are called **sulci**. Deeper grooves are referred to as **fissures**.

The **cerebral cortex** is the outermost layer of the cerebrum. This layer is 2- to 5-mm thick and contains billions of unmyelinated cell bodies of dendrites and neurons, which are often referred to as gray matter. Underneath the cerebral cortex are the white matter (myelinated) tracts, which communicate impulses from the cerebral cortex to other areas of the brain. Three types of fibers—commissural (transverse), projection, and association—are found in the white matter and are named for the role they play in communication of information:

- Commissural fibers are tracts that communicate between corresponding parts of the two hemispheres. The corpus callosum is the largest of these fiber tracts.
- Projection fibers communicate between the cerebral cortex and lower portions of the brain and spinal cord.
- Association fibers allow communication between various regions of the same hemisphere.

The **cerebral hemispheres** are divided into four paired lobes, based on the divisions demarcated by the fissures: the frontal lobes, the parietal lobes, the temporal lobes, and the occipital lobes **Figure 11-6**. Another area found deeper inside the cerebrum can also be classified as a lobe and is called the limbic lobe.

Frontal Lobe

The largest of the four lobes of the cerebral hemispheres is the **frontal lobe**, which accounts for approximately one third of the total cortical tissue. The frontal lobe lies underneath the frontal bone of the skull and is separated posteriorly from the parietal lobe by the central fissure and inferiorly from the temporal lobe by the lateral fissure. It is further divided into different areas based on the functions for which they are responsible **Figure 11-7**.

The **prefrontal area** of the frontal lobe is responsible for a variety of higher functions. This area provides control of thought, concentration, depth perception, the ability to think abstractly, memory, and autonomic nervous system response, concomitant to emotional change, with help from the thalamus and hypothalamus.

The **premotor area** is adjacent to the motor area. A connection between these areas exists with cranial nerves III, IV, VI, IX, X, and XII, allowing coordination of certain movements. For example, stimulation of the lateral portion results in gross generalized movements, such as turning of the eyes and head, turning of the trunk with the head, and coordinated eye movements.

The **motor area** contains pyramidal cells that control voluntary motor function on the opposite side of the body. Body parts that require a great deal of dexterity, such as the thumb and tongue, are allotted a larger motor area than body parts that do not require much dexterity, such as the shoulder and trunk.

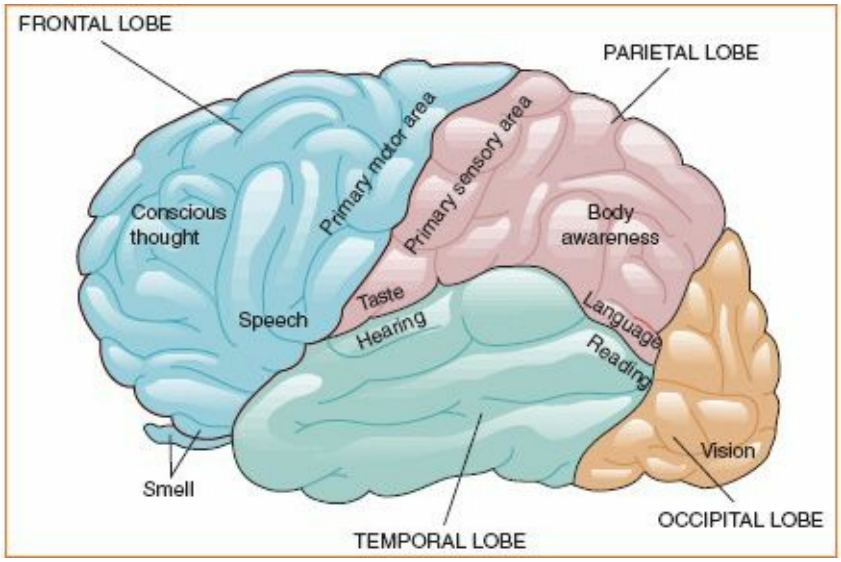

Figure 11-6 The lobes of the cerebrum.

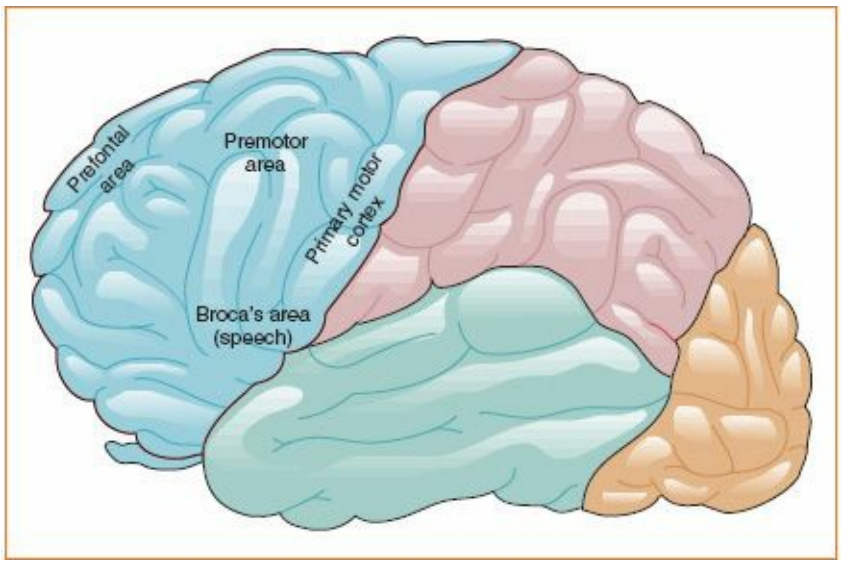

Figure 11-7 The cerebrum, highlighting the frontal lobe and its specific areas.

Broca's area is located at the inferior frontal gyrus. This association area participates in the formulation of words. Any damage to this area either from primary injury (direct trauma) or secondary injury (ischemia) results in expressive or nonfluent aphasia.

Parietal Lobe

The **parietal lobe** is situated directly posterior to the frontal lobe lateral to the central fissure. This lobe is largely responsible for sensory functions, including the integration of sensory information; awareness of body parts; interpretation of touch, pressure, and pain; and recognition of object size, shape, and texture. The parietal lobe consists of a sensory strip that lies adjacent to the motor strip of the frontal lobe. Sensory areas for certain parts of the body lie close to the motor areas for the same body part. Fibers going to the sensory strip bring stimuli associated with cutaneous and deep sensibility sensations, as well as cutaneous sensation of touch, pressure, position, and vibration. Input from the thalamus also reaches the

sensory strip.

Associative areas of the parietal lobe interpret sensory input in terms of size, shape, texture, and weight. They enable individuals to localize sensations and define them in terms of pressure, temperature, or vibration. Interpretive aspects of the parietal lobe's response to stimuli include awareness of body parts, orientation in space, and recognition of environmental spatial relationships.

Occipital Lobe

Occupying the most posterior portion of the cerebrum, the **occipital lobe** is separated from the cerebellum by the tentorium cerebelli. This area of the brain is the primary receptive area for vision, specifically the interpretation of visual stimuli. The primary visual cortex receives impulses from projections of the optic tract; these impulses are then referred to the visual associative areas for interpretation and integration. If a person sustains an injury to the visual associative areas, he or she will be able to see objects but will not be able to recognize or identify objects (visual agnosia).

Temporal Lobe

Located beneath the temporal bone of the cranium, the **temporal lobe** lies in the lateral portion of the cerebrum. It is separated from the frontal and parietal lobes by the lateral fissure. The primary functions of this region relate to hearing, speech, behavior, and memory.

Within the temporal lobe, the primary auditory receptive areas receive sound impulses and assist in determining the source of the sound and interpreting the meaning of the sound. The auditory association area is part of the superior temporal gyrus and is known as **Wernicke's area**. Usually the largest part of the dominant hemisphere, it is responsible for comprehension of both written and spoken words. If Wernicke's area is damaged, a person may hear sounds, but they will be meaningless (receptive aphasia).

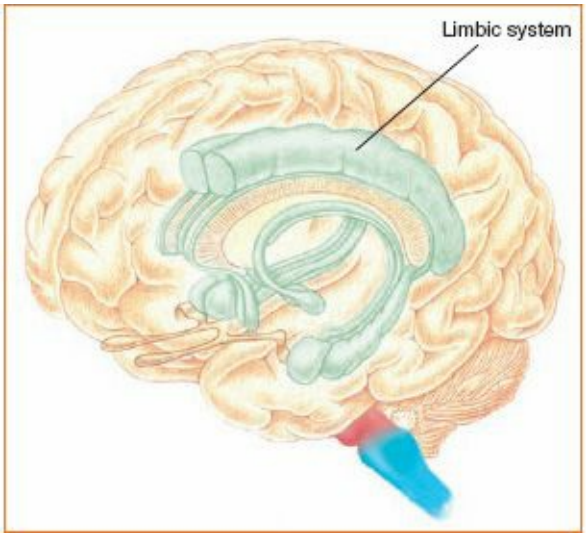

Figure 11-8 The limbic system is the seat of emotions, instincts, and other functions.

In the superior portion of the temporal lobe, at the junction of the frontal, parietal, and temporal lobes, lies the interpretative area. This area is responsible for integrating auditory, visual, and somatic association areas into complex thoughts and memory. It plays a significant role, along with the frontal lobe, in cerebration.

Limbic Lobe

The **limbic lobe** (also called the rhinencephalon) is properly an anatomic part of the temporal lobe,

although its function is sometimes discussed separately from the temporal lobe. This area forms the border of the lateral ventricles and contains the hippocampus, the uncus, the primary olfactory cortex, and the amygdaloid nucleus. Functions of the limbic lobe include self-preservation, primitive behavior, moods, the visceral processes associated with emotion, short-term memory, and the interpretation of smell **Figure 11-8**.

Diencephalon

The **diencephalon** is a major division of the cerebrum and is divided into four regions: the thalamus, the hypothalamus, the subthalamus, and the epithalamus. It is the lowest structure of the cerebrum and actually lies on top of the brain stem surrounding the third ventricle. Also found in this region is the pituitary gland and the internal capsule.

The **thalamus**, the largest portion of the diencephalon, consists of a pair of egg-shaped masses of gray matter that form the lateral walls of the third ventricle and are connected to the midbrain. It acts as a relay station for motor and sensory activity; basic neuronal activity, such as the processing of brain activity; and memory, thought, emotion, and complex behavior. The relay function of the thalamus is a complex function coordinated with the parietal lobe of the cerebrum. All sensory pathways, except for olfactory, communicate with an area of the thalamus. Once a sensory impulse reaches the thalamus, it sorts and sends the impulse to the appropriate area of the cerebral cortex for final processing. The role of the thalamus in motor activity is to coordinate the cerebrum and cerebellum to produce a smooth, integrated motor response.

TABLE 11-2 Functions of the Hypothalamus

Function	Mechanism
Temperature regulation	Temperature of blood flowing through the hypothalamus is monitored. Impulses are sent to the sweat glands, peripheral vessels, and muscles (shivering).
Regulation of food intake	The hunger center produces the sensation of hunger when stimulated. The satiety center decreases the desire for food when the stomach is full or blood glucose is high.
Regulation of water intake	Serum osmotic pressure is monitored and antidiuretic hormone is released when osmotic pressure is high, is inhibited when osmotic pressure is low.
Control of pituitary gland secretion	Releasing or inhibiting factors are sent from the hypothalamus to the pituitary gland.
Control of behavioral responses	Mediation of visible physical expressions in response to emotions, such as blushing, dryness of mouth, and clammy hands
Control of autonomic nervous system responses	The parasympathetic system response is elicited by stimulation of the anterior region of the hypothalamus. The sympathetic system response is mediated by the posterior region of the hypothalamus.

Located below the thalamus, the **hypothalamus** forms the floor and the anterior walls of the third

ventricle. The pituitary gland is situated below the hypothalamus in the sella turcica and is connected to the hypothalamus by the pituitary stalk. The hypothalamus has several functions related to regulating and maintaining the internal body environment and interacting with the limbic system to generate physical responses to emotions. Hypothalamic function falls into two major areas: (1) the maintenance of homeostasis (ie, internal balance) and (2) the implementation of behavioral patterns. The hypothalamus exerts its influence through the endocrine system and neuronal pathways **Table 11-2**.

The **epithalamus** is located in the **dorsal** portion of the diencephalon and contains the pineal gland, which is thought to play a role in physical growth and sexual development. The **subthalamus** is located below the thalamus and is closely related to the basal ganglia in function.

Basal Ganglia

The **basal ganglia** are several masses of nuclei located deep in the cerebral hemispheres. The main role of the structures is associated with fine motor function, particularly of the hands and lower extremities. They provide a pathway and assist in processing information from the cerebral motor cortex and the thalamus. Much of the basal ganglia's function is conducted through the extrapyramidal (involuntary) pathways.

Internal Capsule

As radiation and projection fibers coming from various parts of the cerebral cortex converge at the brain stem, they form the corona radiata. As the fibers enter the thalamus–hypothalamus region, they are collectively called the **internal capsule**. The capsule is a massive bundle of efferent and afferent fibers connecting the various subdivisions of the brain and spinal cord.

Brain Stem

The brain stem acts as a bridge between the cerebral hemispheres and the spinal cord; it is the only structure connecting the cerebellum with the cerebral cortex. All motor and sensory fibers travel through the brain stem—both those ascending to the cerebral hemispheres and those descending to the spinal cord. The brain stem consists of three parts: the midbrain, the pons, and the medulla oblongata.

The **midbrain** is a small area extending between the diencephalon, the pons, and the third ventricle **Figure 11-9**. Several important structures are found in the midbrain, including the cerebral aqueduct (Sylvian, which connects the third and fourth ventricles), the superior colliculi (which controls visual reflex and the center for upward gaze) and inferior colliculi (auditory system), cranial nerves III (oculomotor) and IV (trochlear), and the reticular activating system (RAS).

The major function of the midbrain is to relay stimuli involved in voluntary motor movement of the body. Also found in the region are the tectospinal and rubrospinal tracts of the extrapyramidal (involuntary) motor system. The **tectospinal tract** controls reflex motor movements in response to visual and auditory stimuli, and the **rubrospinal tract** controls the tone of flexor muscles. The **Edinger-Westphal nucleus** is located in the midbrain and is responsible for mediating the autonomic reflex centers for pupillary accommodation to light.

Located between the midbrain and the medulla oblongata **Figure 11-10**, the **pons** relays information to and from the brain and spinal cord along fiber tracts. Motor tracts for motor movement descend through the pons, and sensory tracts necessary for touch, pressure, proprioception, pain, and temperature ascend through the pons. The **ventral** surface of the pons contains fibers that connect to the cerebellum, which allows for efficient and smooth transmission of influences from the cerebellum to the cerebral cortex. Two respiratory control centers are found in the pons: the apneustic center and the pneumotaxic center. The apneustic center is responsible for stimulating and producing sustained respirations. The pneumotaxic

center antagonizes the apneustic center, clinically inhibiting inspiration. Both centers of control communicate with the medullary respiratory center. Cranial nerves V (trigeminal), VI (abducens), VII (facial), and VIII (acoustic) originate in the pons.

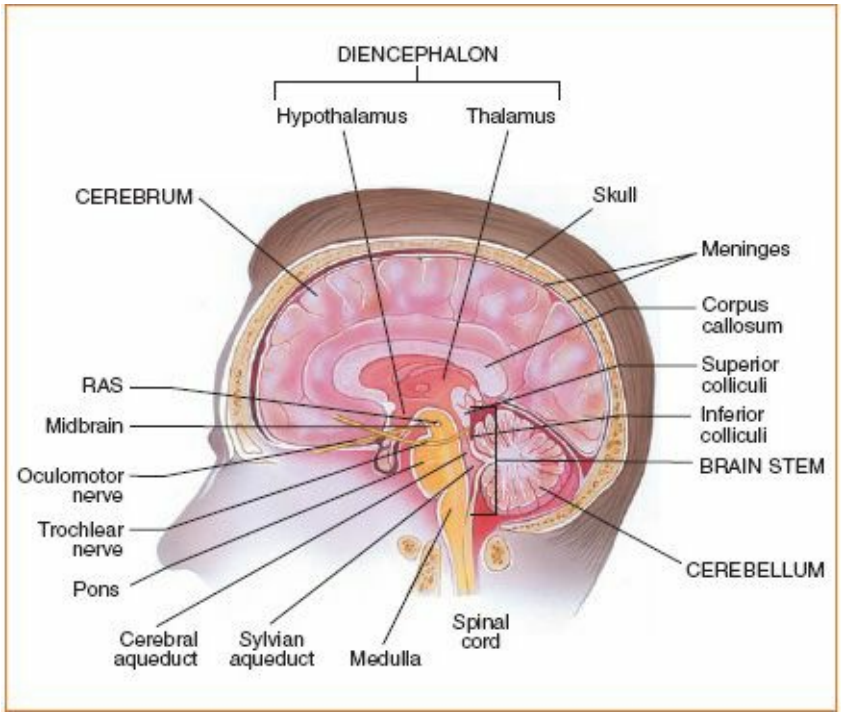

Figure 11-9 The midbrain.

The **medulla oblongata**, the lowermost portion of the brain stem, connects with the spinal cord at the foramen magnum. In the caudal aspect of the medulla, decussation (crossing) of the motor fibers occurs. Inferior to the point of decussation, stimuli from the left side of the brain control movement on the right side of the body, and vice versa.

The medulla also contains groups of neurons that control involuntary functions such as swallowing, vomiting, coughing, vasoconstriction, and respiration. The respiratory center of the medulla works in conjunction with the apneustic and pneumotaxic centers of the pons to produce controlled respirations. The medullary respiratory control center is responsible for the basic involuntary rhythm of respiration, but must be stimulated from higher centers to maintain a life-sustaining respiratory pattern. The reticular formation also has its beginnings in the medulla, with cranial nerves IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal) exiting from the medulla.

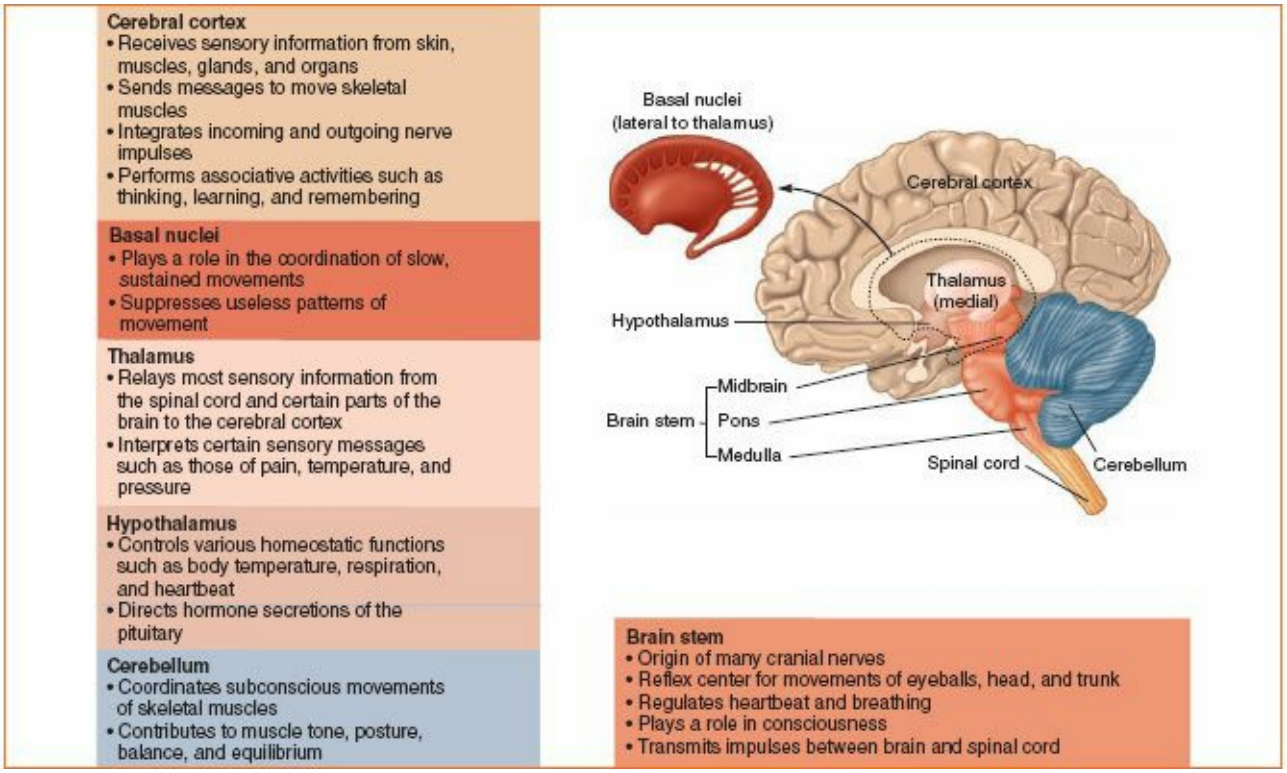

Figure 11-10 The pons.

Cerebellum

The cerebellum is located just superior and posterior to the medulla oblongata and consists of three major parts: (1) the cortex, or the gray outer covering; (2) the white matter, which connects the cerebellum to other parts of the CNS; and (3) four pairs of deep cerebellar nuclei, located deep within the white matter. The gross structure of the cerebellum includes two distinct hemispheres and the vermis, or central portion **Figure 11-11**.

The primary function of the cerebellum is coordination of voluntary movement. The vermis is responsible for trunk control. The three lobes of the hemispheres are responsible for upper and lower extremity control, including control of anti-gravity muscles, proprioception, tactile impulses, motor tone facilitation, volitional breaks in movement, synergy of movement, and equilibrium. Input is received from sensory pathways of the spinal cord, the brain stem, and the cerebrum. Output is transmitted through descending motor pathways. Cerebellar influences work through continual excitatory and inhibiting stimuli, resulting in smooth motor movements instead of rapid, erratic movements.

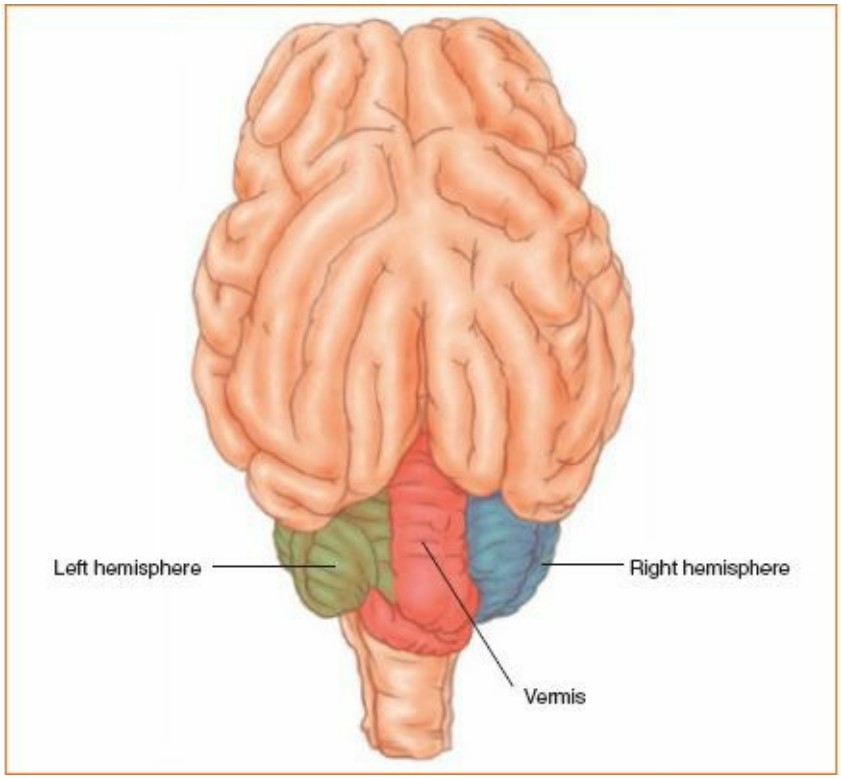

Figure 11-11 The vermis and the hemispheres of the cerebellum.

Reticular Formation

The **reticular formation (RF)** is a set of neurons that extends from the upper level of the spinal cord, through the medulla, pons, and midbrain, and into the thalamus and cerebral cortex. Composed of both motor and sensory tracts, the RF is closely tied to functions of the basal ganglia, thalamus, cerebellum, and cerebral cortex. This bundle of neural fibers has many excitatory and some inhibitory capabilities, and can enhance, suppress, or modify impulse transmission. The main role of the descending RF is to provide a balance between the excitatory and inhibitory stimuli so as to maintain normal muscle tone, which supports the body against gravity. Also located in the RF are centers for blood pressure, respiration, and heart rate function. The ascending RF is essential for arousal, attention, and perceptual association.

Reticular Activating System

The **reticular activating system (RAS)** is a diffuse system, not an actual anatomic structure, that extends from the lower brain stem to the cerebral cortex. Input from multiple sensory pathways is received, and signals are transmitted to dispersed areas of the cerebral cortex, providing multiple opportunities for stimulation of the RAS. The lower portion of the RAS, which is rooted in the brain stem, assists with control of the sleep–wakefulness cycles and consciousness; the upper portion, which is in the thalamus, allows the ability to focus attention on a specific task. When damage occurs to the upper portion of the RAS, the person enters a vegetative state, exhibiting sleep-wake cycles and other brain stem functions but no upper levels of cerebration.

Cerebral Circulation

The brain has huge demands—15% to 20% of total cardiac output and 40% of the oxygen in the available blood to meet normal cerebral metabolic needs. The predominant metabolic process that occurs is the oxidation of glucose to provide energy. Therefore, the overall goal of cerebral circulation is to provide enough blood to supply oxygen, glucose, and nutrients for this process.

The total amount of blood received by the brain is distributed carefully among areas where metabolic demands are high. Carbon dioxide serves as the primary regulator for blood flow in the CNS. A potent vasodilator, its presence causes more blood to flow to certain areas of the brain. The brain is supplied blood by two pairs of arteries: the two vertebral arteries and the two internal carotid arteries **Figure 11-12**.

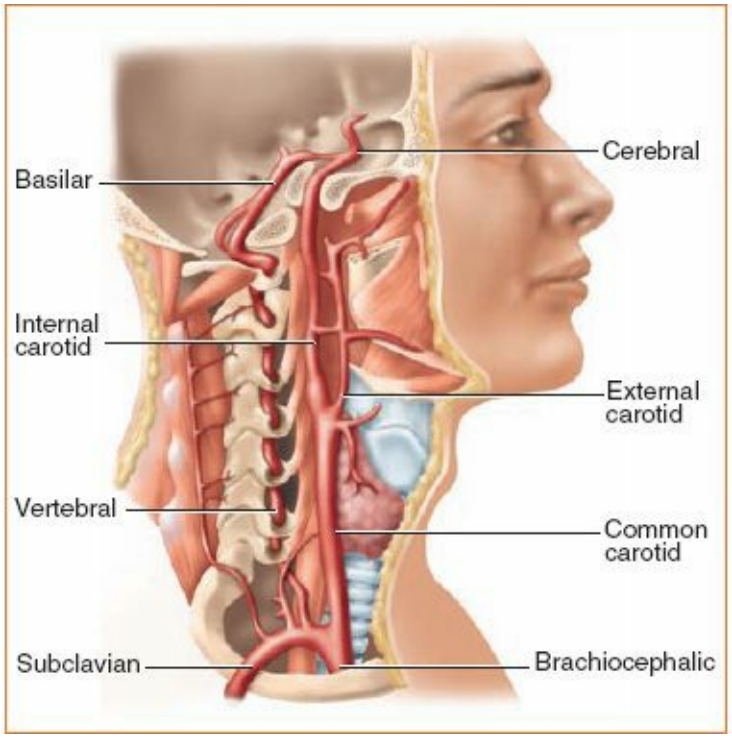

Figure 11-12 Blood supply to the brain via arteries.

Circle of Willis

The **circle of Willis** is a system of arteries located at the base of the skull that is divided into anterior and posterior circulation **Figure 11-13**. It is physiologically significant in that this structure may be able compensate for reduced blood flow from any one of the major contributors to cerebral circulation. Some individuals, however, may have hypoplastic or absent communicating vessels that may inhibit this compensatory mechanism.

The circle of Willis is fed by the internal carotid and basilar arteries. The three cerebral arteries (anterior, middle, and posterior) supplying each hemisphere are connected by communicating arteries to form a complete circle. **Table 11-3** lists the areas of the brain supplied by the cerebral arteries.

Vertebral Arteries

The vertebral arteries, or posterior circulation, arise from the subclavian arteries and enter the skull through the foramen magnum, ventrolateral to the spinal cord. At the level of the pons, the two vertebral arteries join to form the basilar artery. The basilar artery then divides at the level of the midbrain to form paired posterior cerebral arteries. The vertebral arteries and their branches predominantly supply blood to the cerebellum, brain stem, and spinal cord, as well as to some parts of the cerebrum. The basilar artery continues upward into the posterior portion of the circle of Willis and into the two posterior cerebral arteries.

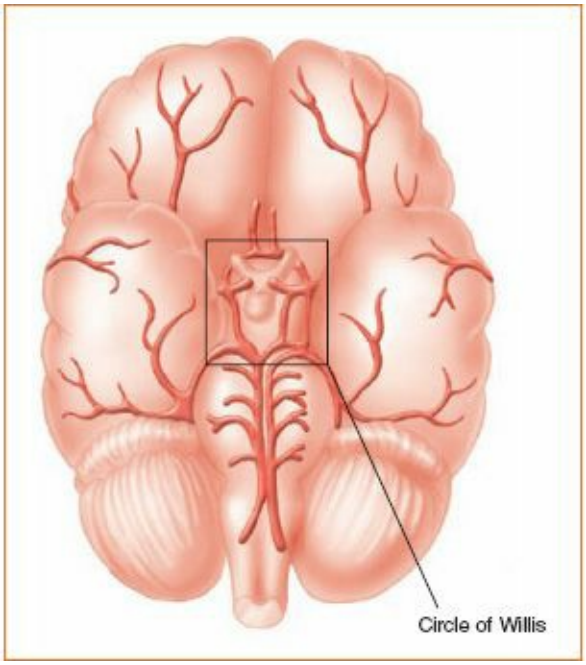

Figure 11-13 The circle of Willis.

TABLE 11-3 Major Cerebral Arteries	
Cerebral Artery Origin	**Structures Supplied**
Anterior	Basal ganglia, corpus callosum, medial surface of cerebral hemispheres, and superior surface of frontal and parietal lobes
Middle	Frontal lobe, parietal lobe, and cortical surface of temporal lobe
Posterior	Occipital lobes and the medial and lateral aspects of the temporal lobe

Internal Carotid Arteries

The internal carotid arteries anteriorly supply a proportionately greater amount of blood flow. They originate from the common carotid arteries and enter the cranium through the base of the skull. At the base of the brain, the internal carotid arteries connect to the circle of Willis and then branch into the anterior and middle cerebral arteries, which provide the majority of anterior circulation.

Venous Drainage

The superficial and deep veins of the brain enter the dural venous sinuses, which subsequently drain into the internal jugular veins. Cerebral veins on the superolateral surfaces of the brain drain into the superior sagittal sinus. Cerebral veins on the postero-inferior aspect drain into the straight, transverse, and superior petrosal sinuses **Figure 11-14**.

Blood-Brain Barrier

The internal environment of the brain is kept in delicate balance by several protective mechanisms. Particularly noteworthy in this respect is the **blood-brain barrier**, the network of endothelial cells and astrocytes (neuroglia) that envelop delicate cerebral capillaries. The blood-brain barrier is found throughout the brain except in small areas of the fourth ventricle, hypothalamus, and pineal gland, where chemoreceptors and osmoreceptors sample circulating plasma. The barrier regulates the transport of nutrients, ions, water, drugs, and waste products through the process of selective permeability.

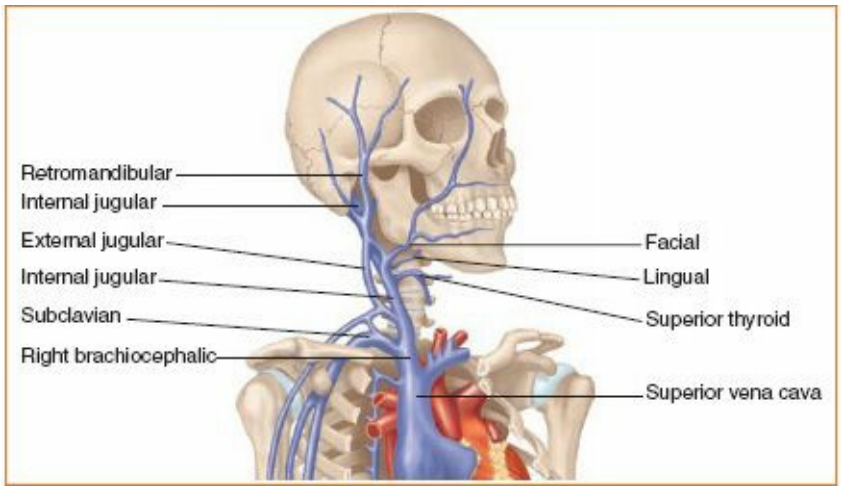

Figure 11-14 The veins of the neck.

Functionally, the blood-brain barrier has tight junctions between adjacent capillary endothelial cells, as opposed to the capillaries found elsewhere in the body, which have pores between adjacent endothelial cells. Molecules are transported through the endothelial cells in order to keep out toxic or harmful compounds and protect the fragile neurons.

Passage of substances across the blood-brain barrier depends on the particles' size, lipid solubility, chemical breakdown, and protein-binding potential. The barrier is readily permeable to water, oxygen, carbon dioxide, and glucose. Most drugs or compounds that are lipid soluble and stable at a physiologic pH rapidly cross the barrier as well. Uptake of sodium and potassium is slow, however, as is uptake of dyes and other organic and inorganic anions and cations.

Anatomy and Physiology of the Spinal Cord

An understanding of the form and function of spinal anatomy coupled with a high level of suspicion for spinal cord injury (SCI) is required to decipher the often subtle findings associated with a possible SCI.

Spine

The spine usually consists of 33 irregular bones (vertebrae) articulating to form the vertebral column, which is the major structural component of the axial skeleton **Figure 11-15**. Some patients may have 32 or 34 vertebrae. These skeletal components are stabilized by both ligaments and muscles. Together these components support and protect neural elements while allowing for fluid movement and erect stature.

Vertebrae are identified according to their location as cervical, thoracic, lumbar, sacral, or coccyx. The **vertebral body**, the anterior weight-bearing structure, is made of bone that provides support and stability. Components of the vertebra include the lamina, pedicles, and spinous processes **Figure 11-16**. Each vertebra is unique in appearance and, with the exception of the atlas and axis (C1 and C2, respectively) **Figure 11-17**, shares basic structural characteristics.

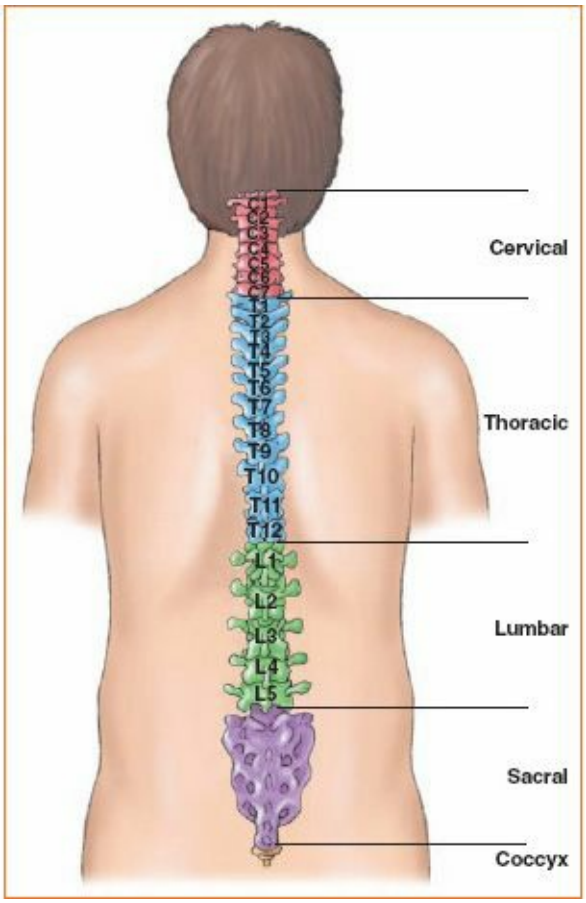

Figure 11-15 The sections of the spinal column, with the letter/number of each vertebra labeled.

The inferior border of each pedicle contains a notch forming the **intervertebral foramen**. This space in the middle of the vertebra allows the exit of a peripheral nerve root and spinal vein as well as the entrance of a spinal artery on both sides at each vertebral junction.

The transverse spinous processes comprise the junction of each pedicle and lamina on each side of a vertebra. They project laterally and posteriorly and form points of attachments for muscles and ligaments. The posterior spinous process is formed by the fusion of the posterior lamina and serves as an attachment site for muscles and ligaments.

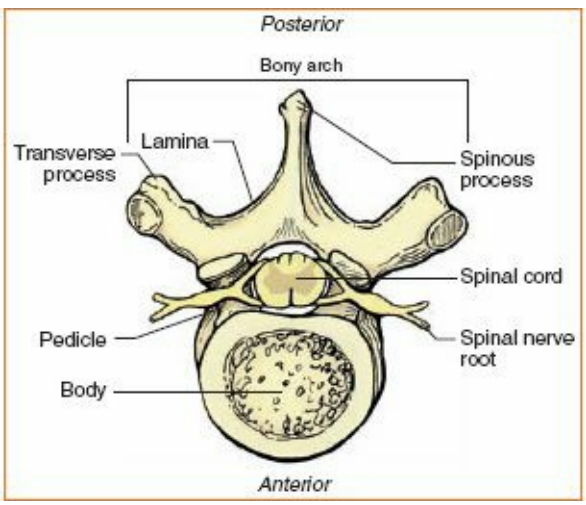

Figure 11-16 The human vertebra.

The cervical spine includes the first seven bones of the vertebral column and its supporting structures. In addition to protecting the vital cervical spinal cord, the cervical spine supports the weight

of the head and permits a high degree of mobility in multiple planes. The atlas (C1) and axis (C2) are uniquely suited to allow for rotational movement of the skull.

The thoracic spine usually consists of 12 vertebrae in addition to the supporting muscles and ligaments found in the vertebral column; the thoracic spine is further stabilized by the rib attachments. The spinous processes are slightly larger, reflecting their role as attachment points for muscles that hold the upper body erect and assist with the movement of the thoracic cavity during respiration. In patients with greater than five lumbar vertebrae, there will be less than 12 thoracic vertebrae. Although this may seem insignificant, for the purposes of radiographic interpretation, thoracic and lumbar bodies are usually counted together rather than separately.

The lumbar spine includes the five largest bones in the vertebral column, and is integral in carrying a large portion of the upper body weight. The lumbar spine is especially susceptible to injury because of this weight-bearing capacity.

The sacrum is composed of five fused vertebrae that form the posterior plate of the pelvis. The coccyx is made up of three to five small fused vertebrae. Coccyx injuries, although often extremely painful, are typically clinically insignificant.

Each vertebra is separated and cushioned by intervertebral disks that limit bone wear and act as shock absorbers. As the body ages, these disks lose water content and become thinner, causing the height loss associated with aging. Stress on the vertebral column may cause a disk to herniate into the spinal canal, resulting in a spinal cord or nerve root injury **Figure 11-18**.

The muscles, tendons, and ligaments that connect the vertebrae allow the spinal column a degree of flexion and extension, limited to an extent by the stabilization they must provide to the spinal column. The vertebral column can sustain normal flexion and extension of 60% to 70% without stressing the spinal cord. Flexion or extension beyond those limits may damage structural ligaments and allow excess vertebral movement that could expose the spinal cord to injury.

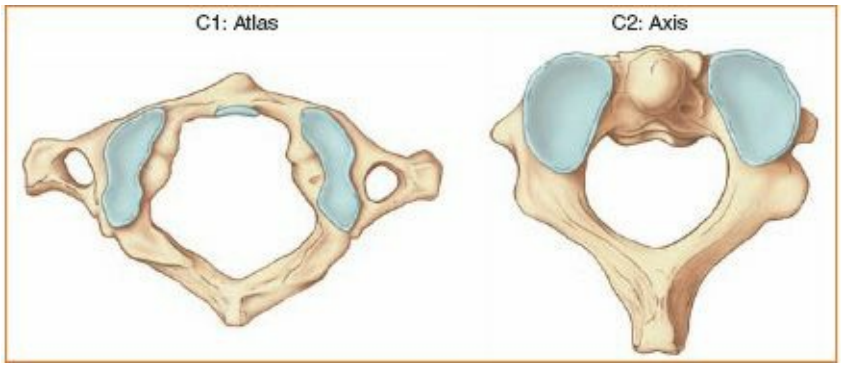

Figure 11-17 Superior view of the structure of the atlas and axis.

Spinal Cord

The spinal cord transmits nerve impulses between the brain and the rest of the body. Located at the base of the brain, it represents the continuation of the CNS. This bundle of nerve fibers leaves the skull through a large opening at its base called the **foramen magnum**. The large size of the foramen magnum relative to other foramina makes it a common location for brain herniation.

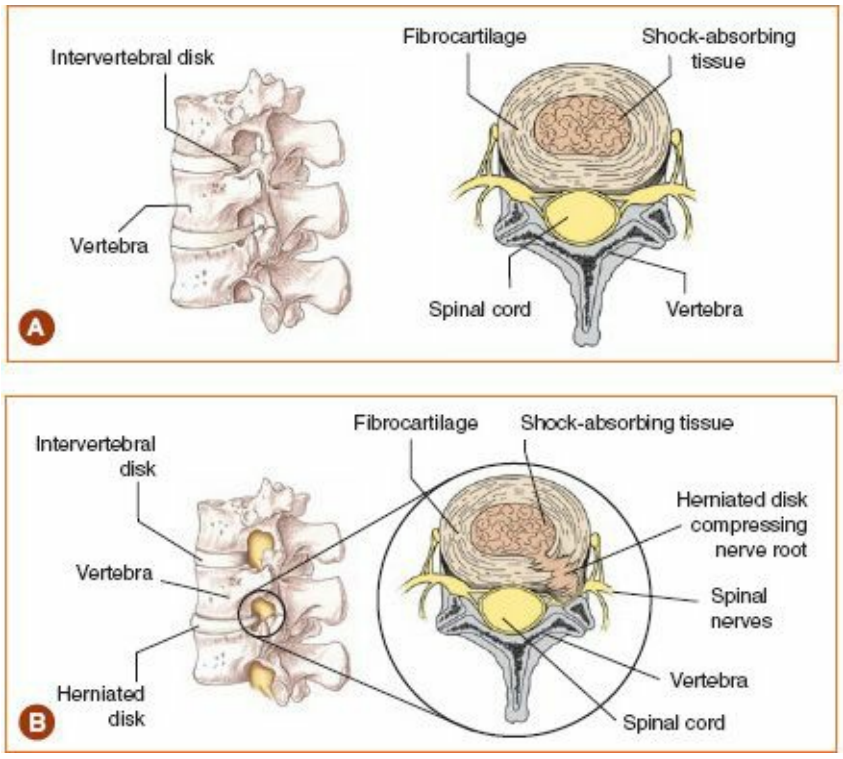

Figure 11-18 **A.** Normal, uninjured vertebral disk. **B.** Herniated disk.

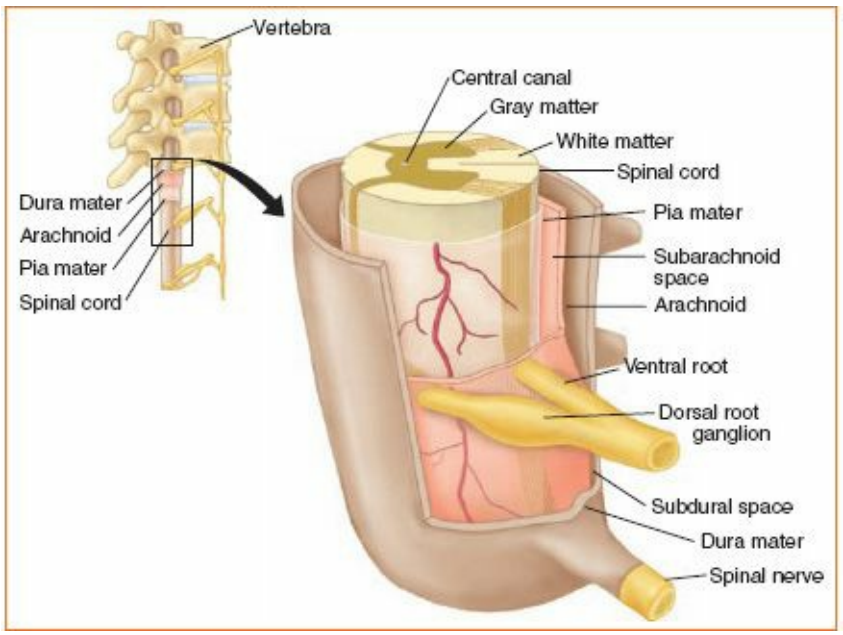

Figure 11-19 The spinal cord and its layers. The meninges enclose the brain and spinal cord.

The spinal cord extends from the base of the skull to L2; here it separates into the **cauda equina**, a collection of individual nerve roots. Thirty-one pairs of spinal nerves arise from the different segments of the spinal cord; each pair is named according to its corresponding segment.

A cross-section of the spinal cord **Figure 11-19** reveals a butterfly-shaped central core of gray matter that is composed of neural cell bodies and synapses. This gray matter is divided into posterior (dorsal) horns, which carry sensory input, and anterior (ventral) horns, which innervate the motor nerve of that segment. Surrounding the gray matter on each side are three columns of peripheral white matter composed of myelinated ascending and descending fiber pathways. Messages are relayed to and from the brain through these spinal tracts.

The brain stem connects the spinal cord to the remainder of the brain. All but two of the 12 cranial

nerves exit from the brain stem. Specific groups of nerves are named based on their source of origin and point of termination. Ascending tracts carry information to the brain, and descending tracts carry information to the rest of the body **Table 11-4**.

Peripheral Nervous System

Spinal Nerves

The 31 pairs of spinal nerves emerge from each side of the spinal cord and are named for the vertebral region and level from which they arise. The eight cervical roots perform different functions in the scalp, neck, shoulders, and arms. The 12 thoracic nerve roots have varying functions; the upper thoracic nerves supply muscles of the chest that help in breathing and coughing, whereas the lower thoracic nerves provide abdominal muscle control and contain nerves of the sympathetic nervous system. The five lumbar nerve roots supply hip flexors and leg muscles, as well as provide sensation to the anterior legs. The five sacral nerves provide for bowel and bladder control, sexual function, and sensation in the posterior legs and rectum. The coccyx has a single nerve root.

TABLE 11-4 Major Spinal Tracts

Spinal Tract	Function
Anterior	
Anterior spinothalamic tracts (ascending)	Carry sensation of crude touch and pressure sensation to the brain
Lateral spinothalamic tracts (ascending)	Carry pain and temperature
Spinocerebellar tracts (ascending)	Coordinate impulses necessary for muscular movements by carrying impulses from muscles in the legs and trunk to the cerebellum
Corticospinal tracts (descending)	Voluntary motor commands
Reticulospinal tracts (descending)	Muscle tone and sweat gland activity
Rubrospinal tracts (descending)	Muscle tone
Posterior	
Fasciculus gracilis and cuneatus	**Proprioception**, vibration, light touch, deep pressure, **two-point discrimination**, and **stereognosis**

Nerve roots occasionally converge in a cluster called a **plexus** that permits peripheral nerve roots to rejoin and function as a group **Figure 11-20**. For example, the cervical plexus includes C1 through C5; the phrenic nerve (C3–C5) arises from this plexus and innervates the diaphragm. The brachial plexus (C5–T1) joins nerves controlling the upper extremities; the main nerves arising from this plexus are the axillary, median, musculocutaneous, radial, and ulnar. The lumbar plexus (L1–L4) supplies the skin and muscles of the abdominal wall, external genitalia, and part of the lower limbs. The sacral plexus (L4–S4) gives rise to the pudendal and sciatic nerves and supplies the buttocks, perineum, and most of the lower

limbs.

Sympathetic Nervous System

The sympathetic nervous system is controlled by the brain's hypothalamus. Information from the brain is transmitted through the brain stem and the cervical spinal cord and then exits at the thoracic and lumbar levels of the spine to reach target structures. The thoracolumbar system provides sympathetic stimulation to the periphery largely through alpha and beta receptors. Alpha receptor stimulation induces smooth muscle contraction in blood vessels and bronchioles. Beta receptors respond with relaxation of smooth muscles in blood vessels and bronchioles, and have chronotropic and inotropic effects on myocardial cells.

An SCI at or above the level of T6 may disrupt the flow of sympathetic communication. Loss of sympathetic stimulation can disrupt homeostasis and leave the body poorly equipped to deal with changes in its environment. Stimulation of sympathetic nerves without parasympathetic input can cause sympathetic overdrive, resulting in autonomic dysreflexia.

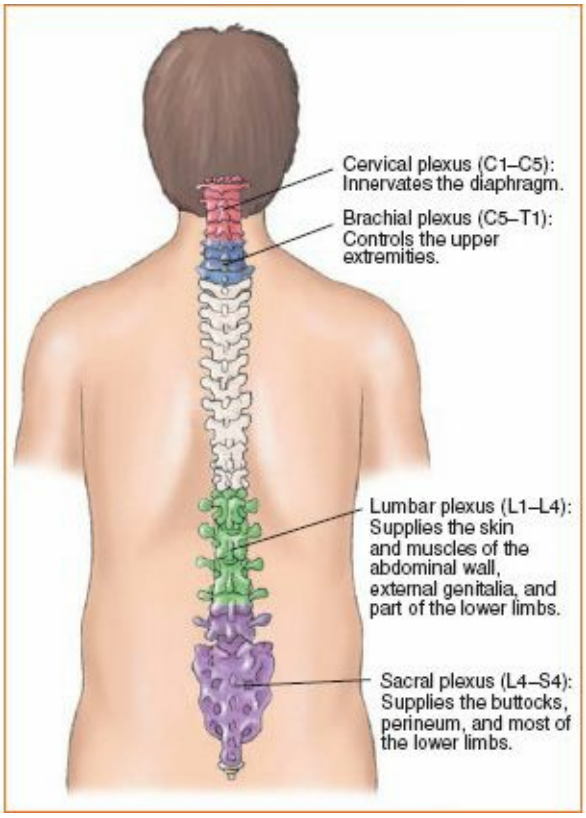

Figure 11-20 Nerve roots converge in plexuses, allowing them to function as a group.

Parasympathetic Nervous System

The parasympathetic nervous system includes fibers arising from the brain stem and upper spinal cord that carry signals to organs of the abdomen, heart, lungs, and the skin above the waist. The vagus nerve travels from its origins outside of the medulla to the heart via the carotid arteries; thus, vagal tone remains intact following a spine injury. When the sympathetic nerves are stimulated and produce autonomic dysreflexia, the parasympathetic nerves attempt to control the rapidly increasing blood pressure by slowing the heart rate. Parasympathetic nerves that supply the reproductive organs, pelvis, and legs begin at the sacral level (S2–S4). The parasympathetic nervous system is also responsible for stimulating salivary gland secretions and peristalsis, micturition (urination), and sexual arousal (erection). Disruption of the lower parasympathetic nerves in the sacrum results in the loss of bowel/bladder tone and sexual function.

Neurologic Examination

The nervous system is a delicate matrix of individual parts that, when functioning properly, afford humans the ability to maintain internal (and external) balance. Although well protected, this system may be affected by both illness and injury. When this occurs, competent medical care often makes the difference in good vs poor outcomes. The foundation of this care is a thorough serial assessment. This integral part of patient care not only allows the tracking of patient trends, but also may allow the CCTP to identify which parts of this delicate system are damaged.

Critical patients with neurologic complications present a variety of examination and management challenges during care and transport. Examination of the patient with neurologic dysfunction is the essential starting point of the entire patient management process. Only when the CCTP has performed a thorough baseline examination can appropriate field diagnoses be made and trends in patient condition followed. The neurologic field diagnosis of the impaired patient is a deductive process that represents a culmination of all of the details from the history, the examination, and laboratory/radiographic studies that may be available. As a CCTP, you will be expected to confidently and competently perform and document a thorough neurologic assessment. The neurologic examination is divided into four main segments: mental and emotional status and assessments of cranial nerves, motor function, and sensory function.

History

The neurologic examination begins at the onset of patient contact. Simple conversation with the patient and family members may prove to be a valuable tool in the examination. If taking a history from the critically ill patient is not possible, the CCTP must also obtain information from secondary sources—for example, other EMS reports, emergency department charts, medical records from previous admissions, and family and friends. The latter individuals can provide information, and also verify patient responses to questions.

The history should focus on the patient's chief complaint and should explore related problems that may influence the chief complaint. The following is a list of significant information that should be obtained from the history:

- The patient's normal baseline status
- Recent trauma that could potentially affect the nervous system
- Recent infections, including sinus, ear, or tooth infections
- Recent headaches or difficulty concentrating
- Feelings of dizziness, loss of balance, blackout episodes, tinnitus, or hearing problems
- Clumsiness or weakness of the extremities
- Numbness, tingling, hypersensitivity, or pain
- Impotence or incontinence (urinary or fecal)
- Visual symptoms such as double vision, blurred vision, or loss of vision
- Tobacco, alcohol, or drug use
- Recent difficulties performing everyday activities, including job performance and social interaction
- SAMPLE history

Physical Examination

Mental and Emotional Status

The mental/emotional component of the neurologic examination assesses the patient's ability to understand and interact with the environment. Specific areas tested in this component include level of consciousness; general behavior; and thought process, including memory, attention and concentration, abstract thought, and judgment. Not every component of the examination will be relevant in all critical care situations and, therefore, may not be tested. Nevertheless, the CCTP should understand how all components are integrated and how they influence decision making for patient care.

Assessment of the level of consciousness (LOC) is an extremely important component of the neurologic examination and should be performed on all patients. The patient's ability to perform should be taken into consideration, as it may be necessary to modify assessment techniques. For example, intubated patients who are otherwise awake and aware may gesture or write answers to questions instead of verbalizing them.

Awareness and arousal are the fundamental constituents of consciousness and should be evaluated and documented repeatedly. The evaluation of arousal is essentially an assessment of the patient's RAS and its connection with the thalamus and the cerebral cortex. Arousal—the lowest LOC—focuses on the patient's ability to respond to a variety of stimuli, and may be described using the AVPU scale **Table 11-5** or terms such as "disoriented," "lethargic," or "obtunded" **Table 11-6**.

In most critical care settings, where time for gathering data may be limited, the Glasgow Coma Scale (GCS), discussed in Chapter 10, is commonly used to document and trend a patient's level of arousal. This scale evaluates three parameters: eye opening, verbalization, and movement. The best response for each category is recorded. A minimum score of 3 indicates a completely unresponsive patient, whereas a score of 15 indicates the patient is awake and alert. Generally, a GCS score of 7 or less indicates a coma.

TABLE 11-5 AVPU Scale
Awake–eyes open spontaneously
Verbal–arouses to stimulation by voice
Painful–purposeful movement to a painful stimulus such as a pectoral pinch
Unresponsive–not responsive to any stimuli

TABLE 11-6 Levels of Arousal
Confusion–loss of the ability to think rapidly and clearly
Disoriented–disorientation to time, followed by place, and then self
Lethargic–limited spontaneous movement or speech; easy arousal with normal speech or touch; may not be oriented to time, place, or person
Obtunded–mild to moderate reduction in arousal with limited responses to the environment; falls asleep unless stimulated verbally or tactilely; answers questions with minimal response
Stuporous–a condition of deep sleep or unresponsiveness from which the person may be aroused or caused to open eyes only by vigorous and repeated stimulation; response is often grabbing at or withdrawal from stimulus
Coma–no verbal response to the external environment or to any stimuli; noxious stimuli such as deep pain yield motor movement ***Light coma***–associated with purposeful movement on stimulation

Coma–associated with nonpurposeful movement only on stimulation

Deep coma–associated with unresponsiveness or no response to any stimulus

TABLE 11-7 Questions Pertaining to Patient Orientation

Category	Sample Questions	Order of Loss
Time	What day is it?	ORDER OF LOSS
	What is the date?	
	What is the month, the year?	
	What is the season?	
	What is the time of day?	
Place	What is the name of the place we are in?	
	What type of vehicle are we in?	
	What is the name of the town or city?	
Person	What is your name?	
	What is your job?	
	Where do you live?	

The evaluation of the patient's awareness is an assessment of the content of consciousness, which is a higher-level function than arousal. In performing this evaluation, the CCTP should assess the patient's orientation to time, place, and person **Table 11-7**.

Assessment requires that the patient provide appropriate answers to a variety of questions. Findings may be documented as alert and oriented (A&O × 3, A&O 2/3, or A&O 1/3). The three aspects of awareness (AAO × 3; **a**wake, **a**lert, and **o**riented) disappear in the order of time, place, and then person (self) as the patient becomes more disoriented. Changes in the patient's answers that indicate increasing degrees of confusion and disorientation may, therefore, be one of the earliest signs of neurologic dysfunction.

Simple observation is the primary tool used to assess the patient's behavior. General behavior is best assessed through observation of gestures, facial expressions, mood, affect, and posture. During this component of the examination, family members or close friends may be able to assist in determining if the responses of the patient are normal or abnormal. A variety of neurologic pathologies—including pain, hypoxia, anxiety, and expanding intracranial lesions—may initially manifest themselves through changes in general behavior.

Most critical patients will not have the ability to undergo lengthy tests to assess cognitive functioning. The **Mini-Mental Examination** **Table 11-8** was developed to provide a simple, easily applied test of higher cognitive functions. It consists of a series of questions that test orientation, registration, attention and calculation, recall, and language. The highest possible score is 30, whereas a score of less than 24 indicates cognitive dysfunction.

Speech Function

Abnormalities of speech may need to be considered early on in the neurologic examination, because they may interfere with the CCTP's ability to accurately assess other, higher-level functions **Table 11-9**. Abnormalities of speech can reflect dysfunction in any component or process of communication.

The term **aphasia** encompasses any loss or impairment of language function as a result of brain damage. Sounds are recognized as language in Wernicke's area, which is connected to the concept area,

where the meaning of the words becomes understood. The concept area is connected to Broca's area, where speech output is generated. Wernicke's area is also directly connected to Broca's area via the arcuate fasciculus. Because the arcuate fasciculus connects the speech comprehension area (Wernicke's area) to the speech production area (Broca's area), damage to this area produces impairment of repetition. These areas are found in the dominant hemisphere of each person's brain (left dominant is most common).

The next sections discuss specific neurologic tests that may or may not be done in the critical care transport environment. With interfacility transports, many of these will already have been done as part of the initial assessment at the hospital. In some cases, the CCTP may perform these if there is not much time for initial assessment or if there is time during transport, but some may not be possible to do in cramped quarters. Which evaluations are performed depend on the patient's condition; if needed, the CCTP will perform certain exams as appropriate. Regardless of whether or not the CCTP actually performs these exams, transport team members must know how to read and interpret these findings and base their care accordingly.

TABLE 11-8 Mini-Mental Examination Components

Parameter	Task	Possible Points*
Orientation	Score 1 point for correct answers to each of the following questions:	
	What is the: time? date? day? month? year?	5
	What is the name of this: hospital? town? country?	5
Registration	Name three objects arbitrarily. Score up to 3 points if, at the first attempt, the patient repeats, in order, the three objects you have randomly named. Score 2 or 1 if this is the number he/she repeats correctly. Encourage the patient, even with prompting, to have all three repeated, so as to test recall later.	3
Attention and calculation	Ask the patient to subtract 7 from 100, and then 7 from the result—repeat this five times, scoring 1 for each time a correct subtraction is performed.	5
Recall	Ask for the three objects repeated in the registration test, scoring one for each correctly recalled.	3
Language	Score 1 point each for two objects (a pencil and a watch) correctly named.	2
	Score 1 point if the following phrase is correctly repeated: "No ifs, ands, or buts."	1
	Have the patient perform a three-stage task. Score 1 for each stage that is successfully performed. For example, the CCTP may state, "with the index finger of your right hand touch the tip of your nose and then your left ear."	3
	On a blank piece of paper, write, "Close your eyes" and ask the patient to obey what is written. Score 1 point if the patient closes his/her eyes.	1
	Ask the patient to write a sentence. Score 1 if the sentence makes sense and contains a subject and a verb.	1
	Ask the patient to construct a pair of intersecting pentagons, each side 1″ long. Score 1 if this is accomplished correctly.	1
TOTAL		30

*Scores of less than 24 indicate cognitive dysfunction. Speech must be intact in order for the test to be valid.

Assessment of Cranial Nerves

Assessment of the cranial nerves, which are located between the midbrain and the pons, provides invaluable information on pressure changes within the cranium and its effects on the brain stem in particular. Many of the cranial nerve tests require patient participation, so they may not be feasible in some critically ill or injured patients. Cranial nerve dysfunction may occur as a result of several pathologies, including lesions to the nerve; lesions in the nucleus, the communicating pathways to and from the cortex, the diencephalon, the cerebellum, or other parts of the brain stem; or as generalized problems of nerve or muscle.

Knowledge of all cranial nerves (areas that they serve, expected response to testing, and indications of abnormal response) is necessary to complete a thorough neurologic examination. Nevertheless, certain nerves are more commonly tested in patients who are critically ill or injured: optic (CN II), oculomotor (CN III), trochlear (CN IV), trigeminal (CN V), abducens (CN VI), facial (CN VII), acoustic (CN VIII), glossopharyngeal (CN IX), vagus (CN X), and hypoglossal (CN XII). **Table 11-10** provides an overview of the cranial nerves, their functions, and methods of testing.

Owing to the nature of the environment in which the CCTP works, most patients encountered are critically ill or injured. It may, therefore, be necessary to perform rapid exams that test the function of the most important cranial nerves simultaneously. **Table 11-11** outlines such nerve groups and their exam results.

TABLE 11-10 Cranial Nerves

Cranial Nerve No.	Cranial Nerve Name	Function	Test
I	Olfactory	Sense of smell	Patient smells aromatic substance (coffee or soap but not ammonia or other irritants)
II	Optic	Vision	Visual acuity test–use of Snellen chart Optic disk–fundoscopy Fields–confrontation
III	Oculomotor	Medial and upward/downward movement of the eye Constriction of the pupil Elevation of eyelids Consensual light response Accommodation and convergence	Extraocular movements, pupillary size and equality, and symmetry of response to light shined in eyes
IV	Trochlear	Moves eyes upward and downward	Tested with CN III and VI
V	Trigeminal	Sensation for face, scalp, cornea, and nasal and oral cavities Movement of jaw	Prick the patient's face with a pin and touch the face lightly with a piece of cotton Patient clenches his/her teeth together
VI	Abducens	Moves eyes laterally	Tested with CN III and IV
VII	Facial	Controls facial expression and taste for anterior two thirds of tongue	Direct the patient to smile, whistle, bare the teeth, and pucker lips Also, the patient should close his/her eyes and wrinkle the forehead
VIII	Acoustic	Hearing and equilibrium	Caloric test in unconscious patients Doll's eyes test
IX	Glosso-pharyngeal	Voluntary muscles for swallowing and phonation Secretory and salivary glands Carotid reflex	Test for palatal elevation, swallowing and gag reflexes,* and glottal and palatal sounds Figure 11-21
X	Vagus	Voluntary muscles for phonation and swallowing Involuntary activity of visceral muscles of the heart, lungs, and digestive tract Carotid reflex	Test for palatal elevation, swallowing and gag reflexes,* and glottal and palatal sounds
XI	Spinal accessory	Shrugging of shoulders and turning of head	Ability to shrug shoulders and turn head against resistance
XII	Hypoglossal	Movement of tongue and taste for posterior third of the tongue	Ability to protrude tongue and push tongue against cheek

**Note:* 10% of the normal population lacks a gag reflex.

Olfactory Nerve

Cranial nerve I, which is responsible for olfaction, should be assessed in patients in whom head trauma has occurred, when pathology at the base of the skull is suspected, and in patients who exhibit an altered mental status. Familiar odors should be used to conduct the exam, such as coffee, vanilla, soap, and lemon oil. Irritant substances such as ammonia or vinegar should *never* be used to conduct the examination. The patient should be able to identify the substance presented with the eyes closed and one nostril occluded. Complete or unilateral anosmia (inability to smell) may suggest damage to the olfactory tract.

Another interesting phenomenon is **Foster-Kennedy syndrome**, which involves the olfactory nerve and is caused by a tumor or abscess at the base of the frontal lobe. Signs and symptoms include ipsilateral blindness and anosmia, ipsilateral atrophy of the olfactory and optic nerves, and contralateral papilledema.

Optic Nerve

The optic nerve (CN II) arises from cells in the retina and then passes into the orbit, where it is contained in meningeal sheaths. The nerve then changes its name to the optic tract when the fibers have passed through the optic chiasm. The fibers from the nasal half of the retina decussate within the optic chiasm;

those from the lateral (temporal) half do not. Each eye should be evaluated individually to assess the optic nerve. The tests should include evaluation of visual acuity, visual fields, and the fundi (via funduscopy).

Figure 11-21 The test for cranial nerve IX, the glossopharyngeal nerve, tests for palatal elevation, swallowing and gag reflexes, and glottal and palatal sounds.

TABLE 11-11 Cranial Nerves and Their Exam Results

Cranial Nerve Group	Specific Test	Significance
III, IV, VI	Extraocular movements	Dysconjugate gaze indicates compression or injury of nerve; eyes are unable to turn together in the same direction.
V, VII, IX, X, XII	Swallowing	Potential for aspiration.
III, VI, VIII	Oculocephalic reflex (doll's eyes)	Brain stem dysfunction.
III, VI, VIII	Oculovestibular reflex (caloric test)	Brain stem dysfunction.
IX, X	Gag reflex	Loss of protective reflex as a result of brain stem dysfunction or nerve injury.
V, VII	Corneal reflex	Loss of protective reflex as a result of brain stem compression or nerve injury.

Data from: Kinney MR, Brooks-Brunn JA, Molter N, et al. *AACN Clinical Reference for Critical Care Nursing*. St Louis, MO: Mosby; 1999.

To formally evaluate visual acuity, a Snellen chart **Figure 11-22** should be used. Each eye should be checked individually using the chart. The patient should be asked to read the line on the chart with the smallest letters that he or she is able to read at a distance of 20′. The number beside each line on the chart is the distance at which a person with normal vision can read the letters. This number is the denominator when recording the vision.

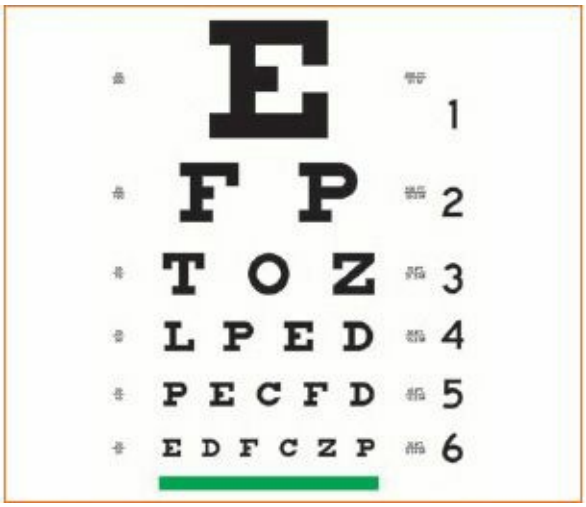

Figure 11-22 The Snellen chart.

Figure 11-23 Rosenbaum Pocket Vision Screener (eye chart).

An alternative to the Snellen chart is the Rosenbaum Pocket Vision Screener **Figure 11-23**, which can be used at a more practical distance of 14″ vs 20′. The ratio is calculated in the same manner as used for the Snellen chart.

Examination of the visual fields provides invaluable information that can often enable the CCTP to determine the location of a lesion on the visual pathway. A normal visual field extends 60° to the nasal side, 100° on the temporal side, and 130° vertically. To evaluate the visual fields, perform the confrontation test. In this test, the CCTP faces the patient at a distance of 2′, and then asks the patient to cover one eye lightly and look at the CCTP's eye directly opposite. The CCTP should then present a stimulus in each of the four quadrants—upper and lower nasal and upper and lower temporal—of the visual field. Acceptable stimuli include finger movement, rapid finger counting, and hand comparison. The CCTP should assess for the presence of a *scotoma*, or spot, which is a deficit of the visual field surrounded by normal vision. The *blind spot* represents the location of the optic disk within the visual field, because the optic disk does not have rods, cones, or ganglion cells necessary for vision.

Figure 11-24 An ophthalmoscope.

The **fundus** of each eye includes the optic disk, macula, and blood vessels on the back wall of the internal eyeball; it should be examined using the ophthalmoscope **Figure 11-24**. During the examination, the patient should look at a distant object, and the CCTP should attempt to observe the optic disk, the blood vessels, and the retinal background. With the ophthalmoscope dial set on zero, the pupillary red reflex (the point at which the retinal reflex is seen glowing pink in the pupil) is located from a distance of about 2′ or 3′. The examiner slowly approaches the patient's eye as if viewing the eye through a keyhole. At the same time, plus or minus lenses, as needed, are dialed on the ophthalmoscope to focus on the patient's retina. The **optic disk** is located by directing the ophthalmoscope toward the nasal side of the patient's retina. The most prominent structure visible, it represents the termination of the optic nerve. **Table 11-12** describes assessment parameters.

Ocular, Trochlear, Trigeminal, and Abducens Nerves

The oculomotor, trochlear, and abducens nerves (CN III, IV, and VI, respectively) are usually examined as a group because they act together in producing eye movement and controlling ocular muscles to ensure that the eyes remain parallel throughout their range of motion. The two parameters that should be closely observed by the CCTP in relation to these nerves are the position of the eyeball and the position of the upper eyelid. The eyeball's position should be observed from a frontal and lateral view as well as from a cephalad view. The upper eyelid should be assessed while having the patient look straight ahead, and the CCTP should look for evidence of drooping or **ptosis**.

To test eye movement, the patient is asked to follow the CCTP's finger in upgaze and downgaze and from side to side; these areas of movement are commonly called the six cardinal fields of gaze. Eye movements can be divided into four types, each controlled by a different part of the brain **Table 11-13**. The brain stem is responsible for integrating inputs from the frontal and occipital lobes and the cerebellum and vestibular nuclei such that both eyes move together in the same direction, called **conjugate movement**. If there is a lack of symmetric movement between the two visual axes, **dysconjugate movement** is said to be present. **Diplopia**, or double vision, may occur if the patient is unable to move the eyeball in one particular direction.

In conducting a neurologic examination on an unconscious patient, the oculocephalic reflex (doll's eye test) and the oculovestibular reflex (caloric test) may be evaluated for reflex movement of the eyeball (see the section on assessment of cranial nerve VIII for this procedure). The presence of these reflexes indicates the brain stem is intact.

During the assessment of cranial nerves III, IV, and VI, assess for the following dysfunctions:

- Gaze abnormalities **Table 11-14**
- Nystagmus—an involuntary rhythmic movement of the eyes that may be horizontal, vertical, or mixed direction with a fast and slow component to the movement **Table 11-15**
- Abnormalities of the pupils in terms of size, shape, equality, and reflexes **Table 11-16**

The oculomotor nerve (CN III) innervates the superior, medial, and inferior rectus muscles, the inferior oblique, and the constrictor of the pupil and the ciliary body, as well as the levator of the eyelid. A complete lesion of the oculomotor nerve results in paralysis of the ipsilateral muscles innervated by the nerve and ptosis, pupillary dilation, and inability to look upward, downward, or inward. Oculomotor nerve palsy is commonly caused by uncal herniation resulting from an expanding intracranial mass.

The trochlear nerve (CN IV) innervates the superior oblique muscle. When the fourth nerve is damaged, the affected ipsilateral eye is higher than the normal opposite eye, and it cannot be turned downward when the eye is rotated inward. The position of the globe is higher relative to the position of the other globe because the superior oblique muscle normally depresses the eyeball. When this muscle is paralyzed, the eyeball will not depress normally relative to the other eye. Thus, it is *higher* than the other eye.

TABLE 11-12 Assessment Parameters of the Eye

Structure	Normal	Abnormal	Interpretation of Abnormal Findings
Optic disk	Round or slightly oval in shape Yellowish-red color Clearly defined margins	Papilledema: swelling of the disk including disappearance of the optic cup (*Note*: you see nothing, and visual acuity is not affected)	Increased intercranial pressure, usually within 24-48 h
		Papillitis: inflammation of the optic nerve (*Note*: you see nothing, and visual acuity is diminished)	Multiple sclerosis, idiopathic
		Optic atrophy: decreased visual acuity and a change in color of the optic disk to light pink, white, or gray	Primary: optic nerve compression, optic nerve ischemia Secondary: following papilledema
Optic cup	Slightly on the nasal side of the center of the optic disk Diameter is normally < 50% of the disk	Cup may appear deep	Chronic (or idiopathic) glaucoma
Blood vessels	Arteries are lightly colored and are two thirds the diameter of veins	Arterial narrowing and vessel irregularity	Hypertensive retinopathy
	Veins are burgundy colored and may pulsate near the disk	Tortuous vessels	Hypertensive retinopathy
Retinal background	Pigmented background: normal in dark-skinned races, if striped it is called *tigroid*	Red lesions	
		Dot hemorrhages: microaneurysms seen adjacent to blood vessels	Diabetic retinopathy
	Pale: clear is normal in fair-skinned people	Blot hemorrhages: bleeds in the deep retinal layer from microaneurysms	Hypertensive retinopathy
		Flame hemorrhages: superficial bleed, shaped by nerve fibers into a fan that point toward the disk	Subarachnoid hemorrhage
		Subhyaloid hemorrhages: irregular superficial hemorrhages usually with a flat top	Diabetes and hypertension
		White/yellow lesions	
		Hard exudates: yellowish, sharply edged lesions that may form a ring around the macula	Diabetes, systemic lupus erythematosus, acquired immunodeficiency syndrome
		Cotton wool spots: white fluffy spots caused by retinal infarcts	Hypertension

TABLE 11-13 Eye Movements

Type of Eye Movement	Definition	Site of Control
Saccadic (command)	Rapid movement from one point of fixation to another	Frontal lobe
Pursuit	Slow eye movement used to maintain fixation on a moving object	Occipital lobe
Vestibular-positional	Eye movements that compensate for movement of the head/neck to maintain fixation	Cerebellar vestibular nuclei
Convergence	Movements that maintain fixation as an object is brought close to the face	Midbrain

TABLE 11-14 Gaze Abnormalities

Type of Gaze	Description	Causes
Normal gaze	Eye movements are smooth and conjugate	N/A
Horizontal gaze	Deviation of both eyes toward the same side	Destructive hemispheric lesion: both eyes deviate *toward* the side of the lesion Irritative hemispheric lesion (eg, hemorrhage): both eyes deviate *away* from the side of irritation, but later the conjugate gaze becomes paralyzed
Vertical gaze	Deviation of both eyes upward	Upper brain stem lesion
Medial-longitudinal fasciculus	Dysconjugate gaze	Lesion between the pons and midbrain
Skewed deviation	One eye looks downward and the other looks upward	Lesion in the pons on the same side as the eye that is directed downward
Roving-eye movements	Spontaneous, slow, random deviation	Seen in comatose patients with intact brain stem oculomotor function
Ocular bobbing	Episodic, intermittent, usually conjugate, downward, brisk eye movement followed by a return to the resting position by a "bobbing action"	Severe destructive lower pontine lesions

TABLE 11-15 Nystagmus Types

Type of Nystagmus	Description	Cause(s)
Retraction nystagmus	Irregular jerks of the eyes backward into the orbit, initiated by an upward gaze	Midbrain tegmental damage
Convergence nystagmus	Slow, spontaneous, drifting, ocular divergence with a final quick, convergent jerk	Midbrain lesion
See-saw nystagmus	A rapid, pendular, dysconjugate see-saw movement accompanied by severe visual field deficits and loss of visual acuity	Lesion around optic chiasma
Downbeat nystagmus	Irregular jerks initiated by a downward gaze	Lower medullary lesion
	A test in which a striped drum is spun in	

Optokinetic nystagmus	front of the eyes, normally evoking nystagmus in the opposite direction of the spin	Present in most patients
Vestibular nystagmus	Mixed nystagmus that can be horizontal, rotational, or both	Vestibular disease
Toxic nystagmus	Nystagmus occurring while the head is in a specific position, caused by certain drugs or alcohol	Induced by treatment with certain drugs, such as phenytoin, barbiturates, and bromides; also caused by alcohol ingestion

The abducens nerve (CN VI) controls the ipsilateral lateral rectus muscle, which makes the eye look outward (laterally). Defects in abduction (from a lesion of the sixth cranial nerve for example) give the patient a *crosseyed* appearance. The normal eye is oriented straight ahead; by comparison, the affected eye is rotated slightly inward (medially) owing to the unopposed action of the medial rectus muscle on that side.

The trigeminal nerve (CN V) has both motor and sensory functions. In sensory testing, its innervation includes the face up to the vertex of the scalp but spares the angle of the mandible. The sensation from the oral and nasal cavities is transmitted through the trigeminal nerve, although these areas are not usually included in the routine neurologic examination.

Pain and temperature should be tested in the three divisions of the fifth cranial nerve: ophthalmic, maxillary, and mandibular. The ophthalmic division innervates the scalp as far back as the vertex of the skull, forehead, cornea, conjunctiva, and skin of the side and tip of the nose. Corneal sensation is tested by gently touching the corneas with a cotton tip or tissue paper while the patient looks in the other direction. This maneuver constitutes the afferent limb of the corneal reflex. The normal response is a rapid, partial, or complete blinking movement of the eyelid elicited by the efferent limb of the corneal reflex via the facial nerve.

The second trigeminal division, the maxillary nerve, conducts stimuli from the skin of the cheek, far lateral aspect of the nose, upper teeth, and jaw. The third division, the mandibular nerve, carries sensory and motor impulses. The sensory distribution is the skin of the lower jaw, pinna of the ear, lower teeth and gums, and the side of the tongue.

The motor fibers supply the muscles of mastication: the temporal, masseter, and pterygoid muscles. The temporal and masseter muscles are examined by having the patient close the jaws together while the CCTP palpates these muscles. The *jaw-jerk reflex* is elicited by a gentle tap on the chin, with resultant closure of the jaw by the masticatory muscles.

TABLE 11-16 Pupillary Exam Results

Size	2–6 mm (average of 3.5 mm)
Shape	Round Patients who have had previous cataract surgery may have the shape of a keyhole
Equality	Diameters are equal Be aware of anisocoria, a nonpathologic unequal pupil found in 15% of the population

Facial Nerve

The facial nerve (CN VII) is a complex nerve with motor, sensory, and parasympathetic fibers. The motor

portion of the nerve innervates the muscles of facial expression and is tested by instructing the patient to wrinkle the forehead, close the eyelids tightly, smile or grimace showing the teeth, and whistle. Two types of facial motor weakness are possible: one with involvement of the upper motor neuron (corticonuclear/corticobulbar pathways), and the other with involvement of the lower motor neurons (*peripheral* seventh nerve palsy). *Central* (upper) motor facial palsy is characterized by the inability to retract the corner of the mouth, whereas forehead function and eyelid closure remain for the most part unaffected. Lesions in the facial nucleus or the nerve proper will cause paralysis of half of the entire face, with inability to wrinkle the forehead or to close the eyelids and lips on the affected side.

The sensory portions of the seventh nerve originate from the taste buds in the anterior two thirds of the tongue and from the posterior wall of the external ear canal. Although this test is rarely performed in the field, taste is examined using sugar, salt, or quinine solutions. The patient is instructed to protrude the tongue; then the test substance is applied with a cotton-tipped applicator on one side of the tongue. The patient must identify the test substance before drawing the tongue back into the mouth. The facial nerve also carries parasympathetic fibers to the maxillary and lacrimal glands.

Vestibulocochlear Nerve

The eighth cranial nerve is made up of two divisions: (1) cochlear, which affects the sense of hearing; and (2) vestibular, which affects the sense of balance.

The vestibular division of the acoustic nerve is assessed using rotational and caloric stimuli to produce changes in the endolymph current in the semicircular canals. Both tests are also used to determine the brain stem function of unconscious patients. Typically, patients with vestibular dysfunction complain of vertigo, nausea and vomiting, and difficulty with balance, especially with movement of the head.

The **caloric test**, or Bárány test, is commonly used to assess vestibular function; it should not be performed on any patient with a ruptured tympanic membrane. This assessment involves raising and lowering of the temperature in the external auditory canal, which induces convection currents in the endolymph of the semicircular canals and stimulates the vestibular nerve endings. With the patient lying down and the head elevated 30° such that the lateral semicircular canal is vertical, cool water (30°C) is instilled into one ear over 40 seconds (usually about 250 mL). If the patient is conscious, he or she should be directed to look forward while the water is being instilled. This step is then repeated in the other ear with warm water (44°C). The direction of nystagmus is then observed. **Table 11-17** identifies the normal and abnormal responses.

TABLE 11-17 Caloric Test Responses

Conscious patient	Cold: nystagmus away from stimulated ear Warm: nystagmus toward stimulated ear Remember the mnemonic COWS (cold-opposite/warm-same)
Unconscious patient	Cold: nystagmus toward the stimulated ear Warm: nystagmus away from stimulated ear

Figure 11-25 Doll's eye test or oculocephalic reflex test.

The **doll's eye test**, or oculocephalic reflex test, is performed on the unconscious patient by rapidly rotating the head from side to side and observing the eye movement **Figure 11-25**. This procedure is contraindicated if neck or cervical spine injury is suspected. If the reflex is intact or doll's eyes are present (indicating brain stem function between CN III, VI, and VIII), the eyes will deviate opposite the movement of the head. The absence of doll's eyes occurs when the eyes move in the same direction of the head as it is turned; this abnormal response indicates severe brain stem dysfunction.

Glossopharyngeal and Vagus Nerves

The glossopharyngeal and vagus nerves (CN IX and X, respectively) are usually tested together owing to their co-innervation of the pharynx. The glossopharyngeal nerve supplies sensory components to the pharynx, tonsils, soft palate, and posterior third of the tongue. It also supplies motor fibers to the muscle that elevates the pharynx. The vagus nerve is responsible for sensation to the pharynx and larynx; motor function of the soft palate, pharynx, and larynx; innervation of the thoracic and abdominal visceral organs; and sensory input from the heart, lungs, and digestive tract.

To test these nerves, direct the patient to open his or her mouth and say, "Ah." The upward movement of the soft palate and any deviation of the uvula should be noted. As part of this assessment, the CCTP may also stimulate the gag reflex (using a tongue depressor or cotton swab), which is also mediated by cranial nerves IX and X. Note that 10% of the population does not have a gag reflex.

Spinal Accessory Nerve

The spinal accessory nerve (CN XI) is tested in two segments. First, the trapezius muscle is palpated, and its strength is evaluated while the patient shrugs his or her shoulders against resistance. Second, the patient turns his or her head to one side and pushes his or her chin against the examiner's hand; the CCTP should then palpate the sternocleidomastoid for tone and strength. This test should not be performed on patients with a suspected injury to the base of the skull or the upper neck.

Hypoglossal Nerve

The hypoglossal nerve (CN XII) innervates the musculature of the tongue. Testing is performed when the CCTP observes the tongue for fasciculations and atrophy, tests for muscle strength by having the patient push the tongue against the inside wall of the cheek, and checks for tongue protrusion. Tongue protrusion is straight when the hypoglossal nerve pair is working together; when only one branch is working, however, the tongue will deviate toward the injured side. Neck trauma, tumor, or brain stem lesions usually cause unilateral weakness. In contrast, bilateral weakness is usually the result of degenerative neurologic diseases.

Assessment of Motor Function

The motor examination includes a consideration of muscle tone and strength. This exam proceeds from the upper limbs, to the neck and truck, and finally to the lower extremities. The symmetry of each side of the body is compared.

The assessment of motor function evaluates how both voluntary and involuntary motor pathways are functioning. The voluntary motor pathway is a descending pathway that originates in the precentral gyrus of the frontal lobe and ends at all levels of the spinal cord (suprasegmental level). The descending neuron synapses with motor neurons of the spinal cord (segmental level), and final motor output is achieved at the muscle level (myoneural junction). Voluntary muscle control involves the orchestrated effort from skeletal structures, muscles, and involuntary motor pathways that control posture, balance, and reflexive activities.

The muscles should be palpated through the normal range of motion. Abnormalities are characterized in the following terms:

- Spasticity or undue resistance of the muscles owing to passive lengthening because of injury to the corticospinal system
- Rigidity or a more constant state of resistance that involves the extrapyramidal motor system
- Flaccidity or a decreased muscle tone (hypotonia)

TABLE 11-18 Muscle Strength Grading Scale

Grade	Description
5	Normal; full strength against resistance
4	Active movement; minimal weakness against resistance
3	Active movement; barely able to overcome gravity and does not overcome active resistance
2	Active movement; does not overcome gravity
1	Slight trace of muscle contraction
0	No muscle contraction

Muscle strength should be assessed as the CCTP puts muscles of the major joints through their normal range of motion. Strength should also be assessed against gravity and finally against resistance. Muscle strength should be rated using a scale of 0 to 5 **Table 11-18**. The CCTP should draw a stick figure and place values at various points along the figure to indicate the assessed motor response.

Assessment of Sensory Function

The purpose of evaluating the sensory system is to determine the patient's ability to perceive various types of sensations with the eyes closed. Sensation arises from specialized receptors in the body that are designed to recognize and transmit stimuli to the CNS (usually the cerebrum or brain stem), where processing takes place and an appropriate response can be initiated. The sensory impulses travel along specialized tracts in the nervous system.

Sensory examination assesses the integrity of both the receptors and the tracts of conduction. It is not useful for all patients, however, as altered levels of consciousness or preexisting conditions may interfere with obtaining a proper examination or may produce abnormalities unrelated to the present illness or injury. The CCTP should be comfortable using a dermatome chart (shown in Chapter 5) to locate sensory

areas and should be especially familiar with certain key dermatomes, such as C4, C7, T2, T10, L5, S1, and S5.

As part of a detailed assessment of sensory function, pain, temperature, and touch should all be examined and documented. These methods of testing will compare symmetric areas on both sides of the body and evaluate distal and proximal areas of the arms and legs for pain, temperature, and touch sensation. The stimuli should be scattered to sample most dermatomes and major peripheral nerves. The patient's eyes should be closed.

Pain is tested by asking the patient to close his or her eyes, applying randomly both sharp (using a disposable pin) and blunt stimuli, and noting the patient's response. Always begin in areas of known altered sensation and move toward areas of normal sensation to find the edges.

TABLE 11-19 Reflex Locations

Reflex	Nerve	Root
Biceps	Musculocutaneous	C5, C6
Brachioradialis	Radial	C5, C6
Triceps	Radial	C7
Finger	Median and ulnar	C8
Knee	Femoral	L3–L4
Ankle	Tibial	S1–S2

Touch is assessed by using a fine wisp of cotton or an alcohol pad. The patient is instructed to close the eyes during the exam, and then his or her skin is stroked with the cotton or alcohol pad symmetrically on alternating sides of the body. This test measures anesthesia or hyperesthesia.

Reflex Testing

Examination of deep tendon reflexes gives information about the integrity of the spinal nerves and may indicate brain stem or spinal cord lesions. A tendon reflex results from the stimulation of a stretch-sensitive afferent nerve from a neuromuscular spindle, which, via a single synapse, stimulates a motor nerve (efferent), leading to a muscle contraction. Tendon reflexes are increased in upper motor neuron lesions and decreased in lower motor neuron lesions **Table 11-19**. The following scale should be used to grade reflexes:

- 0 = absent
- ± = present only with reinforcement
- 1 + = present but depressed
- 2 + = normal
- 3 + = increased
- 4 + = clonus

Pathologic Reflexes

The following list includes the most common pathologic reflexes, all of which indicate pyramidal tract disease. The Babinski reflex (Babinski's sign) is perhaps the most important of the pathologic reflexes.

- **Plantar response**. A designated area is stimulated and the response of the toes is observed. Normally flexion of the toes is observed. An extensor response is an abnormal finding.
- **Babinski's sign**. The lateral aspect of the sole of the foot is rapidly stroked with a key from the heel to the ball of the foot. If a plantar response occurs, it is considered a negative Babinski's sign (normal). An extensor response indicates a positive Babinski's sign (abnormal).
- **Oppenheim's sign**. An extensor response is elicited by stroking the anterior medial tibial muscle.
- **Gordon's sign**. An extensor response is elicited by firmly squeezing the gastrocnemius muscle.
- **Hoffmann's sign**. When the distal phalanx of the index or middle finger is snapped, there is a sudden clawing of the fingers and thumb.

Figure 11-26 Grasp reflex.

Grasp Reflex

The CCTP places his or her fingers on the patient's palm and pulls the hand away, asking the patient to let go of the hand. A normal response is present if the patient is able to let go. An abnormal response consists of the involuntary flexion of the fingers, causing an uncontrollable grasp of the CCTP's hand **Figure 11-26**. Such a positive grasp reflex indicates a frontal lobe lesion.

Superficial Reflexes

Assessment of the cremasteric reflex can be performed in men as the inner aspect of the upper thigh is stroked downward and movement of the testicle in the scrotum is observed. In transport, this test may be done on neonatal or pediatric patients, but would not likely be done on adults during transport. Cremasteric contraction elevates the testicle on the stimulated side. This exam tests the integrity of afferent (femoral nerve L1, L2) and efferent (L1, L2) fibers. Absence of the reflex may indicate a lesion in the reflex arc or a pyramidal lesion above L1, or may be nonpathologic.

Meningeal Irritation and Its Evaluation

Meningeal irritation may result from infections caused by bacteria, viruses, fungi, parasites, and toxins. Infections may be classified as acute, subacute, or chronic. Each type of causative agent results in a different pathophysiology, clinical manifestation, and treatment.

In this condition, the causative agent acts as an irritant, causing an inflammatory reaction around the meninges found in the arachnoid space, the CSF, and the ventricles, and resulting in hyperemia and increased permeability of the meningeal vessels. Eventually, this reaction causes the migration of neutrophils into the subarachnoid space, resulting in the formation of exudates that thicken the CSF and interfere with its normal flow around the brain and spinal cord. These exudates can obstruct the arachnoid villi and produce hydrocephalus. The purulent exudates increase rapidly, causing increased inflammation,

especially around the base of the brain but also extending into the cranial sheaths, spinal nerves, and perivascular spaces of the brain's cortex. The meningeal cells become edematous. Over time, the combination of purulent exudates and cell edema results in increased ICP.

The clinical manifestations of meningeal irritation can be grouped into meningeal, infectious, and neurologic signs. This section focuses on the meningeal signs, which include generalized throbbing headache progressing in severity, progressive photophobia, nuchal rigidity, Kernig's sign, and Brudzinski's sign.

The test for **nuchal rigidity** should not be performed if cervical spine injury is suspected. While the patient is lying flat, the CCTP should place his or her hand behind the patient's head and gently flex the head forward until the chin touches the chest if possible. Marked resistance to head movement in any direction is suggestive of meningeal irritation.

Miscellaneous Tests and Signs

Lhermitte Phenomenon

In **Lhermitte phenomenon**, forward flexion of the neck produces an electric shock feeling, usually running down the back. The presence of this sensation indicates cervical pathology.

Vital Signs

As part of the neurologic examination, the CCTP should obtain vital signs. The centers for control of vital functions are found within the brain stem. Thus, any changes in vital signs, which may be subtle, can provide invaluable information to the CCTP concerning the critical care patient's overall neurologic status. During the examination, both before and during transport, the CCTP should pay particular attention to vital signs pertaining to the respiratory system, the cardiovascular system, and body temperature **Figure 11-27**. **Table 11-20** lists the functions of each control center. The following physiologic variables should be checked repeatedly, as indicated by the patient's condition:

- Blood pressure
- Pulse rate and rhythm
- Respiratory rate
- Pulse oximetry
- End-tidal carbon dioxide (quantitative)
- Central venous pressure
- Temperature
- ICP

Respiratory System

Because much of the control over the respiratory system comes from structures within the brain stem, respiratory patterns often provide the CCTP with valuable information. Abnormal respiratory patterns may signal that neurologic injury/dysfunction is present and allow the CCTP to determine at which anatomic level injury has taken place.

When CCTPs assess respirations, they should pay particular attention to the rate, rhythm, and characteristics of the inspiratory and expiratory phases. A variety of conditions other than neurologic damage may produce alterations in respirations, such as metabolic disturbances and drug overdoses. The breathing patterns that may be observed can be classified as relating to certain types of hemispheric or brain stem activity **Table 11-21**. Chapter 6 provides explanations and illustrations of abnormal respiratory patterns.

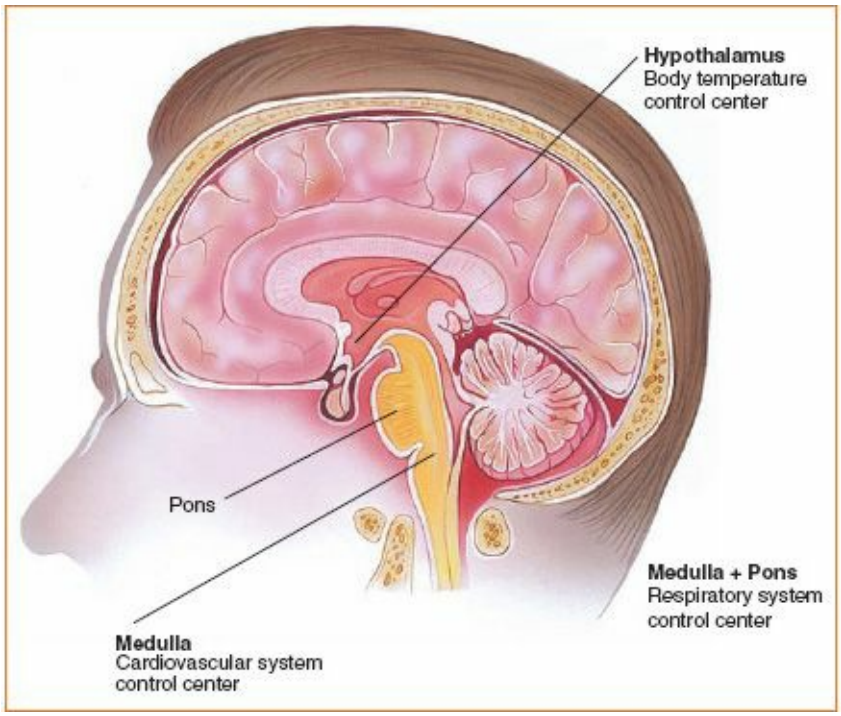

Figure 11-27 The locations of the respiratory system, the cardiovascular system, and body temperature control centers in the brain.

Cardiovascular System

The medulla is the control center for several elements of the cardiovascular system. Inhibitory impulses arising from the medulla travel to the heart via the vagus nerve, where acceleratory impulses travel through the spinal nerves arising from T1 through T5. Given this relationship, the patient's heart rate may indicate not only probable neurologic injury, but also the presence of other pathologic processes. The CCTP should be especially aware of the presence of tachycardia, bradycardia, or arrhythmias. **Table 11-22** gives a nonexhaustive list of probable causes for each variance in pulse rate.

TABLE 11-20 Control Center Location and Function

System	Location	Function
Cardiovascular System		
Cardiac center	Medulla	Regulation of rate and force of contraction
Vasomotor center	Medulla	Regulation of blood pressure
Respiratory System		
Dorsal respiratory group	Medulla	Initiates inspiration; sets the basic rhythm of respiration
Ventral respiratory group	Medulla	Almost inactive except when increased ventilatory effort is needed
Apneustic center	Pons	Exact function is unclear; sends signals to the dorsal respiratory group to prevent apnea (especially in injury)
Pneumotaxic center	Pons	Modifies inspiration rate
Temperature Regulation		

Anterior hypothalamus (response to heat)	Hypothalamus	Cutaneous vasodilation, sweating, increased respiration, anorexia, apathy, and inertia
Posterior hypothalamus (response to cold)	Hypothalamus	Shivering, hunger, increased catecholamine release, cutaneous vasoconstriction, horripilation (bristling of hairs on the skin)

When assessing the heart rate, remember that the presence of multiple illnesses or injuries may mask the characteristic effect on heart rate that would occur with an illness/injury if it were present alone. For example, bradycardia caused by increasing ICP may be counterbalanced by tachycardia in response to hypovolemic shock, thereby hiding the presence of both problems.

Hypertension—an increase in blood pressure—is the effect on blood pressure most often seen as a result of neurologic injury, especially in the case of rising ICP. As cerebral perfusion decreases, ICP rises; in response, the body attempts to maintain adequate perfusion by increasing blood pressure. Hypertension is commonly seen in conjunction with bradycardia and an abnormal respiratory pattern, collectively known as **Cushing's triad**.

TABLE 11-21 Breathing Patterns

Breathing Pattern	Location of Injury
Normal	Response to external stressor—not associated with central nervous system dysfunction
Posthyperventilation apnea	Associated with diffuse bilateral metabolic or structural disease of the cerebrum
Cheyne-Stokes respirations	Bilateral dysfunction of deep cerebrum, diencephalonic structures (thalamus and/or hypothalamus), or basal ganglia
Central neurogenic hyperventilation	Dysfunction of midbrain or upper pons
Apneustic breathing	Respiratory control mechanisms located at the pontine level
Cluster breathing	Dysfunction of lower pontine and upper medullary areas
Ataxic (Biot's) breathing	Dysfunction of medullary control centers
Agonal gasps	Failing medullary control centers

Adapted from: McCance K, Huether S. *Pathophysiology—The Biological Basis for Disease in Adults and Children*. St Louis, MO: Mosby; 2002.

TABLE 11-22 Conduction Variances

Conduction Variance	Probable Causes
Bradycardia	Increasing ICP SCI involving the sympathetic pathways
Tachycardia	Shock

	The end-stage of a neurologic injury
Arrhythmias	Increasing ICP Other intracranial pathologic conditions

Cerebral injury rarely causes hypotension except in the last stages of injury. The CCTP should, however, take all means necessary to ensure that the patient does not become hypotensive (systolic blood pressure, < 90 mm Hg), because even one episode is associated with high mortality owing to its detrimental effects on cerebral perfusion.

Pulse pressure is also a valuable tool in the evaluation of neurologic injury. The CCTP may observe widening (> 40 mm Hg) of the pulse pressure in the presence of increasing ICP.

Body Temperature

Monitor the patient's body temperature closely for changes. Alterations in body temperature—hypothermia or hyperthermia—are possible in the presence of neurologic injury, especially if the hypothalamus is involved. Take special note of hyperthermia because it can cause increased production of harmful metabolic by-products, such as carbon dioxide and lactic acid, that may in turn contribute to secondary injury.

Neurologic Diagnostics

This section discusses neurologic diagnostics of which the CCTP should have background knowledge.

Computed tomography (CT) scanning provides a mathematically reconstructed cross-sectional view of the body, including the brain, and is performed on almost every patient with abnormal neurologic findings. The image that is seen is obtained by passing intersecting x-ray beams through the area of interest and measuring the density of substances through which the x-ray beams pass. As the density of a substance increases, its image appears more white. As the density of a substance decreases, its image appears more black. In a normal CT scan of the head, bone appears white, blood appears off-white, brain tissue appears shaded gray, CSF appears offblack, and air appears black. A CT scan can be performed with or without the use of an IV contrast medium. The benefit of using contrast is for the enhancement of vascular areas and better detection of vascular lesions. Patients receiving contrast should be monitored during infusion of the dye and for 10 to 20 minutes after for evidence of anaphylactic reaction. Patients should also be monitored for evidence of acute tubular necrosis. Noncontrast CT is typically used to view the intracranial area for evidence of intracranial hemorrhage, cerebral edema, or displacement of structures.

Magnetic resonance imaging (MRI) produces images with greater detail than does CT, and has become the standard diagnostic study for many conditions. A non–iodine-containing contrast medium is usually administered IV prior to performing the procedure. The image is created by placing the patient in a large magnetic field, and introducing radiofrequency waves that cause resonance of nuclei. A computer then uses the given resonance to create an image.

Cerebral angiography allows visualization of the lumen of vessels to provide information about patency, size, irregularities, or occlusion. The procedure is typically used in the diagnosis of cerebral aneurysms, arteriovenous malformations, and carotid artery diseases. The procedure requires that a catheter be inserted into the femoral artery, threaded through the aorta and into the origin of cerebral circulation. Once the catheter is in place, a radiopaque contrast medium is injected, allowing visualization of circulation with the use of serial radiologic imaging. Complications associated with this procedure include contrast medium hypersensitivity and renal dysfunction.

Transcranial Doppler (TCD) ultrasound allows monitoring of cerebral blood flow velocity through thinner areas of the skull—temporal bone (transtemporal), the eye (transorbital), and the foramen magnum (transoccipital). Blood flow velocities can be measured in the anterior, middle, or posterior cerebral arteries and the vertebral and basilar arteries depending on the angle of the Doppler probe. This procedure is commonly used in patients following rupture of an intracranial aneurysm to assess for vasospasm, a common problem following rupture of a cerebral vessel. The procedure can also be used to identify intracranial lesions following a stroke and to detect cerebral blood flow changes associated with increased ICP.

Electroencephalography (EEG) involves the recording of electrical impulses generated by the brain to localize abnormal electrical activity. The procedure is commonly used in patients with suspected seizure activity, cerebral infarct, metabolic encephalopathies, altered consciousness, infectious disease, some head injuries, and confirmation of brain death. Waveforms are generated by placing electrodes on the head, which allow electrical impulses to be transferred to a recording unit. Five types of waves are seen most commonly: delta, theta, alpha, beta, and gamma.

Delta bands are normally associated with adults during sleep, and are also normal in infants. Pathologic causes include various types of lesions (including subcortical, diffuse, and deep midline lesions), as well as metabolic encephalopathy and hydrocephalus. Theta bands are normally associated with young children, drowsy older children, and drowsy adults, and are also sometimes seen with meditation. Pathologic causes are similar to those for delta bands (focal subcortical lesions, deep midline disorders, metabolic encephalopathy, and some kinds of hydrocephalus). Alpha bands are normal when relaxing or closing the eyes, but are also associated with coma. Beta bands are normal when a person is active, working, or anxious. They are also an effect of benzodiazepines. Finally, gamma bands are normal and are associated with performing cognitive motor functions.

Intermittent slowing with triphasic wave morphology is associated with metabolic encephalopathy. Continuous generalized slowing in the delta or theta range is associated with anoxic damage. Other abnormal EEG findings that are related to a poor prognosis are the combination of alpha waves that do not change with stimulation and a coma state (alpha coma), occasional generalized bursts of activity with intermittent inactivity (burst suppression), generalized spikes at fixed intervals of 1 to 2 Hz, and no activity (electrocerebral silence).

Lumbar puncture is typically performed by entering the subarachnoid space in the lumbar region of the vertebral column to obtain diagnostic information or to provide a therapeutic intervention. CSF samples can be taken and evaluated for the presence of subarachnoid blood (subarachnoid hemorrhage) or infection, or for laboratory analysis (refer back to Table 11-1 on CSF composition). The most common complication is headache.

Traumatic Brain Injury

Although it is protected by the rigid cranial vault, the brain may be damaged when the skull is impacted by high forces. Current understanding of the pathophysiology of TBI emphasizes the importance, or role, of two types of injury. Primary (direct) injury is caused by traumatic forces that cause physical or functional disruption of brain tissue, whereas secondary (indirect) processes occur after injury and cause brain dysfunction or cellular damage (eg, hypoxia and ischemia). Secondary injuries (ie, physiologic derangements) occur rather frequently in the period following primary injury, but often go unrecorded with standard monitoring equipment. Missing the presence of these injuries correlates with poor outcomes.

Primary Brain Injury

The head is only one part of a collision in an accident; the brain is the other component involved. Primary brain injury can occur as a result of two mechanisms: contact phenomena injuries and acceleration-deceleration injuries.

Contact phenomena injuries occur as the direct result of trauma to the head; they include all local effects such as scalp laceration, skull fracture, hematoma, and intracerebral hemorrhage. For years, clinicians believed that contact phenomena injuries were the major injuring factors in TBI. Later research proved that the brain itself is often damaged by the abrupt changes in velocity that cause strains, compression, tension, and shearing injuries to cerebral tissue. Sudden changes in velocity (acceleration-deceleration) cause the brain to move across its bony interior, resulting in damage. When the head is subjected to **translational force**, the head's center of gravity moves along a linear path; when it is subjected to **rotational force**, the head moves around its center of gravity. Rotational injuries result when forces cause the brain to twist within the cranial cavity, resulting in stretching or tearing of neurons in the white matter as well as tearing of blood vessels that secure the brain to the skull.

Areas of the brain associated with rough portions of the skull (frontal and temporal lobes) have higher incidences of injury compared with areas with smoother surfaces, such as the occipital lobe. The term **contrecoup injury** is used to describe a situation in which an impact occurs on one side of the head, causing the brain to move within the cranial vault and forcibly contact the opposite side of the skull, resulting in damage on that side of the brain. This phenomenon is also referred to as transitional injury, because forces can be transferred to the opposite side of the brain **Figure 11-28**.

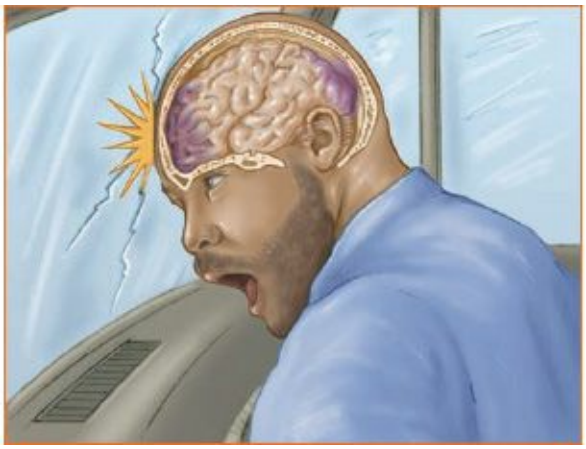

Figure 11-28 Contrecoup injury.

Most current literature cites work by Ommaya and his centripetal theory as the best model to explain the lesions observed after head injury. Ommaya's research simulated acceleration-deceleration injuries and found that certain types of brain injuries can be reproduced without any contact force acting on the head. Additionally, his research showed that the higher the magnitude of the injuring forces, the deeper the functional and structural damage of brain structures. As forces increase, the brain stem eventually becomes involved. Even without direct involvement of the brain stem, interruption of afferent nerve impulses may be sufficient to produce prolonged loss of consciousness.

Secondary Brain Injury

Secondary injury involves the more delayed mechanisms of brain damage. These physiologic derangements, if left uncorrected, will adversely affect brain function integrity. Secondary injuries may be classified as insults of either systemic or intracranial origin **Table 11-23**.

The pathophysiology of secondary brain injury is well understood. After brain injury, there is a failure of the normal protective mechanisms by which blood flow is maintained in the face of falling

perfusion pressure, or by which blood flow is increased during hypoxemia. As a consequence, ischemic or hypoxic damage is more likely to occur **Figure 11-29**. Mechanically injured neurons are more susceptible to the effects of hypoxemia and cerebral hypoperfusion and are vulnerable to damage by the high concentrations of neurotransmitters (eg, glutamate and aspartate) and toxic metabolites that accumulate in the extracellular environment in the wake of TBI.

TABLE 11-23 Causes of Secondary Insult to the Brain

Systemic Origin	Intracranial Origin
Hypoxia	Hematoma
Hypercarbia	Swelling, vasospasm
Arterial hypotension	Raised ICP
Severe hypocarbia	Infection
Fever	Epilepsy
Hyponatremia	Hydrocephalus
Anemia	

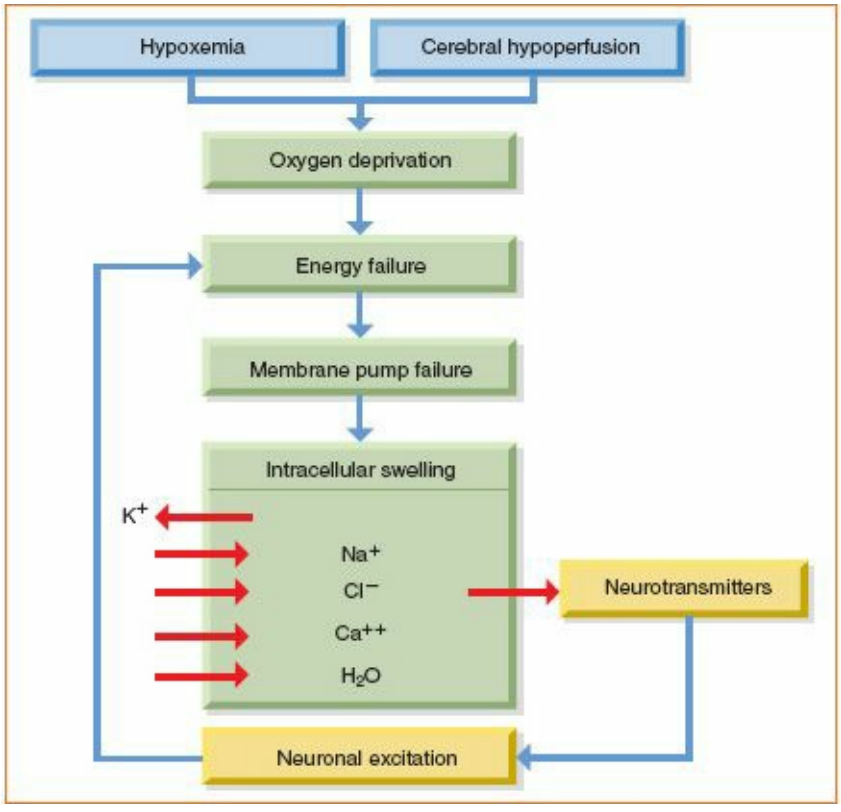

Figure 11-29 Pathophysiology of secondary brain injury. *Adapted from* McCance K, Huether S. *Pathophysiology—The Biological Basis for Disease in Adults and Children*. St Louis, MO: Mosby; 2002.

Neuronal swelling, edema, and cerebral hyperemia from carbon dioxide retention combine to raise the ICP and lower the **cerebral perfusion pressure (CPP)**. This relationship can be expressed mathematically as **mean arterial pressure (MAP)** minus ICP equals CPP:

$$MAP - ICP = CPP$$

where:

$$MAP = DBP + \frac{1}{3}(SBP - DBP)$$

Let's say a patient has a blood pressure of 190/100 mm Hg. The calculation of MAP would be:

$$\begin{aligned} MAP &= 100 + \tfrac{1}{3}(190 - 100) \\ &= 100 + \tfrac{1}{3}(90) \\ &= 100 + 30 \\ &= 130 \end{aligned}$$

CPP is the primary determinant of blood flow to injured brain tissue when the injury has impaired the ability of the cerebral circulation to autoregulate in response to fluctuations in systemic blood pressure **Figure 11-30**. The situation is exacerbated if the ICP is further raised by the presence of a space-occupying lesion or by swelling, or if the CPP is further reduced by extracranial blood loss. The resulting positive feedback loop rapidly causes irreversible clinical deterioration if cerebral perfusion and oxygenation are not quickly improved. Current guidelines identify the ideal CPP to be somewhere between 50 and 70 mm Hg.

Specific Injuries

Scalp Injuries

Injury to the scalp is oftentimes the first indication that a patient has a brain injury. The forces involved in the primary injury determine the type and extent of scalp injury that may be visible. Common injuries to the scalp include abrasions, contusions, lacerations, and avulsions. Like facial injuries, scalp injuries tend to bleed profusely owing to their highly vascular nature.

Abrasions involve the top layer of the scalp, which may be rubbed away, as evidenced by minor bleeding. Treatment usually focuses on controlling bleeding and cleaning and dressing the area. It is important to remember that some of these scalp injuries can occur simultaneously secondary to the mechanism of injury.

When examining an abrasion, the CCTP may also note an underlying contusion. Contusions are scalp bruises with possible accumulation of blood in the subcutaneous layer. Definitive control of bleeding is often best achieved by stapling or suturing significant scalp lacerations. It is also important to rule out more significant (deeper) injuries.

Lacerations can be more serious. In these injuries, the scalp is violently torn, leaving a jagged opening that may extend through multiple layers of tissue and even down to the skull itself. Bleeding may be profuse, and deeper injury to the brain tissue or skull is very likely.

Avulsions occur as a result of forceful, partial, or complete tearing away or separation of the scalp tissue, which appears as a flap. The primary concerns with this type of injury are the underlying integrity of the skull and infection as a result of contaminants. Treatment should focus on evaluation of the skull for fractures and a thorough cleaning of the tissue under the avulsion.

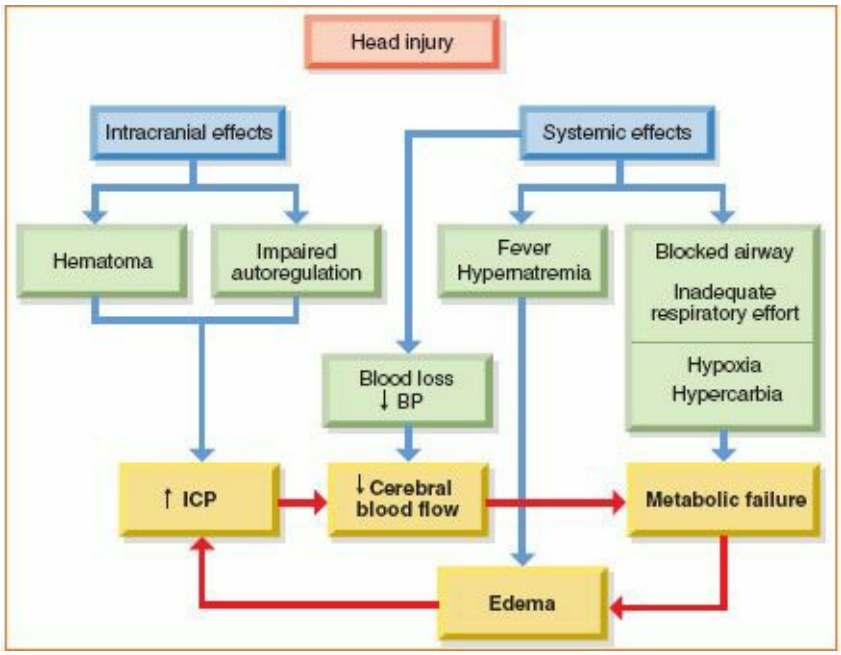

Figure 11-30 Cerebral perfusion pressure as the primary determinant to blood flow to injured brain tissue. *Adapted from* McCance K, Huether S. *Pathophysiology—The Biological Basis for Disease in Adults and Children*. St Louis, MO: Mosby; 2002.

Skull Fractures

Skull fractures occur as a result of a direct, and often highforce, blow to the cranium; they are present in more than 50% of patients with a severe TBI. Any of the bones that make up the skull—the frontal, parietal, temporal, occipital, sphenoid, and ethmoid bones—may be fractured. Between the skull and dura, there are large blood vessels that can be damaged and, if the impact is severe enough, can result in hemorrhaging within the brain.

Although not a part of the cranium, the bones of the face—the maxillary, zygomatic, nasal, lacrimal, and palatine bones; vomer; mandible; and part of the ethmoid and sphenoid bones—may also be fractured. Such fractures may indicate possible underlying brain injury.

Skull fractures are classified into linear, depressed, comminuted, and basilar types.

Linear skull fractures are characterized by a single fracture line and are often an incidental finding on CT. This fracture occurs when two or more bones of the skull separate at the suture line. Hematomas, soft-tissue swelling, and point tenderness are usually present over the site of impact **Figure 11-31A**. A simple closed linear fracture usually does not require any surgical intervention. It is also important to understand stellate fractures. A **linear stellate fracture** is a fracture with multiple linear fractures radiating from the site of impact. These fractures have the potential to do damage depending on the number and depth of the fracture(s). **Diastatic stellate fractures** are described as separation of an epiphysis relating to a center site of impact. Diastatic stellate fractures are prevalent in abused children. The presence of a diastatic fracture to a long bone in a child may arouse suspicion of possible head trauma or shaken baby syndrome.

When a portion of the skull is depressed, and the scalp and/or dura may or may not be torn, the injury is referred to as a **depressed skull fracture** **Figure 11-31B**. This type of fracture may have soft-tissue swelling over the site of the trauma and a bony step-off may be palpated. Depressed skull fractures may be classified as open or closed, with these terms indicating whether there has or has not been a breach in the dura mater in conjunction with the fracture, respectively. An open depressed skull fracture **Figure 11-31C** is the more serious of the two.

Three types of depressed skull fractures are distinguished: true, flat, and ping-pong ball fracture. The

true fracture is the most common, having contact with the cranial vault. The **flat fracture** features a depressed segment without any connection with the cranial vault and is the least common type. The **ping-pong ball fracture** is a pediatric greenstick fracture of the skull. Although these distinctions may be of importance in the hospital setting, during the prehospital phase of the transport, it is most important to identify the existence of a depressed skull fracture, to classify it as open or closed, and to treat it appropriately.

A fracture that occurs when the skull is splintered or shattered into many pieces is referred to as a **comminuted fracture**. These pieces may then act as projectiles and cause direct injury to the meningeal layers or the brain tissue itself. A great deal of blunt force is required to cause this type of skull fracture.

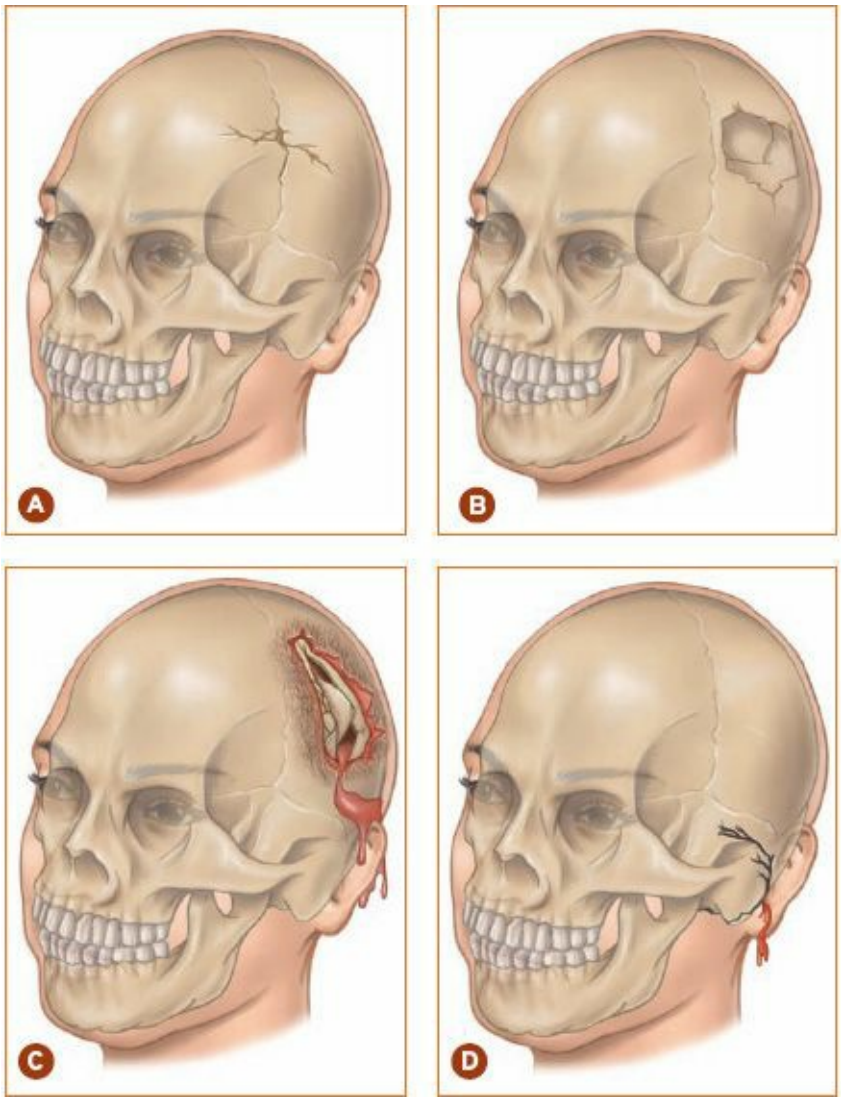

Figure 11-31 Types of skull fracture. **A.** Linear. **B.** Depressed. **C.** Open. **D.** Basilar.

Basilar skull fractures involve fractures along the base of the skull **Figure 11-31D**. This area is permeated with multiple foramina that accommodate the spinal cord, nerves, and blood vessels. Because of the many hollow or open spaces within the skull (eg, the sinuses, eye orbits, nasal cavities, external auditory canals, and middle and inner ears), the skull is weakened here and prone to basal fractures. Basilar fractures usually result from a blow to the parietal, temporal, or occipital regions of the skull, of which the temporal area is the most commonly affected.

Tearing of the dura mater during a basilar skull fracture may also occur, resulting in a wound between the brain and the external environment. This condition may present with leakage of CSF, which may be combined with blood through the dural tear either into the nasal cavity or via the external auditory

canal **Figure 11-32**. Openings in the dura mater also provide a conduit for infection to enter the meninges or brain tissue. The **halo test** for leaking CSF is accomplished by collecting escaping fluid from the nose, mouth, or ears, onto a gauze pad. The appearance of a "target" or "halo" symbol consisting of a dark red circle surrounded by a lighter yellowish one is considered a positive halo sign **Figure 11-33**. The CCTP must exercise caution when using the halo test as the sole diagnostic evaluation of a CSF leak, because other fluids such as lacrimal fluid, nasal fluid, or saliva may cause a similar response.

Other clinical signs may be evident based on the location of the injury. Fractures involving the auditory canal and lower lateral areas of the skull may result in the migration of blood to the mastoid region, posterior and slightly inferior to the ear, resulting in discoloration referred to as retroauricular ecchymosis or **Battle's sign** **Figure 11-34**. Likewise, orbital fractures and hemorrhaging into the surrounding tissue is known as periorbital ecchymosis or **raccoon eyes** **Figure 11-35**. The development of raccoon eyes and Battle's sign may take several hours to develop post-injury and is rarely seen by the CCTP during transport and/or initial treatment of the patient.

Facial Fractures

As many as 60% of patients with significant facial injuries sustain trauma to other organ systems, including the brain. Unfortunately, many facial injuries have very grotesque presentations accompanied by copious bleeding and may potentially distract the CCTP from other, more serious injuries. Fractures of the facial bones are usually very painful and require massive amounts of analgesia to maintain patient comfort. This is especially true with mandible fractures, which can cause life-threatening airway compromise if the patient is in the supine position. Because of the instability of the mandible, the tongue no longer has support and can become lodged in the back of the airway, causing an obstruction.

Figure 11-32 Blood leaking from the external auditory canal after a head injury may contain cerebrospinal fluid and suggests a basilar skull fracture.

Figure 11-33 Halo sign.

Figure 11-34 Battle's sign or ecchymosis behind the ear or over the mastoid process.

Figure 11-35 Raccoon eyes or ecchymosis under or around the eyes.

Airway control is the first assessment priority with facial injuries. After the airway has been secured, the CCTP can assess for the presence of facial fractures by grasping the hard palate and rocking it back and forth. The CCTP should also check for malocclusion and dental trauma, test extraocular muscles to rule out orbital fractures, and look for facial elongation (monkey face) and periorbital ecchymosis.

Some of the most serious facial injuries are maxillary fractures, which are classified using the **Le Fort criteria**, and result from high-energy forces to the face **Figure 11-36**.

- **Le Fort I** is a transverse fracture separating the hard palate from its bony frame. This fracture exhibits slight instability to the maxilla with no associated displacement.
- **Le Fort II** is a fracture involving the central maxilla and palate, and is a pyramidal fracture (the fractured portion is shaped like a pyramid). This fracture extends through both maxilla and the nasal bones.
- **Le Fort III** is effectively a craniofacial disruption, with fractures extending from the frontozygomatic sutures, orbits, and nasoethmoidal regions. This fracture is unstable and is associated with oral and nasal patency problems. It can leave the patient with a monkey face appearance as a result of the protrusion of the face secondary to its instability.

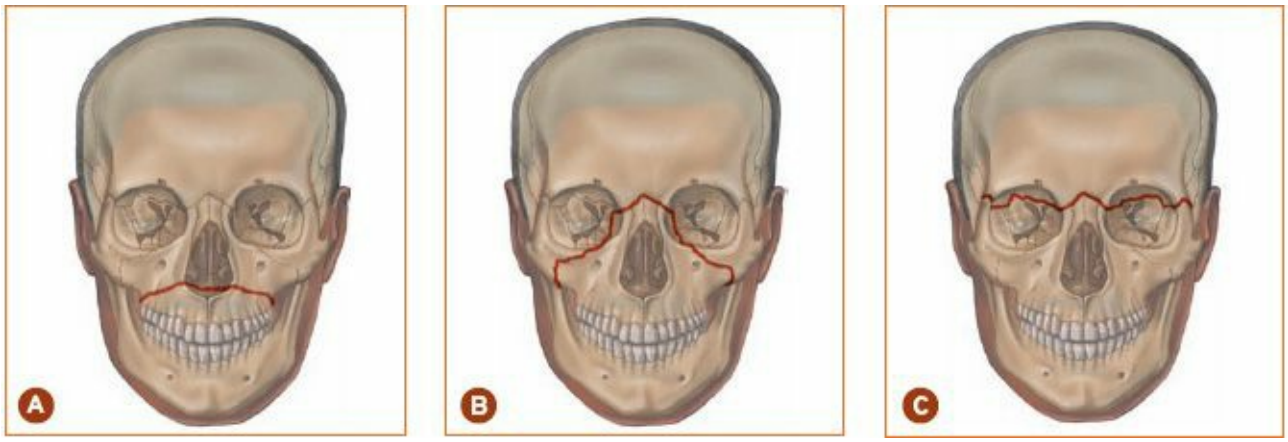

Figure 11-36 Le Fort fractures. **A.** Le Fort I. **B.** Le Fort II. **C.** Le Fort III.

- **Le Fort IV** is essentially a Le Fort III fracture with a concurrent frontal bone fracture.

Le Fort II and III fractures usually result in leakage of the CSF.

Brain Injuries

Injuries to the brain can be either focal or diffuse. Focal lesions are those large enough to be observed directly. Diffuse injuries are not associated with gross localized and visible lesions and include concussions and diffuse axonal injuries **Table 11-24**.

Focal Injuries

A cerebral contusion is a bruising of the brain tissue. The patient with isolated cerebral contusions may exhibit altered mental status, but rarely coma. Contusions commonly occur with rapid deceleration injuries and typically appear on the tips of the frontal and temporal lobes, where the skull base has an irregular shape. Contusions appearing on the same side of the impact are known as coup injuries, whereas injuries on the side opposite the impact are known as contrecoup injuries. Treatment for patients with cerebral contusions is largely supportive because no surgical intervention is usually needed. The patient should be monitored for evidence of rising ICP as a result of hematoma or edema formation; if either of these conditions occurs, it would be treated aggressively.

Lacerations that result in penetration of the cranium may cause tearing of the cortical surface of the brain. A major difference between a contusion and a laceration is that the pia mater–arachnoid mater is torn over a laceration and intact over a contusion. Treatment for cerebral lacerations is identical to that for cerebral contusions, with the CCTP monitoring for signs of rising ICP.

TABLE 11-24 Brain Injury Types

Focal	Diffuse
Contusion Hematoma Epidural Subdural	Axonal injury
Intracerebral	Hypoxia/ischemia
Swelling	Diffuse vascular
Infarct	Fat embolism

Pressure necrosis	Subarachnoid
Abscess	Meningitis

An injury resulting in the accumulation of blood between the inner periosteum and the dura mater is known as an **epidural hematoma (EDH**; also called extradural hematoma). Most EDHs are arterial in origin, occurring as a result of a blow to the temporal region and concomitant disruption of the middle meningeal artery. Blood may accumulate quickly in the potential space as a result of the high arterial pressure gradually stripping away the dura from the inner table of the skull, forming an oval-shaped mass that exerts pressure on the underlying brain tissue **Figure 11-37**. An EDH can be caused by venous bleeding but is limited by the space between the dura and the skull. As the hematoma enlarges, however, the temporal lobe may be displaced and may squeeze over the tentorium.

Special Populations

Indirect and hemorrhagic brain injuries are much more common in the elderly population. This is the result of atrophy of the brain experienced with aging, allowing these patients to tolerate more swelling before herniation occurs and making it easier to tear the bridging veins.

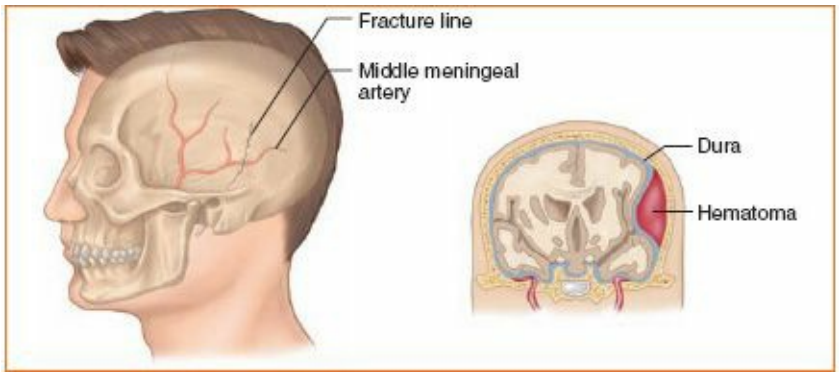

Figure 11-37 An epidural hematoma, resulting from a blow to the temporal region of the head and concomitant disruption of the middle meningeal artery, with the accumulation of blood between the inner periosteum and the dura mater.

The patient with an EDH may present with a history of a brief period of unconsciousness, followed by a lucid period lasting for minutes to several hours. The lucid period ends with a rapid deterioration of consciousness from drowsiness, to lethargy, and to coma as a mass effect and herniation develop. If tentorial herniation (herniation of the tentorium of the cerebellum) occurs, the third cranial nerve may become compressed, causing an ipsilateral fixed and dilated pupil **Figure 11-38**. Tentorial herniation may also occur on the opposite side, causing either contralateral or bilateral blown pupils (Kernochan's notch syndrome). As ICP continues to rise, the patient may develop bradycardia, Cheyne-Stokes respiratory patterns that progress to brain stem patterns, and brain distortion. Other clinical manifestations may include headache, seizures, hemiparesis or hemiplegia, decorticate or decerebrate posturing **Figure 11-39**, respiratory distress, and death. The most common presentation includes vomiting, seizures, unilateral hyperreflexia with a positive Babinski's sign, and elevated CSF pressure.

Signs and Symptoms

Epidural Hematoma

- Brief period of unconsciousness, followed by a lucid period lasting for minutes to several hours
- Following the lucid period, rapid deterioration of consciousness (drowsiness to lethargy to coma)
- Ipsilateral fixed and dilated pupil
- Contralateral or bilateral blown pupils (Kernochan's notch syndrome)
- Headache
- Bradycardia
- Cheyne-Stokes respiratory pattern, progressing to brain stem breathing patterns
- Possible seizures
- Hemiparesis
- Hemiplegia
- Decorticate or decerebrate posturing
- Respiratory distress
- Death
- Vomiting
- Seizures
- Unilateral hyperreflexia with a positive Babinski's sign
- Elevated CSF pressure
- Elevated ICP with brain distortion

Transport Management

Epidural Hematoma

- Provide rapid transport.
- Consider administering an osmotic diuretic (mannitol).

Figure 11-38 Ipsilateral fixed and dilated pupil.

Large hematomas produce a mass effect (ie, act as a space-occupying lesion) and increased ICP. If herniation occurs or will likely occur, the hematoma will be evacuated with a craniotomy. The torn vessel will also be repaired during the craniotomy.

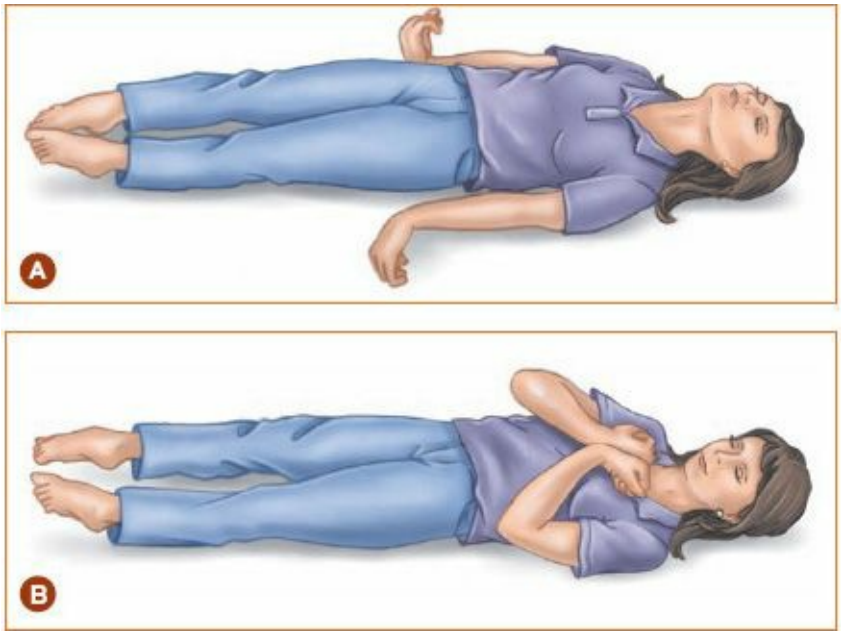

Figure 11-39 Posturing indicates significant intracranial pressure. **A.** Decerebrate (extensor) posturing. **B.** Decorticate (flexor) posturing. (Think of the arms being pulled to the "core" of the body.)

The bleeding can sometimes be so severe that, in some cases, the brain is actually displaced (midline shift) within the skull. Some medications, such as osmotic diuretics (mannitol), can be given in the early stages of midline shift, which will slow the progression until surgical intervention can be obtained.

Mannitol is an osmotic diuretic that is used to reduce increased ICP resulting from an increase in CSF. It is also used to reduce intraocular pressure. In the case of brain hemorrhage, increases in CSF result from inflammation to brain tissue from blood or damage to the subarachnoid villa, which impedes reabsorption of CSF. Mannitol is also useful for patients with cerebral edema not related to a brain bleed.

Mannitol has little effect in reducing the volume of blood accumulated by the hemorrhage. The dosage for adults and children older than 12 years is 1.5 to 2 g/kg in a 15%, 20%, or 25% IV solution given over 30 to 60 minutes via an infusion pump.

Brain stem herniation is a primary concern and occurs when the expanding blood pushes the brain down the foramen magnum, causing a shearing-type force on the brain. Once this takes place, death is imminent, because this condition is irreversible.

High-energy impacts may also result in bleeding that accumulates between the dura and arachnoid mater, known as a **subdural hematoma (SDH)**. Subdural hematomas are six times more common than EDHs and have a higher mortality rate. Most SDHs result from a disruption of the bridging veins located over the crest of the brain and their subsequent bleeding. SDHs are categorized based on the time that elapses between injury and the appearance of signs and symptoms as well as the appearance of blood and fluid composition **Figure 11-40**.

Acute SDH—that is, SDH in which signs and symptoms appear within 24 hours of the injury—is commonly seen with acceleration-deceleration injuries. With this type of injury, clotted blood may be seen on CT as crescent-shaped collections of blood with high attenuation usually along the cranium. Patients usually present with a gradual or sometimes rapid deterioration in level of consciousness, pupillary changes, and hemiparesis or hemiplegia.

In subacute SDH, signs and symptoms appear between 2 days and 2 weeks after injury because the blood accumulates more slowly. This type of hematoma consists of a mixture of clotted and fluid blood; on CT, it may appear as areas that are isodense, hypodense, or of mixed density depending on the age of the lesion **Figure 11-41**. Patients with subacute SDH present with gradual mental status and/or

personality changes as well as many of the symptoms for the acute hematoma that become observable as the lesion expands.

Signs and Symptoms

Subdural Hematoma

- Gradual or rapid deterioration in level of consciousness
- Pupillary changes
- Hemiparesis
- Hemiplegia
- Gradual personality changes
- Headache (progressing in severity)
- Slowed cerebral functioning
- Difficulty speaking
- Confusion
- Drowsiness
- Possible seizures

Transport Management

Subdural Hematoma

- Provide supportive care.

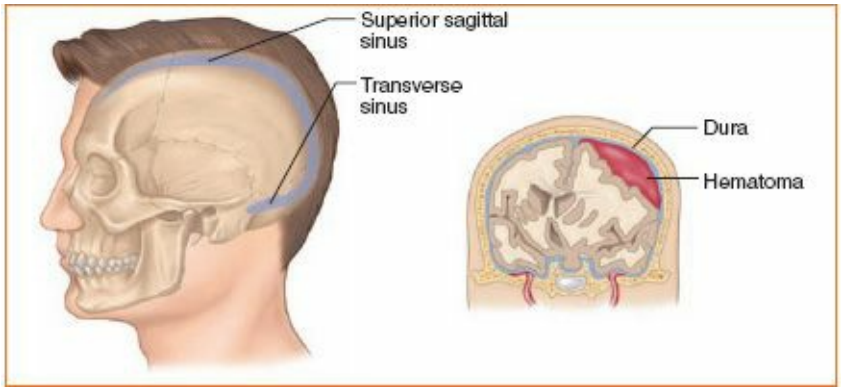

Figure 11-40 A subdural hematoma, in which venous bleeding occurs beneath the dura mater but outside the brain.

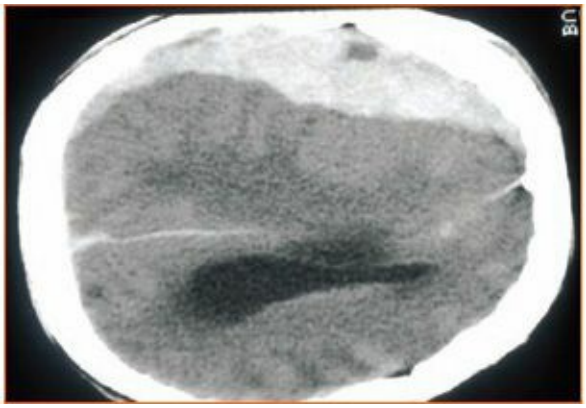

Figure 11-41 Computed tomographic scan of an isodense subdural hematoma.

Chronic SDH manifests as clinical signs and symptoms greater than 2 weeks after the injury. This type of hematoma is composed of fluid only. Because the lesion expands very slowly, the patient may experience headache (progressing in severity), slowed cerebral functioning, confusion, drowsiness, and possibly seizures.

Treatment of SDHs depends on the size of the hematoma and the patient's symptoms, and ranges from watchful waiting to surgical intervention. Small SDHs may be observed and allowed to reabsorb without surgery. All SDHs accompanied by signs and symptoms of increasing ICP require surgical intervention to evacuate the expanding mass and stop the bleeding.

Intracerebral hemorrhages result from direct bleeding into the brain parenchyma and can be observed in as many as 15% of patients with brain injuries **Figure 11-42**. Many of these hemorrhages occur in the same areas as cerebral contusions, making it appear that the rough internal areas of the cranium are oftentimes to blame for these injuries. Intracerebral hemorrhages act as space-occupying lesions, producing headaches, deteriorating levels of consciousness, hemiplegia on the contralateral side, and a dilated ipsilateral pupil.

Patients may also develop a **delayed traumatic intracranial hemorrhage (DTICH)** within the first 3 to 10 days following an injury to the occipital-parietal region via a coup-contrecoup mechanism. Serial CT scans should be performed within the first 72 hours after injury if DTICH is suspected, as part of the effort to decrease the mortality and morbidity that result from such bleeding.

The presentation of a patient with a **subarachnoid hemorrhage (SAH)** depends on the size of the hemorrhage and the coexisting injuries. With this type of injury, bleeding occurs between the arachnoid mater and the dura mater of the brain, resulting in the patient reporting the "worst headache in my life." Patients with SAH are also more likely to have hypoxia, hypotension, and higher ICP, all of which contribute to secondary brain injury. Signs and symptoms include altered mental status, coma, paralysis, slurred speech, mood changes, and seizures, and appear to be due to increased ICP and meningeal irritation.

Signs and Symptoms

Subarachnoid Hemorrhage

- Worst headache of patient's life
- Hypoxia
- Hypotension
- Increased ICP

- Altered mental status
- Coma
- Paralysis
- Slurred speech
- Mood changes
- Seizures

Transport Management

Subarachnoid Hemorrhage

- Provide supportive care, including intubation and mechanical ventilation for patients with an altered level of consciousness.
- Carefully monitor blood pressure, respiratory rate, and level of consciousness.
- Provide appropriate analgesia.
- Consider administering benzodiazepines to reduce stress.
- Insert an indwelling catheter to monitor fluid balance.
- Give an antiemetic to all awake patients.
- Consider administering calcium channel blockers for vasospasm.

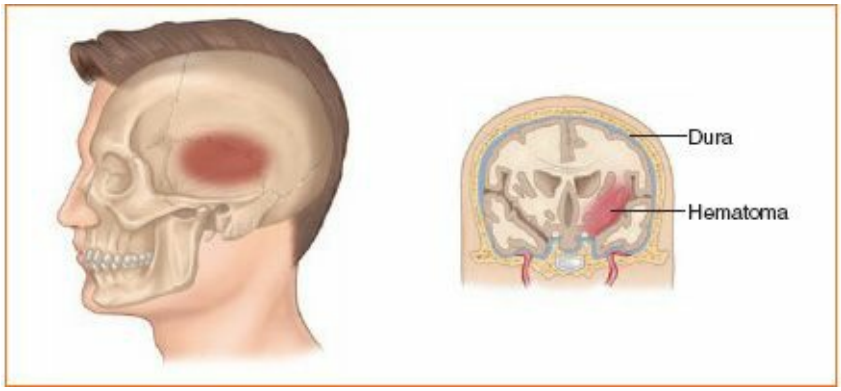

Figure 11-42 An intracerebral hemorrhage is a result of direct bleeding into the brain parenchyma.

Diffuse Injuries

Concussion, also known as **mild TBI**, is a traumatically induced physiologic disruption of brain function that occurs without structural damage. This injury is manifested by at least one of the following signs and symptoms:

- Any loss of consciousness
- Any loss of memory for events immediately before (retrograde) or events immediately after (anterograde) the event that precipitated the injury
- Any alteration in mental status at the time of the injury (eg, feeling dazed, disoriented, irritable, drowsy, giddy, or confused)
- Focal neurologic deficits in which the patient is not unconscious for longer than 30 minutes; after 30 minutes, the patient has a GCS score of 13 to 15

Deep areas of the brain may also be involved in a TBI; such injuries are referred to as **diffuse axonal injury (DAI)**. The mechanism for DAI is usually very rapid acceleration-deceleration forces. In these injuries, shearing forces damage the integrity of the axon at the node of Ranvier, which consequently alters the axoplasmic flow (the flow in the cytoplasm of the axon). Areas especially susceptible to this type of injury include the corpus callosum, the brain stem, and sometimes the cerebellum, because they contain a significant amount of white matter.

DAI accounts for about 50% of all primary brain injuries and 35% of TBI-related deaths. It is characterized by microscopic findings of wide and asymmetric axonal swelling that appear within hours of the injury and may be persistent for much longer, as well as focal hemorrhagic lesions. The resulting injury is graded based on pathologic findings:

- **DAI Grade 1:** histological evidence of axonal damage in the white matter of the cerebral hemispheres, corpus callosum, brain stem, and, less commonly, cerebellum.
- **DAI Grade 2:** in addition to evidence of axonal injury, lesions in the corpus callosum.
- **DAI Grade 3:** in addition to the findings seen in grades 1 and 2, lesions in the dorsolateral quadrant of the rostral brain stem.

The clinical presentation of DAI includes a sequence of events beginning with immediate unconsciousness, leading to a longer period of confusion and associated posttraumatic amnesia, and followed by a protracted recovery time. DAI can be clinically classified as mild, moderate, or severe based on the patient's signs and symptoms.

- **Mild DAI:** coma lasts from 6 to 24 hours, with the patient beginning to obey commands by 24 hours. Death is rare with mild DAI, but cognitive and neurologic deficits are common.
- **Moderate DAI:** coma lasts longer than 24 hours, but prominent brain stem signs are absent. Patients who survive usually have an incomplete recovery.
- **Severe DAI:** coma is protracted and associated with prominent brain stem signs (eg, decortication, decerebration, and an abnormal respiratory pattern). Patients usually die or experience severe disability.

Treatment for all types of DAI is supportive.

Signs and Symptoms

Diffuse Axonal Injury

- Sequence of events
  - Immediate unconsciousness
  - Longer period of confusion and post-traumatic amnesia
  - Protracted recovery time
- Mild DAI
  - Coma lasts from 6 to 24 hours with the patient beginning to obey commands by 24 hours
- Moderate DAI
  - Coma lasts longer than 24 hours, but prominent brain stem signs are absent
- Severe DAI
  - Coma is protracted and associated with prominent brain stem signs (decortication, decerebration, and abnormal respiratory pattern)

Transport Management

Diffuse Axonal Injury

- Provide supportive care.

Intracranial Pressure

Physiology

In adults, the normal ICP is 0 to 15 mm Hg. ICP is not a static state, but rather may be influenced by multiple factors. The recording of ICP shows two forms of pressure fluctuations: a rise with cardiac systole owing to distention of the intracranial arteriolar tree that follows and a slower change in pressure with respiration, with ICP falling with each inspiration and rising with each expiration. Straining and compression of the neck veins can also cause a sudden, considerable rise in pressure.

The **Monro-Kellie doctrine** describes the cranium as a rigid box that is filled with a nearly incompressible brain and whose total volume tends to remain constant. This doctrine assumes that the cranium volume includes three compartments: (1) brain and medulla spinalis with meninges, (2) CSF blood vessels with blood, and (3) CSF space. Expansion of any of these three volumes does so at the expense of the other two elements; such an event may be precipitated by intracranial bleeding, cerebral edema, mass formation, or inability to regulate the production and removal of CSF.

CSF is constantly secreted. After circulating, it is absorbed at a rate equal to the rate at which it is produced. CSF circulation is a slow process, with only 500 to 700 mL being circulated each day. At any given time, the cranium contains 75 mL of CSF. Excesses of CSF can be displaced through the foramen magnum into the spinal theca, a sac between C1 and C2. This may help in cases of cribriform plate damage if the channel for drainage becomes blocked. The spinal dural sheath can accept a quantity of CSF because it does not adhere to the canal closely and it is surrounded by a layer of loose areola tissue and a plexus of epidural veins. In addition, during periods of increased ICP, blood through venous emissaries increases.

Intracranial circulation of blood is approximately 1,000 L/d, delivered at a pressure of 100 mm Hg. At any given time, the cranium contains 750 mL of blood. Obstruction to venous outflow leads to an increase in the volume of intracranial blood, resulting in increased ICP. As the ICP increases, the cerebral venous pressure increases in parallel so that it remains 2 to 5 mm higher than the ICP, a differential that prevents the collapse of the venous system.

Increases in ICP can result from changes in CSF, edema, expansible masses, and changes in vessel size. The ability of the skull contents to compensate for the increased pressure depends on the location and rate of expansion of the lesion and the **brain tissue compliance** or volume-buffering capacity of the system. (Brain tissue compliance is defined as the change in brain volume resulting from a change in pressure.)

Cerebral Blood Flow

The brain accounts for only 2% of total body weight, yet its blood flow represents 15% of resting cardiac output and it uses 20% of the total amount of oxygen consumed by the body. Every 24 hours, the brain requires 1,000 L of blood in addition to its normal diet of 71 L of oxygen and 100 g of glucose. The **cerebral blood flow (CBF)** remains constant over a wide range of arterial pressures between 60 mm Hg and 150 mm Hg; with a rise above 150 mm Hg, however, blood flow increases. CBF ceases when MAP drops to 20 mm Hg, except in the chronically hypertensive patient, in whom this autoregulation limit

appears to be reset. The exact nature of this autoregulation is not known; we know only that many factors, including direct reaction of the cerebral arterial smooth muscles to stretching, various by-products of metabolism, and direct control by nerves surrounding vessels, seem to have a role.

With a normal cerebrovascular system and blood pressure, even moderate alterations of P_{CO_2} are capable of markedly altering CBF. Within the range of 30 to 60 mm Hg, there is a 2.5% change in CBF as the P_{CO_2} changes by 1 mm Hg. With a pressure of less than 20 mm Hg or more than 80 mm Hg, there is no further change. As the body ages and with the development of arteriosclerosis, there is a marked decrease in P_{CO_2} influence.

The effect of P_{O_2} changes is not as obvious as with changes involving carbon dioxide (CO_2). Moderate variation of oxygen above or below the normal level does not affect CBF. The presence of P_{O_2} causes vasoconstriction of a nonischemic brain along with a reduction in CBF. Alternatively, in the ischemic area of the brain, increasing the P_{O_2} has no effect. Cerebral vasodilation begins with a P_{O_2} of 50 mm Hg, resulting in increasing CBF. By the time the P_{O_2} falls to 30 mm Hg, CBF may have already tripled.

ICP influences the CBF through the CPP, which is the difference between MAP and ICP. An increase in ICP leads to a fall in the CPP. Every effort should be made to maintain the CPP at 50 mm Hg or more during treatment of increased ICP **Figure 11-43**.

For the CCTP, the following key points related to CBF are crucial:

- A number of physiologic factors may affect or change CBF. Increases in CBF as a result of hypoxia or hypercapnia (increased levels of CO_2 in blood), for example, will cause an increase in ICP once the normal compensating mechanisms have been exhausted.
- Poor airway and ventilatory control contributes to hypoxia, hypercapnia, and hypotension, and will further damage the already critically ill brain.

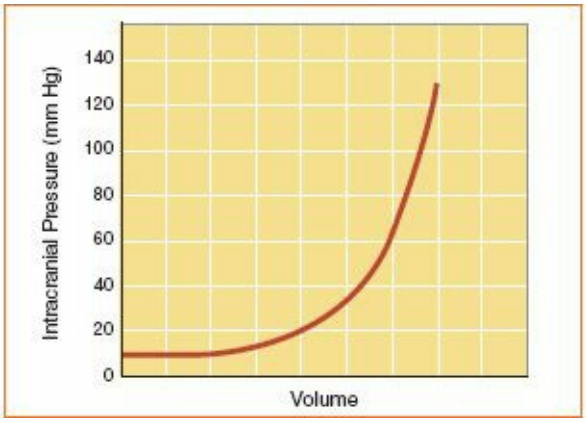

Figure 11-43 An intracranial pressure curve.

Cerebral Perfusion Pressure

CPP is responsible for the movement of blood through the brain and is the result of the difference between MAP and ICP (CPP = MAP – ICP). This relationship represents the pressure gradient driving CBF, and hence oxygen and metabolite delivery. The uninjured brain is capable of autoregulating its blood flow to provide a consistent flow of blood, regardless of blood pressure, by altering the resistance of cerebral blood vessels.

These homeostatic mechanisms are often lost after head trauma. As a consequence, a patient with TBI may have increased cerebral vascular resistance, making the brain more susceptible to changes in blood pressure. Those areas of the brain that are ischemic or at risk for ischemia are critically dependent

on an adequate CBF and, therefore, CPP.

For the CCTP, the following key points related to CPP are crucial:

- Maintenance of CPP reduces mortality in severe head injury.
- CPP should be maintained between 50 and 70 mm Hg to reduce the risk of poor outcomes for patients with increased ICP.
- Systemic hypotension (systolic blood pressure, <90 mm Hg) is associated with a poor prognosis.
- Maintenance of an adequate CPP is the cornerstone of modern brain injury therapy.

After brain injury, and especially in the patient who has suffered multisystem trauma, CBF may be dangerously low, bordering on ischemia. To prevent further neuronal death (secondary brain injury), the flow of well-oxygenated blood must be restored as soon as possible. The optimal level of CPP has not yet been determined, but the CPP target lies within the range of 50 to 70 mm Hg. When CPP is maintained above 70 mm Hg, with fluids and pressors, there is a significantly increased risk of adult respiratory distress syndrome (ARDS).

CPP may be maintained by raising MAP or lowering ICP. In practice, ICP is usually controlled to within normal limits (< 20 mm Hg), and MAP is raised therapeutically to a level of greater than 90 mm Hg. Although it is unknown whether ICP control is necessary, given that outcomes from severe TBI related to ICP seem to lie more in its role in determining CPP, it is clear that ICP plays a role in herniation. Current data therefore support initiating treatment when ICP exceeds 20 mm Hg.

Substantial evidence indicates that early hypotension (systolic blood pressure of less than 90 mm Hg) is associated with increased morbidity and mortality following severe brain injury. Even patients with one episode of hypotension during their intensive care unit (ICU) stay have a significantly poorer prognosis. To ensure that patients remain normovolemic, the CCTP must be vigilant in controlling other sites of hemorrhage while providing adequate oxygenation.

Many patients with TBI, because of the extent of their injuries, will require intensive neurologic monitoring. As previously discussed, CCTPs should perform serial neurologic examinations, especially for patients with TBI. CCTPs may also be required to maintain invasive neurologic monitoring devices. Each device must be maintained in accordance with the manufacturer's requirements, and it is the responsibility of each CCTP to become familiar with all aspects of each device prior to using it on a patient. Because of the often subtle, yet devastating, effects created by rising ICP, invasive monitoring can be a valuable tool that gives a more detailed picture of the patient's overall neurologic condition.

Pathophysiology of Increased Intracranial Pressure

The brain is encapsulated within the skull and surrounded by CSF that is generated in the choroid plexus and reassimilated by the subarachnoid villa to balance ICP between 5 and 15 cm H_2O. Because the skull is essentially an immovable structure, any change causing an additional change in volume will create an increase in ICP. The most common causes of increased ICP are cerebral hemorrhage, tumors, hydrocephalis, and trauma.

CSF volume variations result from many causes, including overproduction of CSF, decreased absorption of CSF, and obstructions in cerebral circulation. All of these conditions lead to an increased volume of CSF within the cranial vault and thus increased pressure on brain tissue.

Brain tissue is the most difficult component within the cranial vault to manipulate without surgical intervention. The parenchyma can respond to increases in ICP, changes in CSF and/or blood volumes, and changes in vessel size (which affect the volumes carried). Minimal volume changes incite the tissue to react by partial collapse of the cisterns, ventricles, and vascular system, which leads to decreased production and increased absorption of CSF.

Increased ICP is defined as a sustained elevation in pressure above 20 cm H_2O. During compensation, the ICP rises and plateaus, at which time the increased level of CSF absorption keeps pace with the increase in volume. Intermittent expansion causes only a transient rise in ICP at first. When a sufficient amount of CSF has been absorbed to accommodate the volume, ICP returns to normal. Once compensatory mechanisms are no longer effective, however, pressure increases rapidly, followed by shifting of the brain tissue toward open spaces in the skull. This shift, which results in decreased blood flow to the medulla, is accompanied by dilation of small arteries in the pia mater and some slowing of venous flow, followed by pulsatile venous flow.

The following compensatory mechanisms help maintain ICP:

- Shunting of CSF into the spinal subarachnoid space
- Increased CSF absorption
- Decreased CSF production
- Shunting of venous blood out of the skull

When ICP rises to the level of the arterial pressure, a cascade of events known as Cushing's triad begins. Cushing's triad is the combination of progressively increasing systolic blood pressure, with a progressively decreasing diastolic blood pressure (widening pulse pressure) and bradycardia. It is a sign of increased ICP, which occurs as the result of Cushing's reflex. Vasoconstriction occurs as the body attempts to shift fluid volumes in the cranium, thereby reducing ICP. If ICP continues to rise, brain displacement accelerates, putting pressure on the medulla oblongata by pushing it into the foramen magnum, resulting in disturbances in breathing, heart rate, and blood pressure. The three effects that result from this process—hypertension, bradycardia, and respiratory irregularities—are collectively Cushing's triad. Cushing's triad is a late sign and often indicates that severe and even irreversible injury has taken place within the cranial cavity. Identification is important because it suggests severe ischemia in the brain. Possible causes are cerebral hemorrhage, a brain tumor, or brain herniation, which can be fatal.

Special Populations

Children are much more sensitive to fluid shifts than adults. Be very careful when administering fluid to children.

The rise in ICP to the level of systemic arterial pressure extinguishes cerebral circulation. This situation will be reversed only if arterial pressure rises sufficiently higher than ICP, which restores CBF. If this effort fails, brain death occurs.

The cause of a rise in ICP and the rate at which it occurs are also important. Many patients with benign **intracranial temperature (ICT)** or obstructive hydrocephalus show few or no ill effects despite their increased ICP, because the brain itself is normal and autoregulation is intact. Conversely, cerebral blood flow may be compromised even when ICP is relatively low if parenchymal lesions—such as tumors, hematomas, and contusions—cause the brain to shift and disrupt autoregulation. In acute hydrocephalus, there is rapid deterioration because there is no time for compensation.

Signs and Symptoms

Increased Intracranial Pressure

- Cushing's triad (widening pulse pressure, bradycardia, and abnormal respiratory patterns)
- Hypertension (increased blood pressure)
- Increased respiratory rate
- Pulmonary edema

Transport Management

Increased Intracranial Pressure

- Intubate and mechanically ventilate the patient. Do not hyperventilate the patient unless he or she acutely deteriorates.
- Consider administering an osmotic diuretic (mannitol).
- Consider administering dexamethasone or methylprednisolone sodium succinate to control inflammation and swelling.
- Control blood pressure to maintain systolic pressures at less than 150 mm Hg.
- If a surgical drain (bolt) has been installed, drain the CSF if the ICP is greater than 20 cm H_2O.
- For patients who have sustained a hemorrhage and who have been taking warfarin (Coumadin) (patients with atrial fibrillation), administer either platelets or whole blood en route. These patients may also require a paralytic agent.

Disruption of brain function secondary to ICP may include the following conditions:

- Reduction in CBF.
- Transtentorial or foramen magnum herniation resulting in selective compression and ischemia of the brain stem.
- Transtentorial herniation with brain stem compression that leads to clinical deterioration even with adequate CBF. A temporal mass may cause uncal herniation without raised ICP. Similarly, a frontal mass can cause axial distortion and impair brain stem perfusion.

Clinical Manifestations of Increased ICP

The clinical features of increased ICP are a result of Cushing's triad and are indicated by arterial hypertension, bradycardia, and respiratory changes. It has traditionally been thought that the hypertension and bradycardia result from ischemia or pressure on the brain stem. Some have suggested, however, that cerebral ischemia might lead to removal of supratentorial inhibition of brain stem vasopressor centers and that bradycardia occurs independently of the rise in blood pressure.

Respiratory changes depend on the level of brain stem involved. Midbrain involvement results in Cheyne-Stokes respiration. When the midbrain and pons are involved, there is sustained hyperventilation. With upper medulla involvement, rapid and shallow respirations are followed by ataxic breathing in the final stages.

Increased ICP also has pulmonary effects. Pulmonary edema seems to be due to increased sympathetic activity as a result of the effects of raised ICP on the hypothalamus, medulla, or cervical spinal cord. This is a direct result of the disruption of the pulmonary capillary integrity and increased left arterial pressures.

Brain Herniation

Brain herniation is a condition in which a portion of the brain is displaced because of increased ICP, resulting in progressive damage to brain tissue that may include life-threatening damage to the brain stem. This condition is commonly the result of brain swelling (cerebral edema) from a head injury, but it also may be the result of hemorrhagic stroke or space-occupying lesions, such as primary brain tumor, metastatic brain tumor, or other lesions within the brain. Brain herniation may also occur with bacterial meningitis.

The most common type of brain herniation occurs when a portion of the temporal lobe is displaced (**uncal herniation**), resulting in compression of cranial nerve III, the midbrain, and the posterior cerebral artery. Uncal herniation typically leads to coma and respiratory arrest.

Another critical type of brain herniation occurs when part of the cerebellum is displaced through the foramen magnum (tonsillar herniation). This compresses the brain stem, resulting in destruction of the respiratory center, apnea, decreased perfusion to the rest of the brain, and death. Because this herniation involves the brain stem and spinal cord, the patient will likely be in a coma, present with decerebrate or decorticate posturing, have ipsilateral pupil dilation, and have difficulty maintaining respirations, heart rate and rhythm, and blood pressure. These patients need immediate surgery to install a drain to remove blood and fluids to alleviate pressure. From a transport point of view, management includes the following:

Signs and Symptoms

Brain Herniation

- Tachycardia (inability to control heart rate and rhythm)
- Decreased blood pressure (inability to control blood pressure)
- Decreased respiratory rate (inability to control respirations—irregular breathing)
- Abnormal posturing (decorticate/decerebrate)
- A worsening (progressive) LOC (GCS score of 5 or less)
- Pupil changes (dilation of one or both pupils or failure of pupils to constrict with light)

Transport Management

Brain Herniation

- Intubate the patient and place him or her on a mechanical ventilator, hyperventilating to maintain CO_2 levels of 25 to 35 mm Hg.
- Administer mannitol or an equivalent osmotic diuretic.
- Consider administering corticosteroids such as dexamethasone, especially in the case of a brain tumor.
- Provide rapid transport to a neurosurgical facility.

1. Intubate the patient and place him or her on a mechanical ventilator. The patient should be hyperventilated to maintain CO_2 levels of 25 to 35 mm Hg.
2. Mannitol or an equivalent osmotic diuretic should be administered.
3. Corticosteroids such as dexamethasone should be considered, especially in the case of a brain

tumor.

4. Provide rapid transport to a neurosurgical facility.

Other areas of the brain may suffer herniation, although such injuries occur with less frequency than either uncal herniation or foramen magnum herniation.

ICP Monitoring

The primary goals of ICP monitoring are identification of ICP trends and evaluation of therapeutic interventions to minimize ischemia in the brain-injured patient. Intracranial hypertension (sustained ICP ≥ 15 mm Hg) results when the brain's protective mechanisms to shunt CSF to the subarachnoid space or to vasoconstrict cerebral arterioles fail to maintain the ICP below 15 mm Hg. Intracranial hypertension compromises the relationship between systemic blood pressure and the resistance that must be overcome to accomplish cerebral perfusion. When CPP falls below 50 mm Hg, secondary brain ischemia, herniation, and ultimately brain death occur. ICP monitoring allows for early detection of intracranial hypertension and subsequent aggressive management.

Indications for ICP Monitoring

The primary reason for ICP monitoring is a critical injury or illness involving components of the skull, specifically the brain. The following indications warrant ICP monitoring:

- Severe TBI (see previous criteria)
- Intracranial hemorrhage
- Cerebral edema
- Post-craniotomy
- Space-occupying lesions, such as epidural and subdural hematomas, tumors, abscesses, or aneurysms that occlude the CSF pathway
- Patients with Reye syndrome who develop coma, posturing, and abnormal responses to noxious stimuli
- Encephalopathy from lead ingestion, hypertensive crisis, or hepatic failure
- Meningitis/encephalitis resulting in malabsorption of CSF
- GCS score of less than 8 or a positive CT (there is evidence of a brain hemorrhage or evidence of a condition that will lead to a brain hemorrhage)

Contraindications for ICP Monitoring

The relative contraindications for ICP monitoring are as follows:

- CNS infection
- Coagulation defects
- Coagulopathy
- Scalp infection
- Severe midline shift resulting in ventricular displacement
- Cerebral edema resulting in ventricular collapse

ICP Monitoring Methods

ICP can be monitored using either noninvasive or invasive techniques. Noninvasive ICP monitoring simply involves assessment for clinical deterioration in neurologic status. Signs such as bradycardia, increased blood pressure, and pupillary dilation are reliable signs of rising ICP. Invasive methods,

however, provide a quantitative measure of pressure, and some allow for CSF drainage. Several invasive devices are available **Figure 11-44**, but the most commonly used are the intraventricular catheter and subarachnoid screw. ICP devices are placed in the hospital setting and never during transport. It is more common to transport a patient to a facility to have an ICP device inserted than to transport a patient with the device already in place.

Intraventricular monitoring remains one of the most popular techniques for monitoring ICP, especially in patients with ventriculomegaly (an enlarged ventricle of the brain). An additional advantage of this method is that it is both diagnostic and therapeutic, with the potential for draining CSF. Insertion of a ventricular catheter is not always a simple matter, however, because placement of such a device can cause hemorrhage and infection.

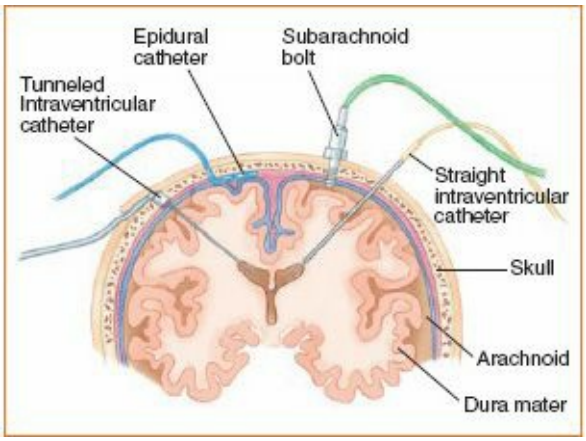

Figure 11-44 Invasive methods for intracranial pressure detection and cerebrospinal fluid drainage.

Advantages of an intraventricular cannula (IVC) are as follows:

- Allows for draining of CSF so as to lower ICP
- Allows CSF cultures to be obtained
- Provides increased accuracy in ICP monitoring
- Is accurate and reliable

Risks associated with use of an IVC include the following problems:

- Infection
- Injury to brain
- Clot formation
- Hemorrhage risk
- Collapsed ventricle
- Difficult or impossible placement

The epidural catheter lies beneath the skull, above the dura mater. It offers two advantages: a decreased rate of infection compared to the IVC and a lower risk that its placement will injure the brain. However, this device is also less accurate than the IVC, and it cannot be used to drain CSF.

The technique of inserting a ventricular catheter requires the insertion of a soft catheter through a burr hole into the lateral ventricle. The catheter allows for both monitoring of ICP and for therapeutic drainage of CSF to reduce ICP. Intraventricular catheters connect to a transducer set, which is never pressurized. Complications associated with the intraventricular catheter include infection and hemorrhage. The device must also be carefully leveled at the foramen of Monro (halfway between the

outer canthus of the eye and the tragus of the ear). Any fluid drained must be monitored for amount, color, and clarity at hourly intervals. Manipulation of the catheter by the CCTP should be avoided, and recalibration should be performed only if the CCTP has been given approval by medical direction and has been properly trained to operate the particular device in use.

The subarachnoid screw (or "bolt") is a device that also may be used to monitor ICP, although its accuracy is lower than the more direct ventriculostomy drain just described. Oftentimes a fiberoptic monitor is inserted through the bolt. Fiberoptic monitoring devices have a pressure sensor at the tip and do not require leveling or zeroing. The fiberoptic cable, however, is fragile and can break if twisted, stretched, or bent. An alternative to fiberoptic monitoring is to use a fluid-filled catheter connected to an arterial pressure monitoring system. Manipulation of the catheter by the CCTP should be avoided, and recalibration should be performed only if the CCTP has been given approval by medical direction and has been properly trained to operate the particular device in use.

The subdural bolt is inserted beneath the dura mater and above the pia mater. The subarachnoid bolt is placed beneath the arachnoid mater and above the pia mater.

Advantages of these devices include the following:

- Not as invasive as IVC or epidural catheter
- Lower rate of infection
- Less injury to the brain
- Easier to place

Disadvantages of these devices include the following:

- Less accurate monitoring
- Cannot drain CSF
- Risk of bleeding and brain injury
- Higher rate of infection than epidural catheter
- Requires closed, intact skull

A fiberoptic transducer-tipped probe is a catheter with a pressure-sensing device that is placed into the subdural space, brain parenchyma, or ventricle. This non–fluid-filled continuous intact system offers the advantages of a good waveform, reliable and accurate pressure readings, and lack of air bubble formation within the catheter. Disadvantages include the inability to access ICP unless an IVC setup is used and the inability to zero the unit once it is in place.

Additional commonly used devices are the hollow screw-and-bolt devices and the subdural catheter. The Richmond screw and Becker bolt are used extradurally. The Ladd device uses a fiberoptic system to detect distortions in ICP; it can be used in the subdura, on an extradural basis, and even extracutaneously.

Mechanically coupled surface monitoring devices include cardio search pneumatic sensors that are used subdurally or extradurally. Electronic devices (Camino and Galtesh design) are fully implantable systems and are valuable in the small group of patients who require long-term ICP monitoring for brain tumors, hydrocephalus, or other chronic brain diseases. A Cosmon ICP telesensor can be implanted as part of a shunt system. The Ommaya reservoir is an alternative that can be implanted for the purpose of administering medications, removing CSF, and obtaining CSF pressure readings. The Ommaya reservoir is placed directly in the spinal fluid; therefore, any medication given (such as chemotherapy agents) can be injected directly into the CSF. The same medications injected into the bloodstream are much less effective because they are blocked by the blood-brain barrier. This device is most commonly used to treat cancers of the brain and spinal column.

Alternatively, a fluid-filled catheter that is placed in the subdural space and connected to an arterial

pressure monitoring system is cost-effective and serves the purpose adequately. The ICP waveform obtained through this system resembles a dampened arterial blood pressure waveform and is considered normal when the pressure is between 0 and 15 mm Hg **Figure 11-45**. In addition, a stopcock within the system allows for therapeutic drainage of CSF and for sampling for infection surveillance.

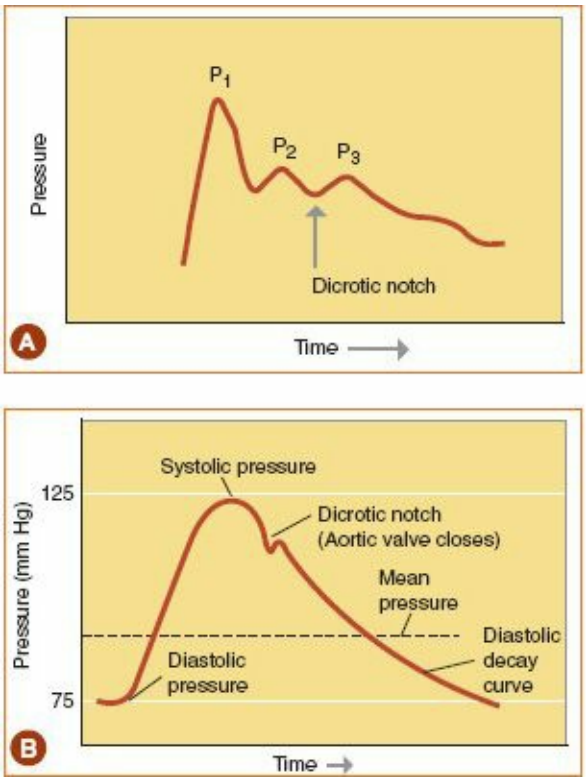

Figure 11-45 **A.** An intracranial pressure waveform. **B.** An arterial blood pressure waveform.

ICP monitoring undoubtedly helps in the management of conditions in which prolonged intracranial hypertension is expected. Indeed, monitoring is the only means by which providers can collect data that allow for selection of the most appropriate therapy and then accurately study the effectiveness of that therapy. ICP monitoring should be employed in all salvageable patients with severe TBI, a GCS score of less than 8 but greater than 3 after resuscitation, and an abnormal CT scan (hematomas, contusions, swelling, herniation, or compressed basal cisterns).

ICP monitoring is also indicated for patients with severe TBI with a normal CT scan if two or more of the following are noted at admission:

- Age over 40 years
- Unilateral or bilateral motor posturing
- Systolic blood pressure of less 90 mm Hg

Patients with severe TBI are intubated to protect the airway and allow maximal oxygenation. Standard monitoring for these patients is required, including oxygen saturation (SpO_2), electrocardiography (ECG), MAP, and urine output. Unless end-tidal CO_2 ($ETCO_2$) can be continuously monitored, these patients also require frequent determination of arterial blood gases, which can be achieved by placement of an intra-arterial catheter. Patients are maintained euvolemic (normal fluid volume status), and central venous pressure measurements are used to guide therapy. Central venous pressure measurement is covered in Chapter 16: Hemodynamic Monitoring.

Normocapnia (normal CO_2 tension) is vital for maintenance of ICP, and patients should have continuous measurement of $ETCO_2$ levels using a capnometer. These measurements represent the baseline

requirements for monitoring of patients with TBI. Patients receiving pressors to maintain MAP and/or CPP would benefit from an arterial line for continuous monitoring of drug effects.

Key points in monitoring ICP are as follows:

- The baseline requirements are SPO_2, ECG, MAP, $ETCO_2$, central venous pressure, and urine output.
- ICP and blood pressure monitoring are the only way to reliably determine CPP and assess cerebral hypoperfusion in patients with severe brain injury.
- Multimodality monitoring, including jugular venous oxygen saturation (SjO_2), brain tissue oxygen tension ($P_{br}O_2$), and TCD ultrasound, should be used when ICP and CPP cannot be maintained by standard methods.

The role of multimodal monitoring devices remains under investigation but approaches a long desired need in neurocritical care to obtain information about cerebral blood flow and metabolism in the brain. Treatment thresholds have been published for SjO_2 (< 50%) and for $P_{br}O_2$ (< 15 mm Hg), which, to date, are the only monitoring systems that have yielded sufficient outcome data in patients with TBI. A full discussion of these technologies is beyond the scope of this text.

As mentioned earlier in this section, CPP is maintained by supporting MAP and/or reducing ICP. ICP transducers should measure the pressure range of 0 to 100 mm Hg, with an accuracy of 2 mm Hg in the range of 0 to 20 mm Hg and at least 10% accuracy for the rest of the measurable range.

ICP monitoring is a complex task that requires knowledge and understanding of the technical components of fluid-filled monitoring systems, the pathophysiology of the CNS, and the interaction between these systems. Personnel performing the setup, data collection, or maintenance procedures should be appropriately trained and credentialed and should be competent in:

- The technical setup and operation of the pressure monitoring system
- CNS physiology and pathophysiology
- ICP waveform analysis
- Appropriate response to adverse reactions
- Application of universal precautions

Complications of ICP Monitoring

In general, complications related to ICP monitoring are rare. The greatest concern is ventriculitis (meningitis), although it has never been demonstrated in prospective studies of clinically significant intracranial infections following ICP measurement. Bacterial colonization does occur (5% ventricular/subarachnoid, and 15% parenchymal), however, and its incidence increases markedly after five consecutive days of monitoring. Irrigation of ICP devices to restore patency of the ventriculostomy catheter using either an isotonic sodium chloride solution or antibiotic solution significantly increases the risk of colonization. Definitive treatment is removal of the ICP bolt.

The risk of hematoma formation associated with ICP monitors varies. Parenchymal catheters have a higher incidence of hematoma than do other monitoring methods. Malfunction of the devices does occur, and readings of more than 50 mm Hg may be inaccurate with higher rates of obstruction and loss of signal.

Complications of ICP monitoring can be summarized as follows:

- Intracranial infection
- Intracerebral hemorrhage
- Air leakage into the ventricle or subarachnoid space
- CSF leakage

- Overdrainage of CSF, leading to ventricular collapse and herniation
- Occlusion of the catheter with brain tissue or blood
- Inappropriate therapy because of erroneous ICP readings owing to dampened waveforms, electromechanical failure, or operator error (ie, inappropriate leveling)

Benefits and Problems of ICP Monitoring

When clinical monitoring is not possible, such as during hyperventilation therapy and high-dose barbiturate therapy, ICP monitoring may prove helpful. Preoperative monitoring, for example, assists in assessment of **normal pressure hydrocephalus (NPH)** before a shunting procedure takes place. ICP monitoring can provide an additional assessment in the event of suspected brain death because brain perfusion effectively ceases once ICP exceeds diastolic blood pressure.

Problems associated with ICP monitoring include its cost, the risk of infection, and the risk of hemorrhage. Effective maintenance of ICP monitoring requires a team effort.

Multimodality Monitoring

Although maintenance of CPP is important, it measures only one parameter affecting the delivery of oxygen to the neurons. Ultimately, the CBF and oxygen content of the blood are the prime parameters of concern. Although CPP provides a pressure gradient governing CBF, flow is subsequently affected by the resistance of the cerebral vessels. Neuronal demand for oxygen is governed by the metabolic rate of the neurons—that is, neurons with high activity levels require greater amounts of oxygen than do quiescent neurons. Globally, this is described as the **cerebral metabolic rate for oxygen ($CMRO_2$)**:

$$CMRO_2 = CBF \times OEF \times SpO_2$$

The **oxygen extraction fraction (OEF)**, or how much oxygen is extracted as it passes by and is, therefore, available to support brain functions, can be measured by the **Fick principle** based on measurements of the arterial and venous oxygen content. The Fick principle is used to determine cardiac output, such that the amount of oxygen uptake of blood as it passes through the lungs is equal to the oxygen concentration difference between mixed venous and arterial blood.

Thus, monitoring only the ICP and CPP provides little information about the overall state of the injured brain and no information about oxygen delivery and usage. Multimodality monitoring involves using a combination of jugular venous bulb oximetry, brain tissue oxygen tension, and transcranial Doppler ultrasound, which allows a greater understanding of cerebral circulation and oxygen consumption.

Jugular venous bulb oximetry involves placing a sampling catheter in the internal jugular vein, directed upward, so that its tip rests in the jugular venous bulb at the base of the brain. Blood samples drawn from here measure the **mixed venous oxygen saturation (SvO_2)** of blood leaving the brain, which is normally in the range of 50% to 75%.

The SvO_2 may fall when there is an imbalance between oxygen consumption and delivery, when there is a fall in CBF, when there is a rise in oxygen use, or when there is increased cerebrovascular resistance (CVR). Vascular spasm and a rise in CVR are very common after brain injury and are significantly worsened by hyperventilation. Jugular venous bulb oximetry should be used whenever the patient has experienced prolonged hyperventilation.

Brain tissue oxygen tension ($P_{br}O_2$) monitoring is accomplished by placement of a commercial probe (capable of measuring temperature and oxygenation) into the brain tissue through a bolt. Placement technique is similar to ICP monitoring placement and can be done simultaneously with ICP monitoring

placement.

Brain tissue oxygenation monitoring is more sensitive for monitoring focal disruption of blood flow to particular areas of the brain (depending on catheter placement). When compared to jugular venous bulb oximetry, which only detects global ischemic insults, brain tissue oxygen tension appears to be more accurate and may be more practical for continuous monitoring.

Transcranial Doppler ultrasound is a noninvasive method of assessing the state of the intracranial circulation. The velocity of flow can be measured in the middle, anterior, and posterior cerebral arteries; the ophthalmic artery; or the internal carotid artery. Doppler waveform analysis can give further information about the state of blood flow, such as flow acceleration and pulsatility index ([systolic velocity–diastolic velocity]/mean velocity).

Vasospasm is common after head injury and can be an important cause of neurologic deterioration. Vasospasm usually occurs in the presence of traumatic subarachnoid hemorrhage. Vasospasm leads to an increase in flow velocity; therefore, TCD is useful for monitoring at-risk patients for signs of vasospasm.

TCD is indicated for patients whose intracranial hypertension and CPP cannot be maintained by standard therapy.

All of the previously mentioned monitoring technologies assess oxygen delivery to and extraction by the brain; none measures cerebral activity directly. A full EEG is too complex for continuous use in the ICU, but the **cerebral function monitor (CFM)** or **cerebral function analysis monitor (CFAM)** can provide summed, averaged, and (in CFAM's case) analyzed outputs of the general state of brain activity. A CFM records a single channel EEG from two electrodes placed on either side of the head and a third electrode that acts as a ground. The CFM is used to assess brain wave activity, indicate the effects of medication administration, and identify seizure activity. It is particularly useful in evaluating the effects of sedation and paralytics.

Performing ICP Monitoring

Prior to performing any procedure, the appropriate equipment should be available and the patient should be prepared for the procedure. It is necessary to ensure the procedure is done in a controlled environment with adequate support staff. Every effort must be made to anticipate difficulties, and providers must have a thorough understanding of troubleshooting techniques. This section outlines the equipment required, precautions, the step-by-step procedure, adverse reactions and interventions to mitigate them, and postprocedure checks and documentation.

Equipment

The equipment necessary for ICP monitoring includes the following items:

- External drainage system with mounting card
- Pressure transducer with 48″ pressure tubing
- Sterile 0.9% sodium chloride (NaCl) with sterile 20-mL syringe
- Pressure monitoring cable
- IV tubing
- Manual resuscitator, mask, and 100% oxygen source
- Cardiopulmonary monitor
- BSI attire

Procedure

Skill Drill 11-1 shows the procedure for monitoring ICP with the Cordis EDS device, one of the most

commonly used ICP monitoring devices. The procedure is also described here:

1. Assemble the Cordis EDS as instructed per the package insert and per the mounting card diagrammatic instructions, using 0.9% NaCl to flush the system. Place the 48″ tubing, with connected pressure transducer, on the plastic mounting card **Step 1**.
2. Avoid tension or kinking of the pressure monitoring cable.
3. Place the patient in a semi-Fowler's position and position the zero reference point at the outer canthus of the eye **Step 2**.
4. Obtain the ICP waveform on the cardiopulmonary monitor. Turn the stopcock nearest the patient so that the ICP waveform is visualized **Step 3**.
5. Zero the transducer at the distal stopcock **Step 4**.
6. Record the ICP on the printer and mark and post the strip. Calculate and record the CPP on the strip **Step 5**.
7. For continuous drainage, turn the stopcock nearest the patient so that drainage resumes and pressure monitoring is discontinued. *Note:* It is recommended that pressure monitoring and CSF drainage not be done simultaneously **Step 6**.
8. Maintain a clean and intact dressing. If the dressing is soiled or contaminated, change it using a sterile technique.

Precautions

To minimize the risk of an infectious agent entering the CNS during ICP monitoring, an aseptic technique must be used at all times when assembling, manipulating, or accessing the fluid-filled monitoring system. Tight connections must be maintained, and the system must remain free of air to ensure maximal accuracy. Never use a flush device for ICP monitoring. Use only sterile 0.9% NaCl to fill the pressure tubing. Never use a heparinized solution.

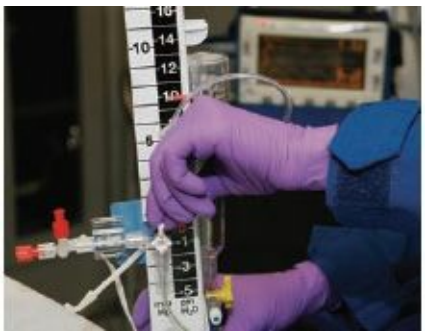
To ensure optimal accuracy, proper leveling and zeroing of the system must be maintained. The proper level for the transducer is at the foramen of Monro measured at the level of the outer canthus of the eye or, alternatively, at the spine for lumbar drainage. Utmost care must be taken when positioning and turning the patient to avoid accidental decannulation or disconnection of the tubing. Patients are maintained at a 30° to 45° head-up and neutral position when necessary to minimize the ICP. Use extreme caution when positioning patients and performing therapy so as to minimize increases in ICP and associated degradations in CPP.

Skill Drill 11-1

Performing ICP Monitoring

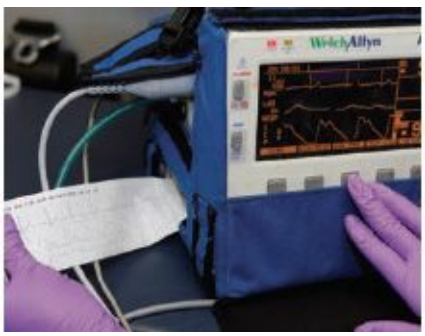
1 Assemble the device as instructed per the package insert and per the mounting card using 0.9% NaCl to flush the system. Place the 48″ tubing, with connected pressure transducer, on the plastic mounting card. Avoid tension or kinking of the cable.

2 Place the patient in a semi-Fowler's position and position the zero reference point at the outer canthus of the eye.



3 Obtain the ICP waveform on the cardiopulmonary monitor. Turn the stopcock nearest the patient so that the ICP waveform is visualized.

4 Zero the transducer at the distal stopcock.



5 Record the ICP on the printer and mark and post the strip. Calculate and record the CPP on the strip.

6 For continuous drainage, turn the stopcock nearest the patient so that drainage resumes and pressure monitoring is discontinued. Maintain a clean and intact dressing.

Avoid flexion and hyperextension of the neck and positioning the patient in a Trendelenburg position, all of which may increase ICP. An alarm for high ICP must be maintained in the "on" position at all times.

Use care when manipulating the drainage system to avoid getting the filter wet. The drainage cylinder should remain in an upright position at all times. If the filter should get wet and drainage is slowed or stopped, some time may be required for the filter to dry out sufficiently before adequate drainage is reestablished.

The Cordis EDS and pressure transducer systems **Figure 11-46** are intended for single-patient use only. Do not sterilize any part of the disposable system for reuse.

Simultaneous drainage and pressure monitoring are not recommended. To ensure precise pressure measurements, perform only pressure monitoring while keeping the stopcock closed to the drainage system.

Only a small amount of CSF (not to exceed 3 mL) should be drained at one time. Rapid cerebral decompression from CSF overdrainage may result in herniation; such overdrainage may occur if the system is inadvertently left open or if the patient is maintained at a higher level than the reference point on the system (as per physician order). The height of the drainage cylinder determines the rapidity at which CSF will drain. The physician's order for drainage must include a pressure reading in either mm Hg or cm H_2O and the height (as marked on the mounting card) at which the drainage cylinder must be maintained. The zero reference point for ICP monitoring always remains the outer canthus of the eye (or for lumbar drainage, the spine).

Figure 11-46 The Cordis EDS.

Adverse Reactions and Interventions

Some patients may experience adverse reactions as a result of ICP monitoring. These reactions and the appropriate interventions to mitigate them are discussed here.

First, if blood is visualized in the pressure tubing (from intracranial hemorrhage), notify the physician.

If a good waveform and/or accurate ICP cannot be obtained (ie, a dampened waveform appears), a flush of the fluid-filled monitoring system (with sterile 0.9% NaCl) may be attempted. All connections should first be checked for tightness. Never flush the system while it is open to the patient. Close the stopcock to the patient and then attempt to flush the monitoring system. Resume pressure monitoring by reopening the system to the patient. If a poor waveform persists, troubleshoot the system as you would any other, including debubbling, releveling and zeroing, and changing the electrical cable. If all of these maneuvers fail to correct the poor waveform, notify the physician. The catheter may be occluded with blood or tissue, requiring physician intervention.

An acutely low ICP may indicate acute decompression due to leakage or overdrainage of CSF. Never attempt to tamponade or block leakage from the site around an ICP monitoring device. In this situation, the physician should be notified immediately.

In the event of acute decompensation (ie, sustained ICP $\geq$ 15 mm Hg), be prepared to hyperventilate the patient with a manual resuscitator (bag-mask device) connected to 100% oxygen. Notify the physician.

Notify the physician immediately if the patient shows signs of decompensation—altered level of consciousness, restlessness, agitation, lethargy, confusion, motor weakness, seizures, alteration in breathing pattern, increases in blood pressure, bradycardia, vomiting, decortication/decerebration, or coma.

Post-Procedure Care and Documentation

Once ICP monitoring is established, do the following.

1. Ensure that all connections are tight and that the drainage system is positioned at the precise height for drainage according to the physician's order before leaving the bedside.
2. Relevel and zero the system every 4 hours and as needed.
3. Change the transducer pressure tubing every 72 hours as per the local policy.
4. Post a strip of the ICP in the patient's chart at least once per shift. It is probable that ICP will be measured much more frequently. Each posted strip should also have documentation of the corresponding CPP.

Treatment Options for Increased ICP

The best treatment for increased ICP is obviously the removal of the causative lesion, such as a tumor, hydrocephalus, or hematoma. Postoperative increased ICP has become less common with more widespread use of the microscope and special techniques to avoid brain retraction. A patient with a basal meningioma (a tumor near the base of the meninges) that has been completely removed usually has a smooth postoperative period. By contrast, a convexity or even falx meningioma (a tumor near the falx cerebri of the meninges) may be easily removed, but the postoperative period may be difficult. In such a case, problems may arise because of impairment of venous drainage, from either intraoperative injury to veins or postoperative diuretic therapy (as practiced in some centers).

Debate persists about whether increased ICP is the cause or the result of brain damage. Not all midline shifts seen in CT scans indicate increased ICP; they simply mean that ICP was high during the shift. A midline shift takes longer to reverse even after ICP returns to normal. In any event, increased ICP tends to be a temporary phenomenon that lasts for a short time unless there is a fresh secondary injury due to a clot, hypoxia, or an electrolyte disturbance.

First-Line vs Second-Line Management

Treatment is aimed at preventing the secondary events. Clinical and ICP monitoring definitely help in this regard. First-line management consists of general measures aimed at making the patient comfortable, along with effective handling of the ABCs of trauma management. Careful attention to nutrition and electrolytes, bladder and bowel functions, and appropriate treatment of infections should be instituted promptly. Adequate analgesia is often forgotten; it is a must even in unconscious patients.

Second-line management of increased ICP involves induced cerebral vasoconstriction, which may take the form of hyperventilation, hyperbaric oxygen, or hypothermia. Osmotherapy consisting of mannitol, glycerol, urea, or furosemide may also be implemented. Anesthetic agents, including barbiturates, gamma-hydroxybutyrate, and etomidate, and paralytic agents may also be used. Paralytics essentially paralyze the patient for the duration of transport and must be used with a ventilated patient. Preventing muscle contraction and movement can prevent exacerbation of a brain hemorrhage in certain cases. One example would be a patient with a brain hemorrhage who is taking warfarin (Coumadin). Warfarin cannot be reversed quickly even with administration of plasma, so administering a paralytic will be helpful to eliminate movement, reduce stress, and improve oxygenation. Usually a long-term nondepolarizing paralytic such as verconium bromide (Norcuron) is used. Paralytics should never be used without adjunctive analgesics or sedatives, because an awake paralyzed patient may develop increased ICP.

Surgical decompression remains controversial. It is performed to combat increased ICP, which is assumed when there is neurologic deterioration or when monitoring reveals that ICP is higher than 25 cm H_2O.

Specific Therapeutic Options

Transport treatment is aimed at reducing ICP and providing rapid transport to a neurologic facility for definitive treatment. Hyperventilation aims at keeping the P_{CO_2} between 25 and 35 mm Hg, so that CBF falls and capillary blood volume is reduced, thereby reducing the ICP. Although widely used, the reduction of CBF carries a significant risk of inducing cerebral ischemia, especially during the first day following injury when CBF has been demonstrated to approach half normal values. Prophylactic hyperventilation is not recommended. Hyperventilation should also be avoided in the first 24 hours following injury when CBF is often critically reduced. As a temporizing measure, hyperventilation is recommended to control elevations in ICP. Some have claimed that a P_{CO_2} of less than 20 mm Hg results in ischemia, although no experimental proof has definitively shown such a relationship. The present trend is to maintain ventilation with P_{CO_2} in the range of 30 to 35 mm Hg and with P_{O_2} in the range of 120 to 140 mm Hg to prevent hypoxia (standard of care for head injuries). When clinical deterioration such as pupillary dilation or widened pulse pressure is observed, hyperventilation may be instituted (preferably by increasing minute volume) until the ICP decreases. Whenever hyperventilation is used, cerebral oxygen delivery should be continuously assessed using jugular venous oxygen saturation or brain tissue oxygen tension measurement.

Controversies

A small group of surgeons initiate second-line management measures in conditions in which ICP is expected to rise without waiting for the rise to actually occur. Many other physicians believe that institution of measures to reduce ICP invariably compromises CBF; they prefer to wait for the rise in ICP before initiating second-line measures.

There is also debate about what the second line of management should be. Some prefer

hyperosmolar therapy; others prefer measures to induce cerebral vasoconstriction, thereby reducing CBF and reducing ICP. Finally, some providers believe it prudent to initiate both.

Ways to manage increased ICP during transport include:

1. Intubate and mechanically ventilate the patient. For intracranial hemorrhage, hyperventilate the patient, maintaining a CO_2 level of 25 to 35 mm Hg.
2. Consider administering an osmotic diuretic. Osmotic diuretics are low-molecular-weight substances that produce a rapid loss of sodium and water by inhibiting their reabsorption in the kidney tubules and the loop of Henle. They also increase the osmolality of plasma, increasing the diffusion of CSF. Osmotic diuretics are used to reduce intracerebral pressure created by excess CSF. Mannitol is the most commonly used osmotic diuretic, but glycerol is also used.
3. Consider administering dexamethasone or methylprednisolone sodium succinate to control inflammation and swelling. Dexamethesone and methylprednisolone sodium succinate are corticosteroids and are used to control inflammation and swelling of brain tissue.
4. Blood pressure should be controlled to maintain systolic pressures of less than 150 mm Hg.
5. If a surgical drain (bolt) has been installed, CSF should be drained if the ICP is greater than 20 cm H_2O.
6. Patients sustaining an intracranial hemorrhage and who have been taking warfarin (Coumadin) (patients with atrial fibrillation) should have either plasma or platelets administered en route and may require a paralytic.

Hyperosmolar therapy using mannitol, similar to hyperventilation, also bears risks of further reducing perfusion to the brain. Mannitol is still effective at reducing ICP, but only if it is used properly. Mannitol is not inert and harmless. Several theories have been advanced concerning the mechanism by which this drug reduces ICP:

- Mannitol increases cardiac output, which leads to better CPP and cerebral oxygenation
- Mannitol causes a decrease in CSF production
- Mannitol's diuretic effect may occur mainly around the lesion, where the blood-brain barrier integrity is impaired, so that the drug has no significant effect on the normal brain. For this reason, intra-axial lesions respond better to mannitol than do extra-axial lesions.
- Mannitol may withdraw water across the ependyma of the ventricles in a manner analogous to that produced by ventricular drainage.
- Mannitol may cause cerebral vasoconstriction, with the resultant changes in CBV being responsible for reduction in ICP.

Mannitol is usually given in a 20% solution in bolus doses as opposed to a continuous infusion. Boluses of 0.25 to 0.5 g/kg given over 10 to 20 minutes may be used and repeated depending on the patient response.

Mannitol's effect on ICP reaches its maximum 30 minutes after infusion and lasts for a variable period ranging from 90 minutes to 6 hours or more. The correct dose is the smallest dose that will have sufficient effect on ICP. When repeated doses are required, the baseline serum osmolality gradually increases. When this level exceeds 330 mOsm/L, mannitol therapy should cease; there is no role for dehydration. Further use is ineffective and is likely to induce renal failure.

Diuretics such as furosemide, given either alone or in conjunction with mannitol, help to hasten

mannitol's excretion and reduce the baseline serum osmolality prior to the next dose. It is speculated that furosemide complements mannitol and increases the output. Furosemide may be given before mannitol, so that it reduces circulatory overload.

Barbiturates can lower ICP when other measures fail but have no prophylactic value. Barbiturates and hypnotic drugs such as propofol and etomidate act by reducing $CMRO_2$ and producing a coupled reduction in CBF. (They also reduce brain metabolism and energy demand, which facilitates better healing.) The consequent reduction in CBV leads to a parallel fall in ICP. Among the barbiturates, phenobarbital is most widely used for this purpose. A loading dose of 10 mg/kg over 30 minutes and 1 to 3 mg/kg every hour is widely used. Close monitoring of ICP and hemodynamic instability should accompany any barbiturate therapy.

High-dose corticosteroid therapy (such as methylprednisone or dexamethasone) was popular some years ago as a means to lower ICP and is still used for this purpose today. Corticosteroids restore cell-wall integrity and help in recovery to reduce edema.

Decompressive craniotomies, such as subtemporal decompression, are not recommended. Herniation of the brain through a defect may cause further injury, further edema, and further increased ICP in some patients who undergo this procedure. In occasional cases, when every other measure has failed, a decompression craniotomy may be justified. This action would need to be substantiated by clear evidence of neurologic deterioration and a CT scan that shows an intracranial lesion.

Hyperbaric oxygen and hypothermia are experimental techniques (used especially frequently in Japan) to induce cerebral vasoconstriction and reduce the CBV and the ICP. Considerable evidence supports the use of mild to moderate hypothermia (32°C to 34°C) for increased ICP, especially when target temperatures are maintained for longer than 48 hours. Cooling reduces the cerebral metabolic rate, leading to a reduction in CBF, ICP, and glutamate release. Fever increases the cerebral metabolic rate (CMR) and $CMRO_2$ and occurs commonly in brain-injured patients, especially after intracranial hemorrhage. Therefore, temperature monitoring and control are vital to patient outcomes.

Spinal Cord Injuries

CCTPs may be called on to provide appropriate transportation of patients with spinal cord injuries (SCIs). These injuries may be highly suspicious as a result of the mechanism or identified at the transferring facility by radiographic imaging. These injuries may also be isolated or associated with other injuries and can complicate management priorities. Rapid and safe transportation of the patient with an SCI to a facility that can provide definitive care is optimum.

Mechanism of Injury

Acute injuries of the spine are classified according to the mechanism, location, and stability of the injury. Vertebral fractures often occur with or without associated SCI. Simply put, the spine is composed of three anatomic columns. First described by Denis, the spine is divided longitudinally into the anterior, middle, and posterior columns. The anterior column includes the anterior longitudinal ligament, the anterior half of the vertebral body, and the anterior half of the intravertebral disk. The middle column is composed of the posterior half of the vertebral body, the posterior half of the intravertebral disk, and the posterior longitudinal ligament. Finally, the posterior column consists of all other structures posterior to the posterior longitudinal ligament and includes pedicles, lamina, spinous process, interspinous ligaments, and the ligamentum flavum. Disruption of two of three of these columns is, by definition, an unstable injury.

Generally the types of forces or mechanisms that affect the spinal column include flexion/extension, vertical compression/longitudinal distraction, rotational, and combined mechanisms.

Flexion-Extension Injuries

Flexion-extension injuries are typically the result of rapid deceleration or from a direct blow to the occiput. They typically involve the cervical region; the spinal cord may be injured as a result by compression in the canal. Hyperextension of the head and neck can result in fractures, ligamentous injury, and SCI of variable stability. The C5-6 level is most susceptible to this injury from a mechanical standpoint.

Vertical Compression

Vertical compression forces are transmitted through vertebral bodies and directed either inferiorly through the skull or superiorly through the pelvis or feet. They typically result from a direct blow to the crown (parietal region) of the skull or rapid deceleration from a fall through the feet, legs, and pelvis. Compression forces can cause the herniation of discs, subsequent compression on the spinal cord and nerve roots, and fragmentation into the canal. Forces transmitted through the vertebral body cause fractures, ultimately shattering and producing a “burst” or compression fracture, sometimes without, but also with varying associated SCI. In falls, most injuries involve the thoracolumbar junction; the lower cervical spine is often involved with axial loads to the spinal column **Figure 11-47**.

Special Populations

Osteoporosis in older adult patients contributes to a high rate of spinal injury, often as a result of minimal trauma (eg, ground level falls or falls from a seated position). The CCTP should maintain a high index of suspicion of spinal injury in this population with special attention to possible C1–C2 injuries that include dens fractures and transverse ligament disruption.

Special Populations

Patients with a history of ankylosing spondylitis or diffuse idiopathic skeletal hyperostosis are a special population that warrants extra care and attention. Because of these conditions, the patients are at increased risk of spinal fractures. Even nondisplaced fractures in this population can be unstable and lead to potential SCI.

Figure 11-47 A compression fracture.

Rotation With Flexion

Rotation-flexion injuries often occur in the thoracolumbar interface. The injury patterns can involve stable or unstable fractures and dislocations.

Primary Spinal Cord Injury

Primary spinal cord injury is a result of the initial trauma. Penetrating trauma may either result in transection of neural elements or cause concussive injury to the spinal cord (as in gunshot wounds), and may be either complete or incomplete injuries. Blunt trauma may displace ligaments and bone fragments, resulting in compression of points of the spinal cord or an incomplete dislocation of the vertebral body. Hypoperfusion and ischemia may also result from this type of injury to the spinal vasculature. Necrosis from prolonged ischemia leads to permanent loss of function.

Spinal cord contusions are caused by fracture, dislocation, or direct trauma. They are associated with edema, tissue damage, and vascular leakage. Hemorrhagic disruption may cause temporary to permanent loss of function despite normal radiographs.

Cord laceration usually occurs when a projectile or bone enters the spinal canal. Such an injury is likely to result in hemorrhage into the cord tissue, swelling, and disruption of some portion of the cord and its associated communication pathways.

Secondary Spinal Cord Injury

Secondary spinal cord injury occurs as a result of progression of the primary SCI. The injury can cause an ensuing cascade of inflammatory responses that may result in further deterioration. These effects can be exacerbated by exposing neural elements to further hypoperfusion, hypoxemia, hypoglycemia, and hypothermia. Although some SCIs may be unavoidable, the prehospital provider should minimize further injury through stabilization—that is, through spinal motion restriction and neutral alignment. In addition,

minimizing heat loss and maintaining oxygenation and perfusion are key elements in the care of a patient with a possible SCI.

SCIs are classified as complete or incomplete. **Complete spinal cord injury** involves complete disruption of all tracts of the spinal cord, with no sensory and motor function more than three segments below the level of injury. When the injury affects the patient in the cervical spine, quadriplegia can result. Injury in the thoracic spine can result in paraplegia. In an **incomplete spinal cord injury**, the patient retains some degree of cord-mediated function more than three segments below the level of injury. The degree of SCI is best determined 24 hours after the initial injury; the initial dysfunction may be temporary, and there is some potential for recovery.

Types of Incomplete Spinal Cord Syndromes

Anterior cord syndrome results from the displacement of bony fragments into the anterior portion of the spinal cord, often the result of flexion injuries or fractures. The anterior spinal artery provides blood to the anterior two thirds of the spinal cord; disruption of this flow will present as an anterior cord syndrome. Typical physical findings include motor paralysis below the level of the insult with loss of pain and temperature sensation with preservation of proprioception.

In **central cord syndrome**, hyperextension injuries to the cervical area present with hemorrhage or edema to the central cervical segments. This type of damage is rarely associated with fractures or bone disruption but more often occurs in conjunction with tears to the anterior longitudinal ligament. Central cord syndrome is frequently seen in older patients, who may already have a significant degree of cervical spondylosis and stenosis as the result of arthritic changes. A brief episode of hyperextension can exert pressure on the spinal cord within the relatively diminished spinal canal. Within the central cord, motor (efferent) fibers are distributed in a unique fashion, with more cervical and thoracic motor and sensory tracts than in the periphery of the cord. The patient with central cord syndrome will present with greater loss of function in the upper extremities than in the lower extremities, with variable loss of sensation to pain and temperature. The patient may also have some bowel and bladder dysfunction. The prognosis for central cord syndrome is typically good; many patients regain all motor function or have only some residual weakness in the hands.

Special Populations

Children who are younger than 10 years have heads that are proportionally larger than their body and, as a result, will frequently have spinal injuries from the occiput to C3. Children older than 10 years have injury patterns similar to adults. Because the head is proportionally larger in younger children, it is important to appropriately immobilize children in a neutral position. This may require padding under the shoulders and back to maintain a neutral alignment in relation to the head.

Brown-Sequard syndrome occurs when penetrating trauma is accompanied by hemisection of the cord and complete damage to all spinal tracts on the involved side. Injury to the corticospinal motor tracts causes motor loss on the same side as the injury, but below the lesion. Damage to the dorsal column causes loss of sensation to light touch, proprioception, and vibration on the same side as the injury (below it). Disruption of the spinothalamic tracts causes loss of sensation to pain and temperature on the opposite side of the injury, below the lesion.

Posterior cord syndrome is associated with extension injuries. This relatively rare syndrome produces dysfunction of the dorsal columns, presenting as decreased sensation to light touch,

proprioception, and vibration, while most other motor and sensory functions remain intact. Recovery of function is less likely than with central cord syndrome, but the overall prognosis remains good with therapy and rehabilitation.

Signs and Symptoms

Spinal Cord Injury

- May have flaccid paralysis below the level of injury
- May have loss of sensation to pain, temperature, and proprioception below the level of injury; loss may be unilateral
- May have disproportionate upper extremity motor impairment compared with lower extremities
- Bradycardia
- Hypotension
- Hypothermia
- Priaprism in males

Transport Management

Spinal Cord Injury

- Identify and correct life-threatening problems (ABCs).
- Maintain spinal stabilization and neutral alignment of the spinal column.
- In patients with multiple injuries, provide appropriate volume resuscitation with intravenous fluids and blood component therapy as appropriate.
- Rapidly identify and treat hypotension and hypoxia.
- Maintain normothermia.
- In patients an with an isolated SCI, support blood pressure after adequate resuscitation with vasoactive medications such as dopamine or phenylephrine.
- Patients may require atropine, transcutaneous pacing, or transvenous pacing for bradycardia.
- Provide rapid, safe transportation to a definitive care facility.

Controversies

Patients should be evaluated for decubitus ulcers, and any findings must be appropriately documented in the medical chart. Consideration during packaging should include appropriate padding of pressure points. Areas to pay particular attention to include the coccyx, shoulders, occiput, and heels.

Assessment of SCIs

A patient with an SCI should have a thorough assessment by the CCTP before transport. During this initial assessment, the CCTP should perform a comprehensive neurologic exam. This will provide a baseline to compare with future assessments when looking for acute changes. SCIs may be severe enough to threaten life and often leave the patient with significant disability. It is important to take the necessary precautions

and properly immobilize trauma patients when indicated. In most cases, the patient will be transported to the accepting facility with full spinal immobilization on the backboard until the receiving unit can properly identify the presence of a spinal injury.

The initial assessment of the patient with a suspected SCI follows the same assessment that is completed in a patient with a head injury. If not in place already, immediate attention to manual stabilization of the cervical spine is imperative, until a cervical collar can be placed. Because cervical collars only provide axial traction, they do not fully stabilize the head. To provide proper full immobilization for transport, the head must be immobilized using an appropriate immobilization device (eg, padded blocks) in addition to a cervical collar when using a backboard.

As part of the initial assessment prior to transport, the CCTP should take the time to perform a physical exam of the patient prior to packaging. For patients with SCI, it may be particularly important to focus on the following aspects of patient assessment. When appropriate, visually inspect the neck, looking for obvious deformities and feeling for crepitus or the presence of pain while maintaining inline stabilization. Evaluate the patient's airway prior to transportation. If the patient is not already intubated, perform a thorough and complete assessment of the airway. Consider the likelihood of respiratory failure and the need for definitive airway management during transportation. Patients with high SCI may have altered ability to breathe and ventilate during transport. They may also tire from their work of breathing as the result of muscular weakness from the SCI or from the inability to clear secretions. Managing an airway in a patient with cervical fractures or SCI can be difficult in the best of circumstances. If judged to be appropriate, intubate the patient at the referral facility under controlled circumstances and with appropriate support, if available, depending on the referral facility's resources (eg, anesthesia, surgeon, emergency medicine).

Assess the back for tenderness and deformity, if not previously done, and when appropriate. Palpate the spine for tenderness and deformity (such as step offs). Assess for strength in upper and lower extremities and the presence of sensation with comparison of both sides. Ongoing patient assessment, particularly of the patient's pulse, motor, and sensory function, is extremely important, because increased swelling can contribute to progressive deterioration of the patient's neurologic status. On arrival at the receiving facility, it will be important to provide an accurate and up-to-date patient report to the accepting medical staff.

Controversies

When spine clearance cannot be done clinically, most emergency medicine textbooks advocate clearing the spine with conventional x-rays. However, this practice is rapidly being replaced with CT scans of the head, neck, and chest. CT can be done more rapidly and with less patient movement and offers much clearer images than conventional films. However, there are reasons why a rapid CT scan cannot be performed by a transferring hospital while awaiting arrival of the CCTP team, such as when a CT scan would delay the transport. It is also prudent to limit CT exposure when possible to decrease a younger person's risk of cancer later in life; with younger patients radiographs may be a better choice, especially when suspicion for injury is low. It is also prudent to avoid exposing women of childbearing age to excess radiation, which can predispose their future children to birth anomalies. Additionally, removing the patient from a backboard helps alleviate discomfort and prevent pressure injuries from prolonged immobility on a hard surface.

The CCTP should always confirm whether or not clearance has been done, and obtain specific details from the transferring personnel. Appropriate documentation of this clearance should be evident in the medical record prior to transportation.

In general, patients with identified or highly suspected cervical or thoracolumbar injury should not be cleared and should be transported in the appropriate manner (immobilized). However, patients with stable lower spine fractures do not necessarily need to be transferred on a backboard. In most cases, patients with the presence of neurologic deficits despite the absence of identified radiologic abnormalities should be assumed to have injury and should be appropriately immobilized. Isolated cervical spine injury may be initially managed with an appropriately fitting collar in place. Thoracolumbar fractures should be managed with spine immobilization during transport. If in doubt, perform full spinal immobilization.

Patients should be transported with either the head of the bed at 30° or in **reverse Trendelenburg** to minimize the risk of aspiration in both ventilated and nonventilated patients. Communication with medical control and preestablished protocols on appropriate transportation methods will assist in providing the most appropriate transportation method.

Spinal shock is the temporary local neurologic condition that occurs immediately after spinal trauma and involves a spinal cord concussion. The patient may present with variable degrees of acute spinal injury, potentially with flaccid paralysis, flaccid sphincters, and absent reflexes. Sensory function below the level of injury will be impaired. Spinal shock usually subsides within 24 to 72 hours when the spinal cord mediated reflex arc below the level of injury resumes function. Patients who regain this arc, yet still have absence of distal motor or sensory function below the level of injury, have a complete cord injury and are unlikely to regain neurologic function. Those with some motor and sensory function below the level of injury are considered to have incomplete injury.

Neurogenic shock results from the temporary loss of autonomic function, which controls cardiovascular function, at the level of injury. Marked hemodynamic and systemic effects are seen and typically result in a triad of hypotension, bradycardia, and hypothermia. Hypotension occurs as the result of absent or impaired peripheral vascular tone with the loss of alpha-receptor stimulation; blood pools in the enlarged vascular space, causing relative hypovolemia and making the patient extremely sensitive to sudden position changes; and cardiac preload decreases, resulting in decreased stroke volume and cardiac output. Bradycardia results from the unopposed vagal response; the adrenal gland loses its sympathetic stimulation and does not produce epinephrine or norepinephrine to compensate for the loss of vascular tone. Hypothermia and absence of sweating are also seen because of the loss of sympathetic stimulation and thermoregulation. The classic presentation of neurogenic shock is a hypotensive, bradycardic patient whose skin is warm, flushed, and dry below the level of the spinal lesion.

Management of SCI

A patient with an SCI should be treated as a true neurologic emergency, and the CCTP should make every effort to rapidly assess, treat, and transport the patient to the closest appropriate facility while maintaining appropriate inline stabilization of the spinal column.

Patients with an SCI should be transported in a way that minimizes jostling and movement to prevent further SCI. Immediate identification and aggressive management of hypotension and hypoxia will also help to prevent further insult of the spinal cord.

Priorities of management include rapid identification and correction of life-threatening problems. The airway should be appropriately secured and managed, especially with higher-level cervical fractures. Breathing should be supported via mechanical ventilator or bag-mask assist for transportation of patients who are intubated or have tracheotomies. End-tidal capnography and pulse oximetry are helpful in assessing and monitoring respiratory status. Careful assessment, including pulse oximetry, of breathing in nonintubated patients is important when monitoring for progressive respiratory failure.

Frequent monitoring of blood pressure by noninvasive means or by an arterial line during transport will alert providers to hypotension. Appropriate large-bore IV access (minimum of two IV sites) or appropriate central venous access should be in place prior to transport, as should bladder catheterization.

Adequate volume resuscitation with appropriate IV fluids and blood component therapy for patients with multiple injuries should occur. Patients with multiple injuries should be suspected to be experiencing hemorrhage and hemorrhagic shock first and foremost unless these are ruled out at the transferring facility. Patients with identified isolated neurogenic shock should be treated with volume resuscitation and vasoactive medications. Patients with SCI may have a loss of thermoregulation from vasodilatation and require monitoring of temperature and treatment to maintain normothermia, including warm IV fluids, blankets, and temperature control in the transporting vehicle. Because bradycardia sometimes results from SCI, the use of atropine, transcutaneous pacers, and transvenous pacemakers may be warranted in high-level cervical lesions (C1-C5).

Pharmacotherapy in SCI

Patients with SCI may require various pharmacologic interventions during transport. Pain associated with fractures or other injuries will require judicious use of narcotics. IV opiates can be useful in the management of pain associated with transportation, movement, and the injury itself. Fentanyl, a short-acting synthetic opiate, has less of an effect on blood pressure and may be used as first-line therapy for these patients to control pain and to reduce the risk of hypotension. Midazolam (Versed) or lorazepam (Ativan) may be used for sedation after appropriate pain control has been established and other correctible causes of agitation such as hypoxia have been excluded. The risk of secondary injury as the result of movements from acute agitation must be balanced with potential airway and ventilatory compromise as well as a reliable neurologic exam.

The use of corticosteroids in the acute phase of SCI remains controversial. In the United States, the practice remains relatively widespread within the initial eight hours after injury. Dosing of IV corticosteroids, developed as a result of the National Acute Spinal Cord Injury Study II and III, calls for use of methylprednisolone in acute nonpenetrating SCI less than 8 hours after injury. The regimen includes a 30-mg/kg bolus of methylprednisolone over 15 minutes. After a 45-minute interval following infusion, a drip of 5.4 mg/kg/h continues over the next 23 hours. One of the principle side effects of corticosteroid administration is hyperglycemia, and patients who have either been given or are receiving a methylprednisolone drip should have point-of-care glucose monitoring and appropriate treatment of hyperglycemia with insulin.

Patients with SCIs may also have neurogenic shock requiring vasoactive medications to support blood pressure once adequate resuscitation has occurred. Agents such as dopamine and phenylephrine may be used to support blood pressure. Patients in neurogenic shock may also have bradycardia, requiring atropine on an urgent basis to support the heart rate and blood pressure.

Controversies

Recent outcomes data on use of corticosteroids immediately following initial injury and during interfacility transfer have failed to show significant improvements. As a consequence, many spine surgeons are beginning to abandon this practice.

Complications of SCI

The complications of SCI are a consistent cause of the high morbidity and mortality and the high financial

cost associated with this type of injury. Acute-phase complications of SCI include the potential for aspiration or respiratory arrest, especially with high cervical injuries. Lower cervical lesions may preserve the diaphragm, but the loss of intercostal muscles ultimately impairs coughing and deep breathing, predisposing the patient to atelectasis and pneumonia. Patients should be transported either in a reverse Trendelenburg position or with the head of the bed elevated to 30° as appropriate. Deep vein thrombosis and pulmonary embolism are late complications that may result from immobility and can become potentially life threatening. Consideration of sequential compression devices to the lower legs should be given for prolonged transports to reduce the risk of deep vein thrombosis subsequent to pulmonary embolism. Pressure ulcers from immobility are also problematic in SCI. Proper padding and judicious use of spinal immobilization boards are important during the transfer phase. Gastric stress ulceration can be reduced with the use of appropriate prophylaxis agents (eg, proton pump inhibitors and histamine 2 blockers). Urinary tract infections can be reduced by appropriately placing sterile Foley catheters, securing the device to the leg, and keeping the Foley bag in a dependent location to prevent backflow of urine into the bladder.

Autonomic dysreflexia is typically a late complication of SCI but may occur acutely. It commonly occurs with injuries above T6 and results from the loss of coordinated autonomic responses. This happens when there is an irritation, pain, or stimulus to the nervous system below the SCI. The affected area sends signals to the brain, but they are unable to reach the brain. The body responds with a reflex action constricting the blood vessels and causing an increase in blood pressure. If left uncontrolled, this can cause a stroke, seizures, and even death. Patients present clinically with evidence of a massive, uninhibited, uncompensated cardiovascular response as the result of noxious stimulation of the sympathetic nervous system below the level of injury. Unabated sympathetic nervous system stimulation results in vasoconstriction and hypertension (sometimes over 200 mm Hg systolic). This leads to compensatory parasympathetic stimulation and causes bradycardia and vasodilation above the level of the lesion, whereas vessels below the SCI remain constricted. This selective vasodilation results in flushed, diaphoretic skin and nasopharyngeal vessel congestion. Other symptoms include headache, nausea, and anxiety. Common precipitators include bladder distention, bowel impaction, bladder infection, pressure ulceration, fractures, and constrictive clothing. Indwelling catheters should be evaluated for obstruction or kinking and flushed to ensure patency. Irritating foci should be identified and treated appropriately, such as removing light clothing, resolving bowel/bladder problems, or treating a decubitus ulcer.

Signs and Symptoms

Autonomic Dysreflexia

- Hypertension
- Headache
- Nasal congestion
- Anxiety
- Nausea
- Blurred vision
- Bradycardia common, but tachycardia may also occur
- Diaphoresis and flushing above SCI
- Piloerection above SCI

Transport Management

Autonomic Dysreflexia

- Monitor blood pressure frequently.
- Search for, identify, and correct inciting stimuli (ie, reposition the patient and check the bladder and bowels for irritation or obstruction).
- If the source cannot be found or minimized, reduce the blood pressure with a beta-blocker or vasodilators.

If the source of autonomic dysreflexia cannot be found or minimized to an effective extent, it may be necessary to reduce blood pressure with vasodilators. Agents to consider are ones with a rapid action and a short duration (eg, nitrates, nitropaste, hydralizine, and labetolol). A trial of beta-blockers may also help to reduce cardiovascular response. Left untreated, the patient may experience seizures, intercranial hemorrhage, and even death.

Stroke

Mechanism of Injury

Stroke, also referred to as cerebrovascular accident, occurs when a disruption of blood flow to the brain results in neurologic deficit persisting for more than 24 hours. When deficits completely resolve within 24 hours, the event is referred to as a **transient ischemic attack (TIA)**. Perfusion to oxygen-sensitive brain tissue may be interrupted when a blood vessel is occluded or when the structural integrity of a blood vessel is compromised, allowing blood to escape into the brain tissue or into the subarachnoid space. Care must be initiated quickly to restore proper blood flow to reduce loss of normal neurologic function.

Types of Stroke

Ischemic strokes occur when cerebral blood flow is decreased, usually because of an occlusion of a blood vessel. The occlusion can be due to either a thrombus or an embolus. Hypoperfusion secondary to hypotension can also cause an ischemic stroke. Between 75% and 85% of all strokes are ischemic strokes.

Thrombotic strokes are largely the result of an accumulation of atherosclerotic plaques inside cerebral blood vessels, especially at bifurcations, which narrow the lumen of the vessel and make blood flow difficult. Rupture of a local plaque can activate localized clotting, which can significantly diminish or completely stop blood flow distal to the occlusion.

Embolic strokes occur when an embolus from the heart or lower circulation travels and lodges in a smaller cerebral vessel, resulting in loss of blood supply. Only 30% of ischemic strokes are thought to be caused by an embolus. Myocardial complications, such as atrial fibrillation, valvular heart disease, myocardial infarction, ventricular aneurysm, and cardiomyopathy, are known risk factors for embolus formation.

Focal ischemic strokes take place when an area of marginally perfused tissue, the ischemic penumbra, surrounds a core of ischemic cells. As a reduction of blood flow continues, ischemic cells become injured and finally die, resulting in infarction and irreversible loss of brain tissue that eventually softens and becomes necrotic. The size of the stroke depends on the size and location of the occluded

vessel and the availability of collateral blood flow.

Global ischemic strokes result when severe hypotension or cardiac arrest produces a transient drop in blood flow to all areas of the brain.

Stroke Side Effects

Cerebral edema sufficient to produce clinical deterioration occurs in 10% to 20% of patients with ischemic stroke and can result in intracranial hypertension. The edema is a result of a loss of normal metabolic function of cells and peaks at 3 to 5 days. Secondary hemorrhage at the site of an ischemic stroke lesion can also occur and is known as **hemorrhagic conversion**. Patients who have had a stroke may also exhibit seizure activity as a result of damaged neurons.

Assessment

The characteristic sign of stroke is the sudden onset of focal neurologic signs that oftentimes occur in combination. The CCTP can also use abbreviated prehospital tools to identify patients suffering from stroke, such as the Cincinnati Prehospital Stroke Scale **Table 11-25** or the Los Angeles Prehospital Stroke Screen (LAPSS) **Table 11-26**. The National Institutes of Health stroke scale is also available, but is very involved; although useful in the hospital setting, it is not practical for evaluation during transport. In addition to focal neurologic signs and stroke tools, noncontrast CT scanning is important to help determine whether the patient's symptoms are being caused by an occlusion or bleeding.

Management

Once stroke is suspected, the CCTP should determine the time of symptom onset. In general, the CCTP should support the patient's cardiopulmonary function, provide continuous monitoring of neurologic function, and maintain normal blood glucose levels. Stroke patients are at risk for respiratory compromise from aspiration, upper airway obstruction, and hypoventilation. Frequent reassessment of airway and respiratory function is necessary because hypoxemia will worsen ischemic brain injury, and contribute to a worse outcome. Stroke patients should be given supplemental oxygen.

TABLE 11-25 Cincinnati Prehospital Stroke Scale*

Assessment	Normal	Abnormal
Facial Droop. Ask the patient to smile and show the teeth.	Both sides of the face move equally well.	One side of the face does not move as well as the other.
Arm Drift. Ask the patient to close the eyes and hold the arms out with palms up for 10 seconds.	Both arms move the same, or both arms do not move.	One arm does not move, or one arm drifts down compared with the other.
Abnormal Speech. Ask the patient to say, "The sky is blue in Cincinnati" or "You can't teach an old dog new tricks."	The patient uses the correct words with no slurring.	The patient slurs words, uses inappropriate words, or is unable to speak.

*Interpretation: If any assessment criterion is abnormal, the probability of a stroke is 72%.

TABLE 11-26 Los Angeles Prehospital Stroke Screen*

1. Age > 45 y	❑	❑	❑
2. History of seizures or epilepsy absent	❑	❑	❑
3. Symptoms < 24 h	❑	❑	❑
4. At baseline, patient is not wheelchair bound or bedridden	❑	❑	❑
5. Blood glucose between 60 and 400 mg/dL	❑	❑	❑
6. Obvious asymmetry (right vs left) in any of the following three exam categories (must be unilateral):	❑	❑	❑
	Equal	**Right Weak**	**Left Weak**
Facial smile/grimace	❑	❑ Droop	❑ Droop
Grip	❑	❑ Weak grip ❑ No grip	❑ Weak grip ❑ No grip
Arm strength	❑	❑ Drifts down ❑ Falls rapidly	❑ Drifts down ❑ Falls rapidly
*Interpretation: If criteria 1 through 6 are marked yes, the probability of a stroke is 97%.			

Fibrinolytic Therapy

In some cases, the CCTP may provide transport of stroke patients who are receiving fibrinolytic therapy. If a patient's symptoms do not resolve, a CT scan shows no hemorrhage, and the symptom onset is within 3 hours, fibrinolytic therapy may be used to restore circulation to ischemic brain tissue. The only fibrinolytic agent currently used for the treatment of ischemic stroke is tPA. Prior to initiation of therapy, inclusion and exclusion criteria for IV fibrinolytic therapy should be reviewed (refer to the American Heart Association inclusion/exclusion criteria) in order to decrease the risk of complications associated with fibrinolytic therapy, including intracranial hemorrhage, orolingual angioedema, acute hypotension, and systemic bleeding. Exclusion criteria generally include these types of concerns:

- History of intracranial neoplasm, arteriovenous malformation, or aneurysm
- Bleeding concerns, either as the result of current bleeding or a bleeding disorder
- History of stroke
- Recent noncompressible vascular puncture
- Major surgery or trauma in the past 3 months
- Systolic blood pressure of greater than 180 mm Hg
- Pregnancy and up to 1 month postpartum

Intracerebral Hemorrhage

Intracerebral hemorrhage is bleeding directly into the cerebral tissue that causes cerebral tissue destruction, cerebral edema, and increased ICP. The most common cause of spontaneous intracerebral hemorrhage is hypertension-induced vessel rupture. Other causes include anticoagulation or fibrinolytic therapy, coagulation disorders, drug abuse, and hemorrhage into cerebral infarcts or brain tumors.

Symptoms of intracerebral hemorrhage may begin as local neurologic dysfunction related to the area of the brain in which a vessel has ruptured. The patient may also report the presence of a severe headache, nausea, and vomiting. As ICP continues to rise, however, the patient will oftentimes become unconscious (a key finding that helps differentiate from ischemic stroke) and may require ventilatory support. The time it takes for deterioration to progress is related to the amount and speed of bleeding.

The CCTP should provide adequate attention to the management of cardiopulmonary function. Intubation may be necessary, and should be provided as soon as the patient's level of consciousness becomes inadequate for airway control or vomiting begins to endanger airway patency. If intracerebral hemorrhage has been confirmed prior to transport, orders may be given to reduce blood pressure to decrease ongoing bleeding. An over-aggressive reduction in blood pressure, however, may compromise

cerebral perfusion pressure, especially in the patient with an elevated ICP.

Signs and Symptoms

Left Hemisphere Ischemic Stroke

- Right hemiparesis
- Right-sided sensory loss
- Right visual field deficit
- Poor right conjugate gaze
- Dysarthria
- Aphasia
- Difficulty in reading, writing, or calculating

Right Hemisphere Ischemic Stroke

- Left hemiparesis
- Left-sided sensory loss
- Left visual field deficit
- Poor left conjugate gaze
- Dysarthria
- **Extinction** of left-sided stimuli
- Neglect of the left visual space
- Spatial disorientation

Brain Stem/Cerebellum/Posterior Hemisphere Ischemic Stroke

- Motor or sensory loss in all four limbs
- Crossed signs
- Limb or gait ataxia
- Dysarthria
- Dysconjugate gaze
- Nystagmus
- Amnesia
- Bilateral visual field deficits

Small Subcortical Hemisphere or Brain Stem (Pure Motor) Ischemic Stroke

- Weakness of face and limbs on one side of the body without abnormalities of higher brain function, sensation, or vision

Small Subcortical Hemisphere or Brain Stem (Pure Sensory) Ischemic Stroke

- Decreased sensation of face and limbs on one side of the body without abnormalities of higher brain function, motor function, or vision

Stroke Council, American Heart Association. *Circulation*. 1994;90(3):1588. Available at: http://www.strokecenter.org/education/ais_evaluation/brain_stem.htm. Accessed March 9, 2009.

Transport Management

Stroke

- Determine the time of symptom onset.
- Support the patient's cardiopulmonary function.
- Provide continuous monitoring of neurologic function.
- Maintain normal blood glucose levels.
- Frequently reassess airway and respiratory function.
- Give supplemental oxygen.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage is bleeding into the subarachnoid space, and is usually arterial in nature. Most subarachnoid hemorrhages are caused by rupture of a cerebral aneurysm or arteriovenous malformation (AVM). Other causes include hypertensive intracerebral hemorrhages that progress to subarachnoid hemorrhage and bleeding from a cerebral tumor. This chapter focuses on the two most frequent causes of subarachnoid hemorrhage.

Aneurysms are an outpouching of the wall of a blood vessel that results from weakening of the wall of the vessel. Most aneurysms are congenital, whereas others can be attributed to trauma or infection, or are of an idiopathic nature. As an individual with a congenital cerebral aneurysm matures, blood pressure rises and places stress on the wall of the weakened vessel. Eventually, ballooning of the vessel occurs, which may lead to compression of adjacent brain tissue and focal neurologic dysfunction. If the aneurysm ruptures, arterial blood is sent into the subarachnoid space at high pressure. As blood fills the space, ICP rises and cerebral perfusion pressure falls.

Arteriovenous malformations (AVMs) are tangled masses of arterial and venous blood vessels that shunt blood directly from thickly walled arteries to thinly walled veins without the benefit of pressure being reduced by an intervening capillary bed. One or more cerebral arteries, known as feeders, provide blood to an AVM. These feeders enlarge over time, increase the volume of blood shunted through the malformation, and increase the overall mass effect on adjacent brain tissue. Eventually, veins may no longer be able to accommodate the high mean pressure, and therefore rupture, causing blood to fill the subarachnoid space. As this happens, ICP rises and cerebral perfusion pressure falls.

Signs and Symptoms

Subarachnoid Hemorrhage

- Onset of pain
- Worst headache of patient's life
- Loss of consciousness
- Nausea
- Vomiting

- Focal neurologic deficits
- Photophobia
- Nuchal rigidity

Transport Management

Subarachnoid Hemorrhage

- Take measures to maintain the patient's cardiopulmonary function.
- Manage the patient's airway.
- Provide ventilatory support if necessary.
- Limit movement of the patient's head; elevate the head during transport.

Assessment

The patient with a subarachnoid hemorrhage characteristically has an abrupt onset of pain, oftentimes described as "the worst headache I have ever had." A loss of consciousness, nausea, vomiting, focal neurologic deficits, photophobia, and nuchal rigidity may accompany the headache. As ICP increases, the patient may become comatose or die.

Management

Management of the patient with a subarachnoid hemorrhage requires that attention be given to maintaining cardiopulmonary function. Airway management and ventilatory support are frequently needed as the patient's level of consciousness and vomiting endanger the airway. The CCTP may also take steps to prevent an unnecessary rise in ICP, such as limiting head movement and elevating the head during transport. Common complications of subarachnoid hemorrhage include rebleeding, which is an occurrence of a second subarachnoid hemorrhage in an unsecured aneurysm, cerebral vasospasm, hyponatremia, and hydrocephalus.

Laboratory Assessment

Laboratory studies, other than routine blood studies, biopsy, and CSF analysis, have not traditionally been used in the diagnosis and management of neurologic emergencies. For most patients, a complete blood count (CBC), basic chemistry panel, coagulation study, and cardiac biomarkers should be obtained.

The CBC serves as a baseline study and may reveal a cause of stroke such as polycythemia or thrombocytosis or provide evidence of a concurrent illness such as anemia. The chemistry panel also serves as a baseline study and may reveal the origin of coma such as hypoglycemia or provide evidence of concurrent illness such as renal insufficiency. Coagulation studies may reveal coagulopathy and are useful when fibrinolytics or anticoagulants are considered for use. Cardiac biomarkers are important because of the association of cerebral vascular disease and coronary artery disease. Finally, a toxicology screening may be useful in selected patients in whom an altered level of consciousness, other abnormal neurologic finding, or vital sign anomalies, such as tachycardia or hypertension, are thought to be caused by a harmful drug or chemical. Chapter 20 discusses toxicologic emergencies.

Axonal Transport

The intracellular transport of protein and organelle materials is essential for all mammalian cells, especially the neuron. Most neuron cell bodies have dendrites on one end and an axon on the opposite

end. Because most neuronal proteins are synthesized in the cell body, mechanisms that direct transport along the axon or along the dendrite are required. Additionally, the distance over which materials have to be moved in the nervous system far exceeds the distances of other cell types because a human motor neuron can exceed a length of 1 m. Finally, even within an individual axon, materials being transported must be targeted to specific compartments.

The feature of neurons that allows the delivery of cellular components to the appropriate site of action is a long-range microtubule-based transport system, which is composed of two key components: the molecular motors that drive the sending of cellular components and microtubules that direct cellular components to the correct site. The type of molecular motor present determines the direction of transport —either away from the cell body and toward the synapse or toward the cell body.

Axonal transport is commonly divided into fast and slow axonal transport based on the bulk speeds of cargo movement. Cellular components such as vesicles and mitochondria move by fast axonal transport speeds, whereas cytoskeleton components move by slow axonal transport speeds.

When transport of materials becomes disrupted, disease can result. Axonal and cell body accumulations of organelles and other proteins are hallmark pathologies for many human neurodegenerative diseases such as Alzheimer's and related diseases, Parkinson's disease, and amyotrophic lateral sclerosis.

Local Anesthetics

Local anesthetics are medications that cause reversible local anesthesia and loss of nociception. They can also be used on specific nerve pathways (nerve block) to produce analgesia and paralysis. Local anesthetics belong to one of two drug classes: aminoamide and aminoester local anesthetics, the difference being in the chemical linkage (amide-linkage or ester-linkage) between the lipophilic part and the intermediate chain of the molecule. Local anesthetics act mainly by inhibiting sodium influx through sodium-specific ion channels in the neuronal cell membrane. When this occurs, an action potential cannot be generated and signal conduction is inhibited.

Seizures and Epilepsy

When a nerve cell is stimulated, its action is transmitted to other cells by excitatory neurotransmitters and balanced by inhibitory neurotransmitters that slow communications. Overactivity by excitatory transmitters or underactivity by inhibitory transmitters can result in a seizure.

Seizure activity can be caused by different factors, such as fever, glucose imbalance, electrolyte imbalances, head injuries and hemorrhagic strokes, and toxins. Epilepsy is a recurrent seizure disorder caused by abnormal discharges in the brain cells. It is often idiopathic. Petite mal seizures should be monitored, but grand mal and focal seizures that may compromise the airway require immediate action.

Management of seizure patients should initially center on maintaining an airway, protecting the patient, and providing oxygen. If the patient is actively seizing, no attempt should be made to restrain him or her. An IV should be established, and the patient's cardiac status should be monitored. Also, the patient's glucose level should be checked, and glucose should be administered if indicated. The patient's temperature should be checked to ensure that fever is not an issue. Body temperature can be lowered by running normal saline, giving acetaminophen (Tylenol), and cooling down without causing shivering. If the patient is actively seizing, an anticonvulsant must be administered. The most common drugs administered during transports are lorazepam (Ativan), diazepam (Valium), and midazolam (Versed). If the patient is seizing and IV access is not possible, rectal diazepam (Diastat) can be administered.

Transport Management

Seizures

- Manage the patient's airway.
- Provide oxygen.
- Do not attempt to restrain the patient if the patient is actively seizing.
- Establish an IV.
- Monitor the patient's cardiac status. Check the patient's blood glucose level and administer glucose if indicated.
- Check the patient's temperature.
- To lower the patient's body temperature, run normal saline, give acetaminophen (Tylenol), and cool down the patient without causing shivering.
- If the patient is actively seizing, administer an anticonvulsant (eg, lorazepam [Ativan], diazepam [Valium], or midazolam [Versed]).
- If the patient is seizing and IV access is not possible, give intranasal, intramuscular, or rectal diazepam (Diastat).
- If the patient has epilepsy, give phenytoin (Dilantin), fosphenytoin sodium (Cerebryx), or, alternatively, carbamazine (Tegretol) or phenobarbital.
- If the patient has a focal seizure, administer etomidate as an induction agent to relax the muscles and allow tracheal access if intubation is necessary.

Patients with a history of epilepsy are most commonly taking phenytoin (Dilantin), which can be given orally or intravenously. If phenytoin is administered IV, it must be given slowly. The maximum rate for phenytoin IV is 50 mg/min (for a 500 mg load, this is 10 minutes; for a 1,000 mg load, this is 20 minutes). If phenytoin is given as a rapid push, it will create severe bradycardia and hypotension. An alternative is fosphenytoin sodium (Cerebryx), which can be given intravenously or intramuscularly. Other first-generation anticonvulsants that may be given are carbamazine (Tegretol) and phenobarbital.

A focal seizure that leaves the patient rigid from the neck up but flaccid from the neck down may compromise the airway in an unconscious patient. The rigidity makes endotracheal intubation impossible, but administering etomidate as an induction agent relaxes the muscles and allows tracheal access.

Transport Considerations

Prior to Transport

Before considering transport, it is imperative that potential complications be anticipated. To this end, it would be advisable to ensure that all diagnostic tests and surgical procedures are completed when at all possible prior to transport.

Although patient-related risk factors are difficult to identify, equipment-related complications (which occur in up to one third of transports) may be controlled more easily. During critical care transport, the following types of equipment may be present:

1. Cardiac monitor, to monitor cardiac status.
2. Ventilator with waveform capnography, to monitor and control ventilation.
3. Infusion pumps, to administer medications.

4. ICP monitoring, to measure and control ICP.
5. Cerebral function monitor, to assess sedation, monitor brain wave activity, predict and monitor seizure activity, and monitor the onset and effectiveness of paralytics.

Complications with equipment would relate to the specific equipment used. For the previously mentioned devices, the following measures can be taken if a malfunction occurs:

1. **Cardiac monitor:** Check for sufficient batteries, charging, general check, and waveform capnography.
2. **Ventilator:** Check for sufficient oxygen and gas supply, ventilator tubing, oxygen and circuit connections, and capnography hookup.
3. **Infusion pumps:** These are usually specific to manufacturers. See the manufacturer's troubleshooting chart.
4. **CFM:** These are usually specific to manufacturers. See the manufacturer's troubleshooting chart.
5. **ICP monitor:** Check for sterility, keep the fluid level, and refer to the manufacturer's troubleshooting manual.

Most interfacility transports do not involve ICP monitoring or CFM monitoring. When ICP or CFM monitoring is utilized, the patients are usually managed with a ventilator, cardiac monitor, and medications administered by IV pump.

Scene and Interhospital Transport Considerations

Apart from intracranial hemorrhage, the major early risks to the patient with head injury are hypoxia and hypertension. The ABCs are always the first priority. The patient with a severe closed head injury should be presumed to have an elevated ICP, and factors that may further increase ICP should be avoided. Some critical care transport systems advocate the use of ear and eye protection for the patient to prevent spikes in ICP as a result of outside stimulus from aircraft or sirens (mostly applicable in seizure patients). Urgent attention to the ABCs will help reduce cerebral hypoxia and hypoperfusion. Normoxia and normocarbia should be achieved as soon as practically possible. ICP can be increased by overperfusion, hypertension, inadequate sedation, hyperpyrexia, and inappropriate anesthetic agents. Intubation and endotracheal suction cause sharp, albeit transitory, spikes in ICP. In patients with reduced volume reserve (hypovolemic), however, these stimuli may initiate a prolonged increase in ICP. Pressure waves may be avoided by adequate fluid resuscitation to maintain CPP. It is important to consider administering sedation at a level that is sufficient to prevent coughing or gagging during transport.

Minimum requirements for monitoring patients during transport are continuous ECG, pulse oximetry, and the intermittent measurement of blood pressure, respiratory rate, and pulse rate. In specific patients, capnometry, continuous blood pressure reading, and further monitoring (such as of ICP and cardiac output and filling pressures) may be beneficial. Unfortunately, many of the complications reported during transport are actually caused by equipment malfunction. It is imperative that the CCTP be familiar with all equipment and monitoring devices in use to ensure optimal patient outcomes and avoid complications from equipment misuse or malfunction.

Of particular importance is the possibility of measuring the major ventilation parameters, such as tidal volume or minute ventilation. Although many transport ventilators do not display actual tidal volumes delivered, judicious use of $ETCO_2$ monitoring allows the CCTP to observe the effects of mechanical ventilation on the patient during transport, and make appropriate adjustments. One possibility to reduce inadvertent ventilation problems may be the use of improved monitoring equipment, particularly equipment that focuses on tidal or minute ventilation. Bearing in mind the limitations of many portable

ventilators, the use of sophisticated transport carts equipped with a standard ICU ventilator and the necessary gas supply should be considered. Such carts can be hooked to the patient bed and moved fairly easily. Monitoring devices and infusion pumps can be implemented into the cart with its battery. Such equipment is being increasingly used during interhospital transport.

In some cases, the hazards of transporting a patient could be prevented by performing diagnostic or therapeutic procedures within the ICU or choosing alternative (albeit equivalently effective) procedures that may render a transport of the patient unnecessary. Such interventions may include the following options:

- Use of chest ultrasound in detecting intrathoracic pathologies
- Introduction of mobile CT scanners that can be used in the ICU
- Application of conventional or dilatational percutaneous tracheostomy in the ICU, instead of transferring the patient to the operating room, for the placement of percutaneous endoscopic gastrostomy tubes and of inferior vena cava filters
- Use of fiber optic pressure monitoring instead of surgical ventriculostomy
- Scheduled reoperations for peritonitis with open abdomen in the ICU

Adverse effects during and after transport of critically ill patients occur all too frequently. Nevertheless, a change in patient management results from about half of the procedures that necessitate transport, indicating good efficiency. Although a few patient-related risk factors can be identified, the rate of equipment-related adverse events may be as high as one third of all transports. Thus, particular attention has to be focused on the personnel, equipment, and monitoring in use.

Table 11-27 lists specific neurologic disorders and conditions, and their treatment during transport.

Flight Considerations

Most fixed-wing aircraft used for medical transport have the ability to pressurize the cabin as the altitude increases and to depressurize the cabin as the altitude decreases. These aircraft have a chart indicating cabin pressure as a function of altitude. It is desirable to come as close to the original ground pressure as possible. If possible, have the pilot fly at altitudes where cabin pressure can be maintained as close to the original departure pressure as possible.

If this is impossible in flight, adjustments must be made. If the patient is intubated, the endotracheal cuff pressure should be decreased with altitude to prevent damage to the trachea and reinflated during descent to prevent leakage. The pressure inside indwelling catheters and colostomy bags must be adjusted to prevent breakage. If the patient has a drain and the ICP is monitored, the ICP must be maintained to less than 20 cm H_2O by draining off excess fluids. If the patient does not have a drain, then the patient must be monitored for any changes in status. If the patient shows changes in respiratory rate or pattern, or develops any changes in cardiac function (ie, arrhythmias or significant changes in heart rate), these signs may indicate herniation and the aircraft must immediately descend to an altitude at which the condition is manageable.

Summary

Management of neurologic emergencies requires an in-depth understanding of brain, spinal, and cranial nerve anatomy and physiology. In addition, the CCTP must be familiar with the complexity of severe TBI, the early recognition of signs and symptoms of TBI, and the associated impact early intervention has on the outcome of these patients.

The CCTP should make every effort to preserve cerebral perfusion and oxygenation as the primary goal in the initial management of neurologic patients. Current guidelines call for careful monitoring of oxygenation and preventing hypoxia by keeping Pa_{O_2} above 60 mm Hg and/or oxygen saturation greater than 90% at all times. Patients who, during field management or transport, exhibit signs and symptoms of cerebral herniation should be initially managed with hyperventilation. Mannitol may be helpful in treating ICP and cerebral herniation, but should be used judiciously given its other physiologic effects. The use of analgesia, sedation, and neuromuscular blockade is critical during transport to minimize the risks associated with the increase in ICP and to maximize safety in the transport setting. Hypoglycemia is a condition of which the CCTP should be mindful when treating neurologic patients, because it may mimic TBI or stroke, and should be considered in all patients with an altered LOC until ruled out by applicable diagnostic and laboratory confirmations.

The treatment of neurologic emergencies is also based on the ability to distinguish between primary and secondary injuries. A large part of managing secondary injuries centers on managing the effects of the injury—namely, CPP and ICP.

A CCTP who is involved in the transport of neurologic patients should be mindful of the complexities. If possible, the majority of diagnostics and/or treatments should be performed prior to transport. Although a number of patient-related risk factors can be identified in any transport involving neurologic transport, the rate of equipment-related adverse events in transport is substantially higher with these types of injuries. This requires careful attention to the personnel, equipment, and monitoring in use at any given time.

TABLE 11-27 Specific Neurologic Disorders and Conditions

Disease	Description	Symptoms and Key Issues	Treatment During Transport
Neuritis	General inflammation of the peripheral nervous system	Can cause pain, paresthesia, paresis, numbness, anesthesia, paralysis, wasting, and disappearance of reflexes	Supportive care and management of pain
Poliomyelitis	Viral disease that can destroy motor neurons (<1% of cases) or cause no symptoms at all (90% of cases)	Transmitted primarily by fecal-oral route; post-polio syndrome can affect polio survivors years after initial infection	Support respiratory effort and body substance isolation
Parkinson's disease	Degenerative disorder of the nervous system normally caused by insufficient formation and action of dopamine	Can cause muscle rigidity, tremor, a slowing of physical movement (bradykinesia) and, in extreme cases, a loss of physical movement (akinesia)	Supportive care
Multiple sclerosis	Autoimmune condition in which the immune system attacks the central nervous system and results in demyelination of neurons	Can cause hypoesthesias and paraesthesias, muscle weakness, muscle spasms, difficulty moving, ataxia, dysarthria, dysphagia, visual problems, fatigue, and chronic pain	Supportive care
Meningitis	Inflammation of the meninges caused by an infection of CSF by bacteria, viruses, fungi, or parasites; non-infectious causes include cancer, SLE, and certain drugs	Can cause headache, nuchal rigidity, photophobia, positive Kernig's and/or Brudzinski's signs, seizures, petechial rash	Supportive care, body substance isolation, and possible monitoring of antimicrobial agent
Encephalitis	Acute inflammation of the brain	Most commonly a viral infection but can be bacterial or parasitic; causes fever, headache, photophobia, weakness, seizure	Supportive care; antiviral agents are not effective (except for herpes origin); and possible monitoring of antimicrobial agent
Bacterial infection	Bacterial infection of brain tissue or CSF	Can lead to encephalitis or meningitis	Possible monitoring of antimicrobial agent
CNS tumors	Intracranial or intravertebral tumors	May be either primary (originating from within the CNS) or secondary (orginating from other organs)	Supportive care
Alzheimer's disease	Most common form of dementia; incurable, degenerative, and terminal disease; characterized by loss of neurons and gross atrophy	Staged according to clinical manifestations -Predementia -Early dementia -Moderate dementia -Advanced dementia	Supportive care

Amyotrophic lateral sclerosis	Progressive, usually fatal, neurodegenerative disease caused by degeneration of motor neurons	Causes muscle weakness and atrophy as motor neurons degenerate	Supportive care; may require ventilatory support
Guillain-Barre syndrome	An acute inflammatory autoimmune disease that results in demyelination	Marked by ascending paralysis	Supportive care; may require ventilatory support; treatment with immunoglobulins or plasmapheresis
Myasthenia gravis	Autoimmune disorder in which antibodies attack acetylcholine receptors at the post-synaptic neuromuscular junction	Causes fluctuating muscle weakness and fatiguability	Supportive care; treatment with cholinesterase inhibitors or immunosuppressants
Neuroleptic malignant syndrome	Rare, but life-threatening idiosyncratic reaction to a neuroleptic medication	All antipsychotic agents, typical or atypical, may be causes; Causes fever, muscle rigidity, altered mental status, and autonomic dysfunction	Supportive care; cooling measures; benzodiazepines may be used
Malignant hypertension syndrome	Acute or ongoing vital target organ damage in the setting of severe hypertension	Hypertension, severe headache, altered mental status, confusion, seizures, nausea/vomiting	Supportive care; anti-hypertensive agent that does not cause CNS effects
Creutzfeldt-Jakob disease	Rare, rapidly progressing, degenerative brain disorder that leads to spongy degeneration of the brain and dementia	Thought to be caused by prions Causes personality changes, anxiety, depression, memory loss, impaired thinking, impaired muscle coordination, blurred vision, insomnia, speech impairment	Supportive care
Bovine spongiform encephalopathy	Transmissible, neurodegenerative, fatal brain disease in cattle	Causes spongy degeneration of brain with severe and fatal neurologic signs and symptoms	No treatment exists
Neurotoxic poisoning	Exposure to a natural or artificial toxic substance that affects the normal activity of the nervous system in such a way as to cause damage to nervous tissue	Can be caused by exposure to chemotherapeutic agents, illicit drugs, heavy metals, and pesticides	Supportive care; specific treatment depends on nature of exposure

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; SLE, systemic lopus erythematosus.

Case Study

YOU AND YOUR CRITICAL CARE TRANSPORT TEAM ARE REQUESTED at the three-bed emergency department of a small community hospital to transfer a 60-year-old woman who was brought in moments ago by local EMS complaining of a severe headache.

As part of your history taking, you interview the patient's husband who is present at her bedside. He reports that his wife had just buried her mother yesterday and has been under a lot of stress dealing with her mother's affairs. He states that she has been complaining of a headache for the past few days, but it has become worse, increasing in severity.

When he arrived home after work, he found her lying on the couch. He states that he dimmed the lights, put a cool washcloth on her forehead, and gave her two aspirins. He went into the kitchen to start preparing dinner when he heard her vomiting. Upon entering the room, he saw that his wife was projectile vomiting and called 9-1-1. On your interview with the patient, she confirms what her husband reported and adds that she has been having blurred vision today as well. She states that she attributed the headache and nausea to stress over her mother's death. While you are obtaining information on her past medical conditions, she reports that she has a history of high blood pressure and has not been taking her medication for the past week, trying to save on money to pay for her mother's funeral. She denies having

any other medical problems or taking any other medications.

Your initial physical exam of the patient reveals a normal GCS score of 15. She is able to follow complex commands and move all extremities. She has no decreased level of consciousness and has equal strength bilaterally in all extremities, and all of her cranial nerves are intact. Her blood pressure is 192/110 mm Hg, consistent with the emergency department measurements. She is on a cardiac monitor, which reveals a heart rate of 95 beats/min, with normal sinus rhythm. Her respiratory rate is 18 breaths/min, and her lungs are clear to auscultation in all lung fields. Oral temperature is 99.6°F. She rates her headache a 10 on a scale of 1 to 10, with 10 being the worst pain in her life.

The patient is prepared for transport. The emergency department staff has placed the patient on 2 L of oxygen via nasal cannula. An IV has been placed in the patient's right antecubital vein, infusing normal saline at a keep-the-vein-open rate. She is placed on the stretcher with the head of the bed elevated at 45°. You and your team load the patient into your critical care ambulance and initiate seizure precautions during the transport. She is transported to the referral hospital.

1. What is going on with this patient?
2. Why is the head of the bed elevated at a 45° angle?
3. Why are seizure precautions initiated and what does the seizure precaution entail on the ambulance?
4. What are some possible complications that could occur during the transport of this patient and how would the critical care transport team handle them?

On arrival to the emergency department of the referral center, the patient has a grand mal seizure. An emergency CT scan of her head was ordered, which revealed a small, right subarachnoid hemorrhage with bleeding into the suprasellar cistern, indicating a grade 2 subarachnoid hemorrhage. (A grading scale for the classification of cerebral aneurysm was developed in 1968 by Drs Hunt and Hess. The grading scale ranges from grade 1, an asymptomatic or minor headache, to grade 5, a deep coma.) Neurosurgery was consulted and a cerebral angiogram was ordered. The cerebral angiogram revealed a 4-mm, berry-shaped, right middle cerebral aneurysm located at a bifurcation.

The patient was admitted to the neurosurgery intensive care unit and was scheduled for surgery the next morning. A clipping of the right middle cerebral artery was performed without complication. An intraventricular catheter was placed to monitor the patient's ICP. The surgeon's postoperative order stated to maintain a systolic blood pressure of 140 mm Hg or lower, to perform hourly neurologic exams, and to maintain an ICP of less than 15 mm Hg and a CPP of greater than 80 mm Hg. The patient remained on the ventilator until the following morning when a postoperative CT scan was performed. The scan revealed no complications and no recurrence of bleeding. She was extubated that day and was discharged home 6 days later without further complications.

5. What are some of the common reasons for an individual to develop a cerebral aneurysm?
6. List the three major postoperative complications that may occur following a cerebral aneurysm.

Analysis

The patient has a cerebral aneurysm. Elevating the head of the bed will help reduce increased ICP.

Seizure precautions include the following: Avoiding the use of lights and sirens; keeping lights dimmed in the compartment; padding side rails of the patient's stretcher; verifying that airway equipment is readily available, such as oxygen delivery systems, nasal and oral airways, Ambu-bag and mask, suction, catheters, and suction equipment; and being prepared to administer diazepam or lorazepam.

Possible complications in this patient include increased ICP, hypertension, respiratory depression and failure, and brain herniation. Hypertension should not be treated during transfer unless directed by the

receiving facility or neurosurgeon. The reason for this hypertension state is to provide increased cerebral perfusion to any potentially vasospastic areas. In general, patients should be maintained normotensive with a systolic blood pressure of 110 to 160 mm Hg. Keeping the head of the bed elevated and avoiding overstimulation of the patient will help in the reduction of ICP.

Patients with respiratory depression and failure may require rapid-sequence intubation. Patients with a potential increased ICP should be premedicated with a 1 mg/kg IV push of lidocaine and a defasciculating dose of vecuronium at 0.01 mg/kg IV push at least 2 minutes prior to intubation (doses may vary based on local protocol). (Defasciculating doses of nondepolarizing neuromuscular blockers consist of roughly one tenth the full intubating dose and provide enough blockade to prevent muscle fasciculations.) Lidocaine will blunt sympathetic responses to intubation and limit the associated increase in ICP, but it does not sedate the patient; it is cruel to paralyze and intubate an awake patient. A sedative should always be used unless the patient is comatose. Both lidocaine and etomidate can be used together, if necessary. Vecuronium, unlike succinylcholine, does not cause fasciculation, which is the involuntary contraction or twitching of muscle fibers that increases ICP. Etomidate may be used as an alternate induction agent. It is a hypnotic and will not cause an increase in ICP, but it is contraindicated in patients younger than 10 years. If etomidate is used, lidocaine will not be required.

Levels of $PaCO_2$ should be maintained between 36 and 42 mm Hg. Hyperventilation should be avoided unless the patient shows signs of herniation.

The causes of cerebral aneurysms include neoplastic disease, atherosclerosis, brain trauma, infection, and congenital defects. Cerebral aneurysms are usually surgically repaired by blocking the aneurysm off from the circulation with a clip, a procedure called clip ligation.

Potential postoperative complications of a cerebral aneurysm include recurrence of bleeding (especially in the first 24 hours), cerebral vasospasm, and electrolyte disturbances, such as hypernatremia. Vasospasm decreases blood flow to the brain and causes the death of nerve cells, so medication may be administered to prevent it. The patient may be given medications to address other potential complications as well.

Prep Kit

Ready for Review

- A large majority of neurologic patients who require transport will have traumatic brain injury (TBI).
- The nervous system can be divided into the CNS, which consists of the brain and spinal cord, and the PNS, which consists of the spinal and cranial nerves.
- Afferent pathways (ascending pathways) carry sensory impulses toward the CNS; efferent pathways (descending pathways) carry motor impulses away from the CNS to effector organs, such as muscles (smooth and skeletal) or glands.
- The voluntary (somatic) nervous system is composed of nervous system fibers that connect the structures of the CNS with skeletal muscles and the integument; the involuntary (autonomic) nervous system is divided into the sympathetic and parasympathetic branches.
- The brain is a very delicate substance that requires the protection afforded by the skull. Although the skull is primarily protective, excessive forces can cause a fracture to the adult skull and force bone fragments into the vulnerable brain tissue.
- Openings at the base of the skull (foramina) allow cranial nerves and blood vessels to enter and exit the cranial cavity. These openings also weaken the area, leaving it susceptible to fracture.

- The cranial meninges consist of three layers: the dura mater (a two-layer structure adherent to the internal surface of the cranium), the arachnoid mater (a thin layer loosely enclosing the brain), and the pia mater (a vascular membrane that adheres to the surface of the brain and follows its contours).
- The lateral ventricles extend from the frontal lobe to the occipital lobe of the brain. They are important structures for ICP monitoring, CSF drainage, or placement of a CSF shunt.
- CSF fills the ventricular system and surrounds the brain and spinal cord in the subarachnoid space. It protects the CNS by acting as a shock absorber for minor acceleration and deceleration and helping to remove waste products from cerebral tissue.
- Any obstruction to the normal flow of CSF may produce high CSF pressure and lead to brain damage.
- The cerebrum consists of two cerebral hemispheres, which are themselves divided into four paired lobes: the frontal, parietal, temporal, and occipital lobes.
- The brain stem acts as a bridge between the cerebral hemispheres and the spinal cord; all motor and sensory fibers travel through this structure. The brain stem consists of three parts: the midbrain, the pons, and the medulla oblongata.
- The cerebellum, which coordinates voluntary movement, consists of three major parts: the cortex, the white matter, and four pairs of deep cerebellar nuclei.
- The reticular formation, which is composed of both motor and sensory tracts, includes centers for blood pressure, respiration, and heart rate function.
- The overall goal of cerebral circulation is to provide enough blood to supply oxygen, glucose, and nutrients so that oxidation of glucose can take place.
- The blood-brain barrier regulates the transport of nutrients, ions, water, drugs, and waste products to and from the brain through the process of selective permeability.
- The spine usually consists of 33 irregular bones (vertebrae) articulating to form the vertebral column; these skeletal components are stabilized by both ligaments and muscle.
- Flexion of the vertebral column beyond the range of 60% to 70% may damage structural ligaments and allow excess vertebral movement that could expose the spinal cord to injury.
- The spinal cord transmits nerve impulses between the brain and the rest of the body. The 31 pairs of spinal nerves emerge from each side of the spinal cord and are named for the vertebral region and level from which they arise.
- The sympathetic nervous system is controlled by the brain's hypothalamus. A spinal cord injury at or above the level of T6 may disrupt the flow of sympathetic communication.
- When the sympathetic nerves are stimulated and produce autonomic dysreflexia, the parasympathetic nerves attempt to control the rapidly increasing blood pressure by slowing the heart rate.
- The foundation of neurologic care is a thorough serial assessment, which not only allows the tracking of patient trends, but also may allow the CCTP to identify which parts of the system are damaged.
- The neurologic field diagnosis of the impaired patient is divided into four main segments: mental status, cranial nerves, motor and cerebellar, and sensory.
- The history focuses on the patient's chief complaint. If taking a history from the critically ill patient is not possible, the CCTP must obtain information from secondary sources—other EMS reports, emergency department charts, medical records from previous admissions, and family and friends.
- The mental/emotional component of the neurologic examination assesses the patient's ability to understand and interact with the environment by addressing the level of consciousness; general

behavior; and thought process, including memory, attention and concentration, abstract thought, and judgment.

- Awareness and arousal are the fundamental constituents of consciousness and should be evaluated and documented repeatedly.
- Arousal is assessed initially by the AVPU scale. The GCS is then commonly used to document and trend a patient's level of arousal over time.
- In evaluating the patient's awareness, the CCTP should assess the patient's orientation to time, place, and person.
- A variety of neurologic pathologies—including pain, hypoxia, anxiety, and expanding intracranial lesions—may initially manifest themselves through changes in general behavior.
- The Mini-Mental State Examination is a simple, easily applied test of higher cognitive functions that consists of a series of questions testing orientation, registration, attention and calculation, recall, and language.
- Abnormalities of speech can reflect dysfunction in any component or process of communication. For example, aphasia encompasses any loss or impairment of language function as a result of brain damage.
- In some cases, the CCTP may perform assessment of cranial nerves, motor function, and sensory function; reflex testing; and evaluation of meningeal irritation if there was not much time for initial assessment or if there is time during transport.
- Certain nerves are more commonly tested in patients who are critically ill or injured: optic (CN II), oculomotor (CN III), trochlear (CN IV), trigeminal (CN V), abducens (CN VI), facial (CN VII), acoustic (CN VIII), glossopharyngeal (CN IX), vagus (CN X), and hypoglossal (CN XII).
- Cranial nerve I, which is responsible for olfaction, should be assessed in cases in which head trauma has occurred, when pathology at the base of the skull is suspected, and in patients who exhibit an altered mental status.
- Each eye should be evaluated individually to assess the optic nerve. The tests should include evaluation of visual acuity, visual fields, and the fundi.
- The two parameters that should be closely observed by the CCTP in relation to the oculomotor, trochlear, and abducens nerves are the position of the eyeball and the position of the upper eyelid.
- The motor portion of the facial nerve is tested by instructing the patient to wrinkle the forehead, to close the eyelids tightly, to smile or grimace showing the teeth, and to whistle.
- The vestibular division of the acoustic nerve is assessed using rotational and caloric stimuli; this evaluation is performed to determine the brain stem function of unconscious patients.
- To test the glossopharyngeal and vagus nerves, the CCTP should direct the patient to open his or her mouth and say, "Ah."
- To assess the hypoglossal nerve, the CCTP observes the tongue for fasciculations and atrophy, tests for muscle strength by having the patient push the tongue against the inside wall of the cheek, and checks for tongue protrusion.
- The motor examination includes a consideration of muscle tone and strength, during which the CCTP puts the muscles through the normal range of motion.
- As part of the assessment of sensory function, pain, temperature, and touch should be examined and documented.

- The most common pathological reflexes, all of which indicate pyramidal tract disease, include the plantar response, Babinski's sign (the most important), Oppenheim's sign, Gordon's sign, and Hoffmann's sign.
- Signs of meningeal irritation include generalized throbbing headache progressing in severity, progressive photophobia, and nuchal rigidity.
- The centers for control of vital functions are found within the brain stem, so changes in vital signs can signal changes in the patient's overall neurologic status.
- The CCTP should repeatedly check the following physiological variables: blood pressure, heart rate and rhythm, respiratory rate, pulse oximetry, end-tidal carbon dioxide, central venous pressure, temperature, and ICP.
- When assessing the critical care patient's respirations, pay particular attention to the rate, rhythm, and characteristics of the inspiratory and expiratory phases.
- The patient's heart rate may indicate not only probable neurologic injury, but also the presence of other pathologic processes. The CCTP should be especially mindful of the presence of tachycardia, bradycardia, or arrhythmias.
- Hypertension is the effect on blood pressure most often seen as a result of neurologic injury, especially in case of increased ICP.
- Alterations in body temperature—hypothermia or hyperthermia—are possible in the presence of neurologic injury, especially if the hypothalamus is involved.
- Two types of TBI are distinguished: primary (direct) injury, in which traumatic forces cause physical or functional disruption of brain tissue; and secondary (indirect) processes, which occur after injury and lead to brain dysfunction or cellular damage (eg, hypoxia and ischemia).
- Primary brain injury can occur as a result of two mechanisms: contact phenomena injuries (direct trauma to the head) and acceleration-deceleration injuries (sudden changes in velocity).
- Secondary injury involves more delayed mechanisms of brain damage and, if left uncorrected, will adversely affect brain function integrity.
- Cerebral perfusion pressure (CPP) is the primary determinant of blood flow to injured brain tissue when an injury has impaired the ability of the cerebral circulation to autoregulate in response to fluctuations in systemic blood pressure.
- Common injuries to the scalp include abrasions, contusions, lacerations, and avulsions. Treatment usually focuses on controlling bleeding, cleaning and dressing the area, and, in case of avulsions, evaluating for fractures.
- Skull fractures occur as a result of a direct, and often highforce, blow to the cranium; they are present in more than 50% of patients with a severe TBI.
- Fractures of the bones of the face may indicate possible underlying brain injury.
- To perform the halo test for leaking CSF, collect escaping fluid from the nose, mouth, or ears onto a gauze pad. The appearance of a "target" or "halo" symbol consisting of a dark red circle surrounded by a lighter yellowish one is considered a positive halo sign.
- The development of raccoon eyes (periorbital ecchymosis) and Battle's sign (retroauricular ecchymosis) may take several hours to develop post-injury.
- Many facial injuries have very grotesque presentations accompanied by copious bleeding and may potentially distract the CCTP from other, more serious injuries.

- Mandible fractures can cause life-threatening airway compromise if the patient is in the supine position.
- Airway control is the first assessment priority with facial injuries. After the airway has been secured, the CCTP can assess for the presence of facial fractures by grasping the hard palate and rocking it back and forth. The CCTP should also check for malocclusion and dental trauma, test extraocular muscles to rule out orbital fractures, and look for facial elongation and periorbital ecchymosis.
- Injuries to the brain can be either focal (lesions large enough to be observed directly) or diffuse (eg, concussions and diffuse axonal injuries).
- Types of focal injuries include contusion (bruising of the brain tissue), hematoma (epidural, subdural, or intracerebral), swelling, infarct, pressure necrosis, and abscess.
- Types of diffuse injuries include axonal injury, hypoxia/ischemia, diffuse vascular, fat embolism, subarachnoid, and meningitis.
- Treatment for patients with cerebral contusions and lacerations is largely supportive and includes monitoring for—and aggressively treating—evidence of rising ICP as a result of hematoma formation.
- An epidural hematoma (EDH) is an injury resulting in the accumulation of blood between the inner periosteum and the dura mater. The patient with an EDH may present with a history of a brief period of unconsciousness, followed by a lucid period lasting for minutes to several hours, which ends with a rapid deterioration of consciousness from drowsiness, to lethargy, and to coma as a mass effect and herniation develop.
- Mannitol is an osmotic diuretic that can reduce the increased ICP resulting from an increase in CSF and reduce intraocular pressure. It does not reduce the volume of blood accumulated by the bleed in the case of an EDH.
- High-energy impacts may result in a subdural hematoma (SDH)—bleeding that accumulates between the dura mater and arachnoid mater. These injuries are six times more common than EDHs and have a higher mortality rate.
- Intracerebral hemorrhages often occur in the same areas as cerebral contusions. They produce headaches, deteriorating levels of consciousness, hemiplegia on the contralateral side, and dilated ipsilateral pupils.
- Patients with a subarachnoid hemorrhage (SAH) often describe their pain as “the worst headache in my life” and are likely to have hypoxia, hypotension, and higher ICP. Signs and symptoms of SAH include altered mental status, coma, paralysis, slurred speech, mood changes, and seizures.
- Signs and symptoms of concussion (mild TBI) include loss of consciousness, loss of memory for events immediately before or the event that precipitated the injury, altered mental status, and focal neurologic deficits.
- The clinical presentation of diffuse axonal injury includes a sequence of events beginning with immediate unconsciousness, leading to a longer period of confusion and associated posttraumatic amnesia, and followed by a protracted recovery time. Treatment is supportive.
- In adults, the normal ICP is 0 to 15 mm Hg. Increased ICP may be precipitated by intracranial bleeding, cerebral edema, mass formation, or inability to regulate the production and removal of CSF.
- Many physiologic factors may alter cerebral blood flow (CBF). Increases in CBF as a result of hypoxia or hypercapnia (increased levels of CO_2 in blood), for example, will cause an increase in ICP once the normal compensating mechanisms have been exhausted.
- Poor airway and ventilatory control contribute to hypoxia, hypercapnia, and hypotension, and will

further damage the already critically ill brain.

- CPP is responsible for the movement of blood through the brain. The homeostatic mechanisms that manage CPP are often lost after head trauma, such that the patient with TBI may have increased cerebral vascular resistance, making the brain more susceptible to changes in blood pressure.
- CPP should be maintained between 50 and 70 mm Hg—by using fluids and pressors if necessary—to reduce the risk of poor outcomes for patients with increased ICP.
- The CCTP should perform serial neurologic examinations to monitor for increased ICP, especially for patients with TBI.
- The CCTP may also be required to maintain invasive neurologic monitoring devices; it is the responsibility of each CCTP to become familiar with all aspects of each device prior to using it on a patient.
- Increased ICP is a sustained elevation in pressure above 20 mm Hg. The most common causes of increased ICP are cerebral bleeding, tumors, hydrocephalus, and trauma.
- Cushing's triad is the combination of progressively increasing systolic blood pressure with progressively decreasing diastolic blood pressure (widening pulse pressure) and bradycardia.
- Respiratory changes noted with increased ICP include Cheyne-Stokes respirations (with midbrain involvement), sustained hyperventilation (with midbrain and pons involvement), and rapid and shallow respirations followed by ataxic breathing (with upper medulla involvement).
- Increased ICP produces pulmonary edema as a result of increased sympathetic activity as a result of the effects of the raised ICP on the hypothalamus, medulla, or cervical spinal cord.
- Brain herniation is a condition in which a portion of the brain is displaced because of increased ICP, resulting in progressive damage to brain tissue that may include life-threatening damage to the brain stem. Transport management includes intubation, mechanical ventilation, administration of an osmotic diuretic (eg, mannitol), possibly corticosteroids, and rapid transport.
- The primary goals of ICP monitoring are identification of ICP trends and evaluation of therapeutic interventions to minimize ischemia in the brain-injured patient.
- Contraindications to ICP monitoring include CNS infection, coagulation defects, anticoagulant therapy, scalp infection, severe midline shift resulting in ventricular displacement, and cerebral edema resulting in ventricular collapse.
- Noninvasive ICP monitoring involves assessment for clinical deterioration in neurologic status, evidenced by signs such as bradycardia, increased blood pressure, and pupillary dilation.
- Intraventricular monitoring is one of the most popular techniques for invasive ICP monitoring. It is also therapeutic, because it provides the ability to drain CSF; any fluid drained must be monitored for amount, color, and clarity at hourly intervals.
- A subarachnoid screw ("bolt") may be used to monitor ICP, although its accuracy is less than that of the more direct ventriculostomy drain.
- Patients with TBI should be intubated to protect the airway and allow maximal oxygenation. Standard monitoring for all such patients is required, including oxygen saturation, ECG, mean arterial pressure, and urine output.
- Normocapnia (normal carbon dioxide tension) is vital for maintenance of ICP, and patients should have continuous measurement of $ETCO_2$ levels using a capnometer.
- Potential complications of ICP monitoring include intracranial infection, intracerebral hemorrhage, air

leakage into the ventricle or subarachnoid space, CSF leakage, overdrainage of CSF (leading to ventricular collapse and herniation), occlusion of the catheter with brain tissue or blood, and inappropriate therapy because of erroneous ICP readings.

- Brain tissue oxygen tension monitoring is accomplished by placement of a commercial probe (capable of measuring temperature and oxygenation) into the brain tissue through a bolt. This type of monitoring is relatively sensitive for monitoring focal disruption of blood flow to particular areas of the brain.
- To minimize the risk that an infectious agent will enter the CNS during ICP monitoring, aseptic technique must be used at all times when assembling, manipulating, or accessing the fluid-filled monitoring system.
- To ensure optimal accuracy, proper leveling and zeroing of the ICP monitoring system must be maintained.
- Avoid flexion and hyperextension of the neck and positioning the patient in a Trendelenburg position when conducting ICP monitoring. Simultaneous drainage and pressure monitoring are not recommended.
- Notify the physician immediately if the patient shows signs of decompensation—altered LOC, restlessness, agitation, lethargy, confusion, motor weakness, seizures, alteration in breathing pattern, increases in blood pressure, bradycardia, vomiting, decortication/decerebration, or coma.
- The best treatment for increased ICP is the removal of the causative lesion (eg, tumor, hydrocephalus, or hematoma). In the field, treatment is aimed at preventing the secondary events associated with increased ICP; it focuses on reducing ICP and providing rapid transport to a neurologic facility for definitive treatment.
- First-line management consists of general measures aimed at making the neurologic patient comfortable (including adequate analgesia), along with effective handling of the ABCs of trauma management.
- Second-line management of increased ICP involves induced cerebral vasoconstriction, which may take the form of hyperventilation, hyperbaric oxygen, or hypothermia. Osmotherapy consisting of mannitol, glycerol, urea, or furosemide may also be implemented.
- Anesthetic agents, including barbiturates, gamma-hydroxy-butyrate, and etomidate, and paralytic agents may also be used in the event of increased ICP.
- Hyperventilation aims at keeping the P_{CO_2} between 25 and 30 mm Hg, so that CBF falls and CBV is reduced, thereby reducing ICP. Prophylactic hyperventilation is not recommended.
- Acute injuries of the spine are classified according to the associated mechanism, location, and stability of the injury.
- Stable vertebral fractures do not involve the posterior column; therefore, they pose less risk to the spinal cord. Unstable injuries involve the posterior column of the spinal cord and carry a higher risk of complicating SCI and progression of injury without appropriate treatment.
- Flexion injuries result from forward movement of the head, typically as the result of rapid deceleration (eg, in a car crash), or from a direct blow to the occiput. Rotationflexion injuries, which often result from high acceleration forces, can produce a stable dislocation in the cervical spine. Hyperextension of the head and neck can result in fractures and ligamentous injury of variable stability.
- Vertical compression injuries typically result from a direct blow to the crown (parietal region) of the skull or rapid deceleration from a fall through the feet, legs, and pelvis. Forces transmitted through the vertebral body cause fractures, ultimately shattering and producing a “burst” or compression fracture with or without associated SCI; patients may also develop herniation of disks, subsequent compression

on the spinal cord and nerve roots, and fragmentation into the canal.

- Primary spinal cord injury—injury that occurs at the moment of impact—can involve either penetrating or blunt trauma. Penetrating trauma typically results in transection of nonregenerative neural elements and complete injuries; blunt trauma may displace ligaments and bone fragments, resulting in compression of points of the spinal cord or an incomplete dislocation of the vertebral body. Spinal cord concussion, spinal cord contusion, and cord laceration are all types of primary spinal cord injury.
- Secondary spinal cord injury occurs when multiple factors permit a progression of the primary SCI and result in further deterioration. These effects can be exacerbated by exposing neural elements to further hypoxemia, hypoglycemia, and hypothermia.
- The CCTP should minimize the chance of secondary SCI through stabilization (ie, spinal motion restriction and neutral alignment). Minimizing heat loss and maintaining oxygenation and perfusion are other key elements in the care of a patient with a possible SCI.
- Because many SCIs can be so severe that they threaten life and leave the patient with a lifelong disability, CCTPs must always take the necessary precautions and properly immobilize trauma patients as indicated.
- Immediate attention to manual stabilization of the cervical spine is imperative, until a cervical collar and backboard can be placed. In most cases, the patient will be transported to the accepting facility in a supine position on the backboard.
- In conjunction with manual stabilization of the cervical spine, evaluation of the patient's airway must be done. While maintaining in-line stabilization of the spine, any blood or secretions present in the airway must be suctioned, and the preparation for a definitive airway must be done.
- The management of a patient with SCI should be treated as a true neurologic emergency, and the CCTP should make every effort to rapidly assess, treat, and transport the patient to the closest appropriate facility while maintaining in-line stabilization of the spinal column.
- Short-acting, reversible sedatives are recommended for the acute agitated patient after a correctible cause of agitation (eg, hypoxia) has been excluded.
- Acute-phase complications of SCI include the potential for aspiration or respiratory arrest, especially with high cervical injuries.
- Autonomic dysreflexia is evidenced by hypertension, headache, blurred vision, anxiety, cool clammy skin, and sweating above the injured site. Treatment consists of identifying and treating the cause (ie, repositioning the patient and checking the bladder and bowels for irritation or obstructions) and reducing the blood pressure with a beta-blocker.
- Stroke occurs as a result of disruption of blood flow to the brain that results in a neurologic deficit persisting for more than 24 hours. When deficits completely resolve within 24 hours, the event is referred to as a transient ischemic attack.
- Types of stroke include ischemic (caused by occlusion of a blood vessel by a thrombus or embolus), thrombotic (caused by accumulation of atherosclerotic plaques inside cerebral blood vessels that block blood flow), embolic (occurring when an embolus lodges in a smaller cerebral vessel), focal ischemic (caused by ongoing reduction of blood flow to already ischemic cells), and global ischemic (caused by severe hypotension or cardiac arrest that produces a transient drop in blood flow to all areas of the brain).
- The characteristic sign of stroke is the sudden onset of focal neurologic signs that oftentimes occur in combination.

- The CCTP can use abbreviated prehospital tools to identify patients suffering from stroke, such as the Cincinnati Prehospital Stroke Scale or the Los Angeles Prehospital Stroke Screen (LAPSS).
- Once stroke is suspected, the CCTP should determine the time of symptom onset.
- The CCTP should support the stroke patient's cardiopulmonary function, provide continuous monitoring of neurologic function, and maintain normal blood glucose levels.
- Frequent reassessment of airway and respiratory function is needed to avoid hypoxemia in stroke patients; supplemental oxygen may be given to hypoxemic patients.
- If a stroke patient's symptoms do not resolve, a CT scan shows no hemorrhage, and the symptom onset is within 3 hours, fibrinolytic therapy (tPA) may be used to restore circulation to ischemic brain tissue.
- Intracerebral hemorrhage is bleeding directly into the cerebral tissue. The most common cause of spontaneous intracerebral hemorrhage is hypertension-induced vessel rupture. Symptoms include local neurologic dysfunction, severe headache, nausea, and vomiting. As the ICP continues to rise, the patient may lose consciousness and require ventilatory support. Intubation may be necessary, and orders may be given to reduce blood pressure so as to decrease ongoing bleeding.
- The patient with a subarachnoid hemorrhage (typically caused by either an aneurysm or an arteriovenous malformation) characteristically has an abrupt onset of pain, sometimes accompanied by loss of consciousness, nausea, vomiting, focal neurologic deficits, photophobia, and nuchal rigidity. As the ICP increases, the patient may become comatose or die.
- Management of the patient with a subarachnoid hemorrhage requires measures to maintain cardiopulmonary function, manage the airway, provide ventilatory support (if necessary), and limit movement of the patient's head.
- Seizure activity can be caused by fever, glucose imbalance, electrolyte imbalances, head injuries and hemorrhagic strokes, and toxins.
- Epilepsy is a recurrent seizure disorder caused by abnormal discharges in the brain cells.
- Management of seizure patients focuses on the ABCs and administration of an anticonvulsant, if the patient is actively seizing.
- Minimum requirements for monitoring patients during transport are continuous ECG, pulse oximetry, and the intermittent measurement of blood pressure, respiratory rate, and pulse rate.
- Other pieces of equipment that should be available—and working properly—to monitor the neurologic patient during transport include a cardiac monitor, a ventilator with waveform capnography, infusion pumps, an ICP monitor, and a cerebral function monitor.
- Apart from intracranial hemorrhage, the major early risks to the patient with head injury are hypoxia and hypertension. For this reason, management of the ABCs is always the first priority.
- The biggest challenge when transporting patients by aircraft is dealing with pressure variations and oxygen availability at increasing altitudes. Oxygen content in pressurized cabin air is less than that at normal ground level, so be prepared to administer supplemental oxygen to nonintubated patients.

Vital Vocabulary

afferent pathways Ascending pathways that carry sensory impulses toward the central nervous system.

aneurysm A weakened portion of the wall of an artery where the blood creates a localized dilation or bulge; can involve the wall intact or be classified as dissecting, in which the artery wall ruptures and blood pools between the inner and outer artery wall.

anterior cord syndrome Displacement of bony fragments into the anterior portion of the spinal cord, often as the result of flexion injuries or fractures, that disrupts blood flow in the anterior spinal artery.

aphasia Any loss or impairment of language function as a result of brain damage.

arachnoid mater The middle layer of the meninges, which contains blood vessels that give it the appearance of a spider web.

arteriovenous malformation (AVM) Abnormally formed blood vessels that have a higher rate of bleeding than average vessels.

autonomic dysreflexia A potentially life-threatening complication of spinal cord injury that results from the loss of parasympathetic stimulation. It is characterized by a massive, uninhibited, uncompensated cardiovascular response as the result of some stimulation of the sympathetic nervous system below the level of injury. Also called autonomic hyperreflexia.

axonal transport The movement of organelles and proteins along a nerve cell axon into and out of the cell body.

basal ganglia Masses of nuclei located deep in the cerebral hemispheres that play a major role in fine motor function.

basilar skull fracture A fracture along the base of the skull.

Battle's sign Migration of blood to the mastoid region, posterior and slightly inferior to the ear, resulting in discoloration; also called retroauricular ecchymosis.

blood–brain barrier A network of endothelial cells and astrocytes (neuroglia) in the brain that regulate the transport of nutrients, ions, water, drugs, and waste products to and from the brain through the process of selective permeability.

brain herniation Displacement of a portion of the brain from its correct location within the cranial cavity to a different location.

brain tissue Compliance The change in brain volume resulting from a change in pressure.

brain tissue oxygen tension ($P_{br}o_2$) A method of monitoring temperature and oxygenation via placement of a commercial probe into the brain tissue through a bolt; can be done simultaneously with ICP monitoring placement.

Broca's area Part of the frontal lobe that is located at the inferior frontal gyrus and that participates in the formulation of words.

Brown-Sequard syndrome Loss of function as a result of penetrating trauma accompanied by hemisection of the spinal cord and complete damage to all spinal tracts on the involved side; characterized by loss of motor function and sensation of light touch, proprioception, and vibration on the ipsilateral side and temperature and pain sense on the contralateral side.

caloric test A method for assessing vestibular function that involves the raising and lowering of the temperature in the external auditory canal; also called Bárány test.

cauda equina The collection of individual nerve roots into which the spinal cord separates at the L2 vertebra.

central cord syndrome A syndrome in which cavities form in the central portions of the spinal cord, usually in the cervical area; may be due to a tumor, genetic origin, or trauma; presents along with hemorrhage or edema to the central cervical segments.

cerebral angiography A procedure that uses imaging and a contrast material or dye to view the blood

vessels in the brain and is used to find abnormalities.

cerebral aqueduct The narrowest portion of the brain's ventricular system; it provides communication with the fourth ventricle, which lies between the brain stem and the cerebellum.

cerebral blood flow (CBF) The amount of blood flow the brain requires to maintain homeostasis. In a 24-hour period, the brain requires 1,000 L of blood to obtain 71 L of oxygen and 100 g of glucose.

cerebral cortex The outermost layer of the cerebrum.

cerebral function analysis monitor (CFAM) A device that can provide summed, averaged, and analyzed outputs of the general state of brain activity.

cerebral function monitor (CFM) A device that can provide summed and averaged outputs, but not analysis, of the general state of brain activity.

cerebral hemispheres The name for each half of the brain (right or left), each of which contains one of the paired lobes (occipital, parietal, temporal, and frontal).

cerebral metabolic rate for oxygen ($CMRO_2$) A measurement used to determine neuronal demand for oxygen. Neurons with high activity rates require greater amounts of oxygen.

cerebral perfusion pressure (CPP) The pressure gradient across the brain; it provides an estimate of perfusion adequacy: CPP = MAP – ICP.

choroid plexus A cluster of nerve roots at the lateral and the third and fourth ventricles of the brain that produce cerebrospinal fluid.

circle of Willis A system of arteries located at the base of the skull that (in most people) is able to compensate for reduced blood flow from any one of the major contributors to cerebral circulation.

comminuted fracture A type of skull fracture in which the skull is splintered or shattered into many pieces.

complete spinal cord injury A complete disruption of all tracts of the spinal cord, with permanent loss of all cord-mediated functions below the level of transaction.

computed tomography (CT) A type of scan that provides a mathematically reconstructed view of multiple cross-sections of the body, including the brain; performed on almost every patient with abnormal neurologic findings.

conjugate movement Movement of both eyes together in the same direction.

contact phenomena injuries Injuries that occur as the direct result of trauma to the head, including local effects such as scalp laceration, skull fracture, hematoma, and intracerebral hemorrhage.

contrecoup injury A situation in which an impact occurs on one side of the head, causing the brain to move within the cranial vault and forcibly contact the opposite side of the skull, resulting in damage on that side of the brain; also called transitional injury.

corpus callosum A large tract of transverse fibers that provides a communication link between the two cerebral hemispheres.

cranial nerves (CN) The 12 nerves arising directly from the brain that govern many of the senses and the functions of muscles in the eyes, face, and pharynx.

Cushing's triad A cascade of events provoked when intracranial pressure rises to the level of the arterial pressure, vasoconstriction occurs in an effort to shift fluid volumes in the cranium, and the ensuing brain displacement puts pressure on the medulla oblongata by pushing it into the foramen magnum, resulting in disturbances in breathing, heart rate, and blood pressure.

delayed traumatic intracranial hemorrhage (DTICH) Hemorrhage that occurs within the first 3 to 10 days following an injury to the occipital-parietal region via a coup-contrecoup mechanism.

depressed skull fracture A type of skull fracture in which a portion of the skull is depressed; the scalp and/or dura may or may not be torn.

diaphragma sellae An extension of the dura mater that forms a roof over the sella turica, which contains the pituitary gland.

diastatic stellate fracture A fracture involving injury to a bone with separation of an epiphysis; prevalent in abused children.

diencephalon Portion of the cerebrum consisting of the thalamus, the hypothalamus, the subthalamus, and the epithalamus.

diffuse axonal injury (DAI) A deep-brain injury in which shearing forces damage the integrity of the axon at the node of Ranvier, which consequently alters the axoplasmic flow.

diplopia Double vision.

doll's eye test An oculocephalic reflex test that is performed on the unconscious patient by rapidly rotating the head from side to side and observing the eye movement.

dorsal Toward the back surface of an object; posterior.

dural venous sinuses Endothelial-lined spaces between the periosteal and meningeal layers of the dura mater.

dura mater The outer membrane of the meninges.

dysconjugate movement Lack of symmetric movement between the two visual axes.

Edinger-Westphal nucleus Part of the midbrain that is responsible for mediating the autonomic reflex centers for pupillary accommodation to light.

efferent pathways Descending pathways that carry motor impulses away from the central nervous system.

electroencephalography (EEG) A procedure that records the electrical activity of the brain by measuring brain waves.

embolic stroke Occurs when a blood clot, known as an embolus, forms in one part of the body and travels through the bloodstream to the brain or neck.

epidural hematoma (EDH) An injury resulting in the accumulation of blood between the inner periosteum and the dura mater; also called extradural hematoma.

epithalamus An area of the cerebrum that is located in the dorsal portion of the diencephalon and contains the pineal gland.

extinction A test of sensation discrimination in which the CCTP simultaneously touches opposite, corresponding areas of the body, and asks the patient where the touch is felt; it is intended to identify sensory inattention.

extradural space A potential space between the cranial bones and the periosteal layer of the dura that becomes a real space only when blood from torn vessels pushes the periosteum from the cranium and accumulates; also called epidural space.

falx cerebelli A fold of dura mater that forms the division between the two lateral lobes of the cerebellum.

falx cerebri A double fold of dura mater that divides the cerebrum into right and left hemispheres by descending vertically into the longitudinal fissure that extends from the frontal lobe to the occipital lobe.

Fick principle A method of indirectly determining cardiac output, in which the amount of oxygen uptake of blood as it passes through the lungs is equal to the oxygen concentration difference between mixed venous and arterial blood.

fissures Deep grooves between adjacent gyri of the brain.

flat fracture The least common type of depressed skull fracture, in which the depressed segment does not have any connection with the cranial vault.

flexion-extension injury A spinal cord injury that results from forward movement of the head, typically as the result of rapid deceleration, or from a direct blow to the occiput.

focal ischemic stroke Occurs when an area of marginally perfused tissue, the ischemic penumbra, surrounds a core of ischemic cells, and the cells will eventually die without medical intervention.

foramen of Luschka An opening at the base of the fourth ventricle that leads to the subarachnoid space and is essential for the normal flow of cerebrospinal fluid; part of the brain's ventricular system.

foramen of Magendie An opening at the base of the fourth ventricle that leads to the subarachnoid space and is essential for the normal flow of cerebrospinal fluid; part of the brain's ventricular system.

foramen magnum The opening at the base of the skull through which the bundle of nerve fibers constituting the spinal cord exits.

foramen of Monro An opening in the skull that connects the two lateral ventricles with the third ventricle, a central cavity; part of the brain's ventricular system.

Foster–Kennedy syndrome A tumor or abscess at the base of the frontal lobe that impacts the olfactory nerve.

frontal lobe The largest of the four lobes of the brain; it lies underneath the frontal bone of the skull and is separated posteriorly from the parietal lobe by the central fissure and inferiorly from the temporal lobe by the lateral fissure; responsible for a variety of cognitive and motor functions.

fundus The optic disk, macula, and blood vessels on the back wall of the internal eyeball.

global ischemic stroke Results when severe hypotension or cardiac arrest produces a transient drop in blood flow to all areas of the brain.

gyri Convolutions on the surface of the cerebrum that functionally increase the cortical surface area.

halo test A test for leaking CSF that is accomplished by collecting and assessing fluid that drains from the nose, mouth, or ears; a "halo" consisting of a dark red circle surrounded by a lighter yellowish one is a positive halo sign.

hemorrhagic conversion After the brain tissue surrounding the stroke has died, renewed blood flow to the region, for example as triggered by medication, is no longer held in place by the tissue, resulting in hemorrhage.

hypothalamus An area of the cerebrum located below the thalamus that forms the floor and the anterior walls of the third ventricle. It is responsible for the maintenance of homeostasis and the implementation of behavioral patterns.

incomplete spinal cord injury A disruption of the tracts of the spinal cord in which the patient retains some degree of cordmediated function.

internal capsule A massive bundle of efferent and afferent fibers connecting the various subdivisions of the brain and spinal cord.

intervertebral foramen A space in the middle of the vertebra that allows the exit of a peripheral nerve root and spinal vein as well as the entrance of a spinal artery on both sides at each vertebral junction.

intracranial pressure (ICP) The pressure exerted by brain tissue, intracranial vascular contents, and cerebrospinal fluid in the closed, nondistensible cranial cavity.

intracranial temperature (ICT) Core brain temperature or homeostatic mean gradient temperature of 38.4°C.

intracerebral hemorrhage Direct bleeding into the brain parenchyma.

involuntary (autonomic) nervous system The sympathetic and parasympathetic branches of the nervous system, whose fibers connect the structures of the CNS with smooth muscle, cardiac muscle, and glands.

ischemic stroke Occurs when an artery to the brain has been blocked by a thrombus, embolus, trauma, or vasospasm (often due to drugs).

jugular venous bulb oximetry A technique in which a sampling catheter is placed in the internal jugular vein and directed upward so that its tip rests in the jugular venous bulb at the base of the brain; samples of blood can then be drawn to measure mixed venous oxygen saturation (SvO_2).

Le Fort criteria A categorization of facial fractures involving the maxilla that are differentiated based on the location of fracture lines and the extent of mobility of facial structures on physical examination.

Lhermitte phenomenon A condition in which forward flexion of the neck produces an electric shock feeling, usually running down the back.

limbic lobe (rhinencephalon) Part of the temporal lobe that is the seat of emotions and instincts.

linear skull fracture A type of skull fracture characterized by a single fracture line.

linear stellate fracture A fracture with multiple linear fractures radiating from the site of impact.

lumbar puncture A procedure in which a needle is inserted into the lumbar portion of the back and into the subarachnoid space to obtain spinal fluid for testing or to administer drugs.

magnetic resonance imaging (MRI) A noninvasive procedure that provides computer images of internal organs and the body through the use of radio frequency pulses and a magnetic field.

mean arterial pressure (MAP) The mean between the systolic and diastolic blood pressures (SBP and DBP): MAP = DBP + 1/3(SBP – DBP).

medulla oblongata The lowermost portion of the brain stem.

midbrain A small area of the brain stem extending between the diencephalon, the pons, and the third ventricle.

mild TBI Concussion; a traumatically induced physiologic disruption of brain function that occurs without structural damage.

Mini-Mental State Examination A simple, easily applied test of higher cognitive functions.

mixed venous oxygen saturation (SvO_2) A measurement of the oxygenation of blood leaving the brain, which is normally in the range of 50% to 75%.

Monro–Kellie doctrine A theory developed by two Scottish anatomists, who stated that the central nervous system is enclosed in a rigid compartment along with cerebrospinal fluid, whose total volume

tends to remain constant; an increase in any component—whether brain, blood, or CSF—will cause an increase in pressure and decrease the volume of one of the other elements.

motor area Part of the frontal lobe that contains pyramidal cells that control voluntary motor function on the opposite side of the body.

neurocranium The part of the skull that encloses and protects the brain.

neurogenic shock A temporary loss of autonomic function, which controls cardiovascular function, at the level of a spinal cord injury; it is characterized by marked hemodynamic and systemic effects.

normal pressure hydrocephalus (NPH) An accumulation of CSF that causes the ventricles of the brain to enlarge. The enlarged ventricles of a patient with this condition may not cause increased intracranial pressure.

nuchal rigidity Marked resistance to head movement in any direction that is suggestive of meningeal irritation.

occipital lobe The lobe of the brain that occupies the most posterior portion of the cerebrum; it is the primary receptive area for vision, specifically the interpretation of visual stimuli.

optic disk The most prominent structure visible in the eye; it represents the termination of the optic nerve.

oxygen extraction fraction (OEF) The fraction of oxygen extracted from the blood as it passes by to maintain normal oxygen delivery and, consequently, normal brain functions.

parietal lobe The lobe of the brain situated directly posterior to the frontal lobe on the other side of the central fissure; it is largely responsible for sensory functions.

pia mater The innermost layer of the meninges, which rests directly on the brain or spinal cord.

ping-pong ball fracture A pediatric greenstick fracture of the skull.

plexus A cluster of nerve roots that permits peripheral nerve roots to function as a group.

pons Part of the brain stem located between the midbrain and the medulla oblongata; it relays information to and from the brain and spinal cord along fiber tracts.

posterior cord syndrome Extension injury that produces dysfunction of the dorsal columns, presenting as decreased sensation to light touch, proprioception, and vibration.

prefrontal area Part of the frontal lobe that provides control of thought, concentration, depth and ability to think abstractly, memory, and autonomic nervous system response, concomitant to emotional change.

premotor area Part of the frontal lobe that is adjacent to the motor area and helps coordinate certain movements.

primary spinal cord injury Spinal cord injury that occurs at the moment of impact.

proprioception The ability to perceive the position and movement of one's own body or limbs.

ptosis Drooping of an eyelid.

raccoon eyes Orbital fractures and hemorrhage into the surrounding tissue; also called periorbital ecchymosis.

reticular activating system (RAS) A diffuse system that extends from the lower brain stem to the cerebral cortex; it controls the sleep-wakefulness cycle, consciousness, the ability to direct attention to a specific task, and the perception of sensory input that might alter behavior.

reticular formation (RF) A set of neurons that extends from the upper level of the spinal cord, through

the medulla, pons, and midbrain, and into the thalamus and cerebral cortex. It has both excitatory and some inhibitory capabilities, and can enhance, suppress, or modify impulse transmission.

reverse Trendelenburg Supine position with head higher than feet.

rotational force An injury-producing force in which the head moves around its center of gravity.

rotation–flexion injury A spinal cord injury to C1-C2, the only area of the spine that allows for significant rotation, in which rotation with abrupt flexion produces a stable dislocation in the cervical spine. In the thoracolumbar spine, rotation-flexion forces typically cause fracture rather than dislocation.

rubrospinal tract Part of the midbrain that controls the tone of flexor muscles.

secondary spinal cord injury Spinal cord injury in which multiple factors permit a progression of the primary spinal cord injury; the ensuing cascade of inflammatory responses may result in further deterioration.

spinal shock The temporary local neurologic condition that occurs immediately after spinal trauma; it is characterized by swelling and edema of the spinal cord and can lead to a physiologic transection, mechanically disrupting all nerve conduction distal to the injury.

stereognosis The ability to sense an object's form through touch.

stroke Results from a disruption of blood flow to the brain that results in neurologic deficit persisting for more than 24 hours.

subarachnoid hemorrhage (SAH) Bleeding between the arachnoid mater and dura mater of the brain.

subdural hematoma (SDH) Bleeding that accumulates between the dura mater and arachnoid mater.

subdural space The dura-arachnoid junction; this potential space may develop into a real one if a blow to the head causes a loss of blood into the cranial meninges.

subthalamus An area of the cerebrum that is located below the thalamus and is closely related to the basal ganglia in function.

sulci Grooves between adjacent gyri.

tectospinal tract Part of the midbrain that controls reflex motor movements in response to visual and auditory stimuli.

temporal lobe The lobe of the brain that is located beneath the temporal bone of the cranium; its primary functions relate to hearing, speech, behavior, and memory.

tentorium cerebelli A fold of the dura mater that separates the occipital lobes of the cerebrum from the cerebellum and brain stem, thereby dividing the brain into upper and lower compartments.

thalamus The largest portion of the diencephalons; it acts as a relay station for motor and sensory activity; basic neuronal activity; and memory, thought, emotion, and complex behavior.

thrombotic stroke Occurs when the blood supply to part of the brain is disrupted by a thrombus, or blood clot.

transcranial Doppler (TCD) ultrasound A noninvasive method of assessing the state of intracranial perfusion and monitoring of cerebral blood flow velocity through thinner areas of the skull; used in patients following rupture of an intracranial aneurysm to assess for vasospasm, used to identify intracranial lesions following a stroke, and used for the detection of cerebral blood flow changes associated with increased ICP.

transient ischemic attack (TIA) A temporary disruption in the blood flow to the brain that lasts less

than 24 hours with temporary side effects.

translational force An injury-producing force in which the head's center of gravity moves along a linear path.

true fracture The most common type of closed skull fracture, in which the depressed segment has contact with the cranial vault.

two-point discrimination A test of sensation discrimination that measures the shortest distance at which the sides of two separate points of a compass or calipers can be distinguished from one another.

uncal herniation The most common type of brain herniation, in which a portion of the temporal lobe is displaced, resulting in compression of cranial nerve III, the midbrain, and the posterior cerebral artery.

uncus The medially curved anterior part of the hippocampal gyrus.

ventral Toward the abdomen; anterior.

vertebral body The anterior weight-bearing structure within the spine.

vertical compression Forces transmitted through vertebral bodies and directed either inferiorly through the skull or superiorly through the pelvis or feet (eg, from a direct blow to the parietal region of the skull or rapid deceleration from a fall through the feet, legs, and pelvis).

viscerocranium The bones making up the facial skeleton.

voluntary (somatic) nervous system The nervous system fibers that connect the structures of the CNS with skeletal muscles and the integument.

Wernicke's area Part of the temporal lobe that is responsible for comprehension of both written and spoken words.

Burns

Authors

Phillip L. Coule, MD

Dawn Pecora, PA-C, MMS, CCEMT-P

Jeffrey S. Rabrich, DO, EMT-P

William M. Sherrod, MD, FACEP

Objectives

1. Describe the layers and functions of the skin (p 444).
2. List the major causes of burn injury (p 445).
3. Describe the anatomy of a burn (p 446).
4. Explain the process of the body's systemic inflammatory response to a burn (p 446).
5. Explain the factors that determine the classification of burn injury, including body surface area and burn depth (p 446).
6. List the classifications of burn injuries, including superficial burns, partial thickness burns, deep partial thickness burns, full-thickness burns, subdermal burns, as well as minor burns, moderate burns, and major burns (p 446–447).
7. Identify the methods for calculating the total body surface area burned, including the rule of nines and the Lund and Browder chart (p 448).
8. Describe how to evaluate a burn patient and what constitutes a pertinent history (p 449).
9. Discuss assessment considerations for a burn patient's airway, breathing, and circulation (p 449–452).
10. List situations in which the CCTP should suspect an inhalation injury (p 451).
11. Discuss the roles of edema and compartment syndrome in relation to a burn injury (p 451–452).
12. Describe the process of stopping a burn, including irrigation, cooling, decontamination, and special considerations (p 453).
13. Discuss management of a burn patient's airway, breathing, and circulation (p 453–455).
14. Discuss special considerations for patients who may have carbon monoxide poisoning or cyanide poisoning in conjunction with a burn injury (p 451).
15. Explain various fluid resuscitation formulas, including the Parkland formula and the Galveston formula, and describe parameters for adjusting the infusion rate (p 455).
16. Describe how to manage and dress burn wounds (p 455–456).
17. Discuss pain management of burn patients (p 456–457).
18. Recognize which patients require transport to a burn center or unit (p 449, 456, 457, 458–464).
19. Discuss special situations relating to burn injuries such as hypothermia, the need for gastric decompression, renal failure, and rhabdomyolysis (p 457–458).
20. Discuss management of specific burns, including ocular burns, facial burns, ear burns,

circumferential burns, hand and foot burns, genitalia burns, pediatric burns, electrical burns, and chemical burns (p 458–463).

21. List the types of burns that may suggest potential child maltreatment (p 460).
22. Discuss toxic epidermal necrolysis (TENS) and Stevens-Johnson syndrome (SJS) and the similarity between their management and the management of severe burn patients (p 464).

Introduction

According to the American Burn Association there are approximately 1 million burn injuries per year in the United States resulting in approximately 500,000 emergency department visits, 40,000 hospitalizations, and 4,000 fire and burn-related deaths. Approximately 25,000 of the admissions per year are to specialized burn units, with the majority of these patients requiring transfer to receive their specialized care. In the year 2000, there were 125 burn centers in the United States with an average of 200 admissions per year. The average size of a burn injury that requires admission is 14% total body surface area (TBSA). Six percent of burn center admissions do not survive. The highest incidence of burns occurs in the first few years of life and between 20 and 29 years of age. Serious burns occur most often in males (67%), with the majority of these burns resulting from flame.

Most of the approximately 25,000 admissions to burn units require transfer via EMS to specialized care. Specialized burn care may be provided at burn centers or burn units. Burn centers are large facilities that admit more than 100 patients per year, whereas burn units are specialized facilities that have fewer than 100 admissions per year. The principles of acute burn management taught in basic paramedic and nursing courses are the foundation for caring for these patients. However, the first 24 hours of care after a burn are crucial. Factors such as unrecognized injuries from associated trauma, complications of treatment such as fluid overload, and comorbidities such as diabetes or chronic obstructive pulmonary disease may complicate care, and the conditions of patients who appear stable may acutely worsen. Given that complications of burns may develop during the transport of the patient to a burn facility, the CCTP must ensure that adequate resuscitation and stabilization continue during transport. Knowledge of common complications and the timing of their treatment are important for safe and effective transport to specialty care centers.

Anatomy and Function of the Skin

The skin is the largest organ of the body and its function is as vital to survival as any other organ. A basic understanding of skin anatomy and function will help the CCTP understand burn treatment and potential complications. The skin is a multilayered structure composed of the epidermis and dermis as the principle components **Figure 12-1**. The epidermis and dermis are divided into additional levels that have specific functions.

The Epidermis

The epidermis generally consists of four layers (thin skin) except on the palms, fingertips, and soles of the feet, where five layers exist (thick skin). Each layer has a different composition.

The layers of the epidermis from deep to superficial are the stratum basale, which is attached to the underlying dermis, the stratum spinosum (prickly layer), stratum granulosum, stratum lucidum (thick skin only), and most superficially, the stratum corneum.

The epidermis contains the pigment cells known as melanocytes, immune cells known as Langerhans cells, as well as capillaries in the lower layers. It is important to note that while the epidermis does

contain some receptors for touch, the nerve receptors that transmit pain are located in the deeper dermis layer. The outer layer of the epidermis, the stratum corneum, provides a barrier to prevent water loss from deeper structures, and is constantly losing cells as a result of sloughing. It takes approximately 2 to 3 weeks for a cell to make its way from the lowest layer to become a keratinocyte and eventually be sloughed off. As the epidermis is the first barrier to injury and infection, it is injured more often than other layers and is constantly repairing itself.

The Dermis

The dermis lies beneath the epidermis and is a dynamic layer of thick connective tissue that, like the epidermis, is in constant turnover. The cell types found here are fibroblasts, macrophages, white blood cells, and the occasional mast cell. The dermis is also richly supplied with nerve fibers, blood vessels, and lymphatic vessels. The major portions of the hair follicles and the oil and sweat glands are also found in the dermis.

The dermis is divided into two layers: the papillary and reticular layers. The thin superficial papillary layer is composed of connective tissue forming the anchoring system for the epidermis. It is also heavily invested with blood vessels yielding the highest blood flow of the dermal layers, which is important for temperature regulation. These blood vessels are found in nipple-like projections called dermal papillae that indent the overlying epidermis. These dermal papillae also house free nerve endings (pain receptors) and touch receptors.

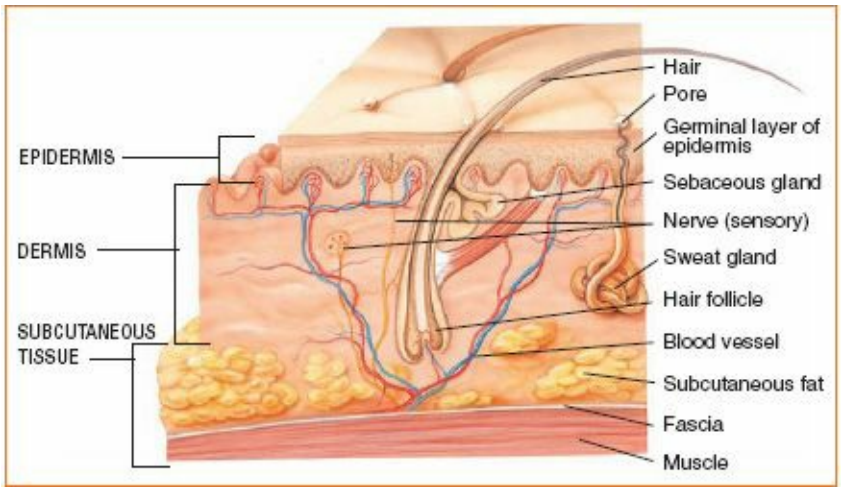

Figure 12-1 The skin has two principal layers: the epidermis and the dermis.

The reticular layer accounts for 80% of the dermis. Its dense irregular connective tissue is responsible for the durability of the skin and anchors skin appendages. Interlocking collagen fibers run in various planes, usually parallel to the skin. Regions between these bundles form *lines of cleavage* in the skin **Figure 12-2**. These cleavage lines run longitudinally in the skin of the head and limbs and in a circular pattern around the neck and truck. This becomes important when considering where to make incisions for escharotomies and fasciotomies because incisions made parallel to these lines cause the skin to gape less and heal more readily than incisions made across cleavage lines.

Collagen fibers give the skin strength and resiliency against injury. Collagen also helps maintain hydration of the skin, an important concern after a major burn. Another concern is the adverse effect burns have on the elastin fibers, which provide the stretch-recoil properties of the skin.

Deep in the dermis lies the hypodermis, which is composed of subcutaneous fat, connective tissue, sweat glands, muscle, and bone.

The Process of Healing

Proteins that are produced in the dermis, such as collagen and fibronectin, support the continuously reproducing epidermis and play a major role in wound healing. Multiple cell types are contained in the dermis when undamaged, but many more are attracted to the area when it is wounded.

Fibroblasts produce proteins such as collagen, fibronectin, and others responsible for skin repair. Macrophages are normally present in the tissues, but increase in numbers after an injury. Macrophages release chemical messages that help attract other cells and orchestrate organized healing. Endothelial cells produce capillaries and restore blood flow after an injury. Fibroblasts, macrophages, platelets, and endothelial cells play a vital role in the wound healing process of the skin. The inflammatory response that is responsible for burn healing is also responsible for multiple complications that will be discussed later.

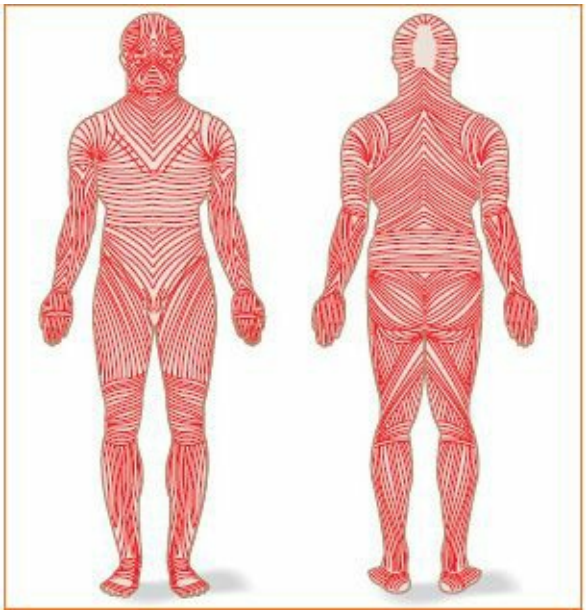

Figure 12-2 The skin's lines of cleavage. Incisions made parallel to these lines heal more easily than incisions made perpendicular to these lines.

Functions of the Skin

The skin has multiple functions including protection, immunologic, thermo-regulation, maintenance of fluid and electrolyte balance, metabolism, neurosensory, and social. All of these functions of the skin are essential to the normal functioning of the body, and any or all of these functions can be impaired in a burn injury. The epidermis serves as a barrier that protects the body from desiccation (drying out) and maintains fluid balance by preventing excess loss of fluid through evaporation. An intact epidermis is also relatively effective at preventing the entry of toxins and bacteria. Burn injuries result in damage to the epidermis, increasing the risk of fluid loss through evaporation from the skin and allowing the direct entry of bacteria through the compromised skin.

The neurosensory function of skin is also important for social and interactive functioning. This ability to sense temperature and touch may be impaired or absent in the burned patient.

The skin has a complex mechanism by which wound healing and skin repair occur. In severe burns this intrinsic healing mechanism may be irreparably damaged, necessitating skin grafting for wound closure.

Because of its elastic properties, the dermis protects a person from minor trauma and assists in the regulation of fluid balance through its regulation of blood flow. This regulation of blood flow is also a major mechanism by which the body regulates temperature. Because the skin is responsible for fluid and

temperature regulation, large burns (greater than 20% in adults and 15% to 18% in children) can cause massive fluid loss, shock, and hypothermia, even on a hot day. The skin also serves as a barrier from infection, and burn damage gives bacteria easier access to the body. Damaged skin is also more susceptible to pressure injuries such as bed sores. Finally, the skin is a sensory organ that can cause intense pain and jeopardize the patient's ability to recognize touch after a burn. Any burn, regardless of the cause, can alter these vital functions; the degree of dysfunction is determined by the extent and depth of the burn.

Physiology of Burns

Causes of Burns

Burns occur from a variety of mechanisms: flame/flash, scald (for example, water or grease), contact, electrical, chemical inhalation, radiation, or any thermal source. In addition, some medical conditions such as **Stevens-Johnson syndrome** and **toxic epidermal necrolysis syndrome** cause burnlike injuries and are treated similar to heat-related burns. Regardless of the mechanism of injury, all burns share common features—the destruction of skin and an impairment of its ability to perform its functions. The size and depth of the burn are determined by the agent, temperature, and duration of exposure. **Thermal burns** having temperatures greater than 113°F can cause cell damage and denaturing of cellular proteins. This denaturing of proteins eventually causes cell death. At temperatures of 120°F, an exposure for 5 minutes is enough to cause a full-thickness burn, and at temperatures above 159°F, it only takes 1 second to create a full-thickness burn in a healthy adult. These temperatures and times may vary when children and the elderly are affected.

Anatomy of a Burn

The most damaged area of a burn is referred to as the **zone of coagulation** and is the area of skin that came into direct contact with the source of the heat. In the zone of coagulation, the tissue is destroyed and clotting results in impairment of circulation to the surrounding tissues. The surrounding areas of injury are referred to as the zone of stasis and the zone of erythema. The **zone of stasis** has injured tissue and stagnant blood flow resulting in ischemic tissues. It may appear red and **hyperemic** (filled with an increased amount of blood) initially, but within 24 hours after injury, blood flow will cease in the area and ischemia results. By the third day after the injury the zone of stasis becomes white because of avascular necrosis. The area surrounding the zone of stasis is the outermost area known as the **zone of erythema** owing to its increased blood flow. This area has sustained minimal damage and will recover from the injury.

Systemic Inflammatory Response of the Burned Patient

Although inflammation is necessary for the normal healing process to occur, excessive inflammation results in undesirable effects on other tissues and organs. Burns of greater than 25% TBSA result in a systemic inflammatory response. Cells in the body migrate to areas of injury to affect repairs at the injury site. A blood-rich environment is necessary for these cells to function properly. In larger areas of injury, however, the vascular endothelium becomes "leaky" in order for "repairing" cells to make their way from the vasculature into the wound. When this occurs at noninjured sites in the body, undesirable results occur, such as those that follow:

- Proteins may leak into subcutaneous tissues at uninjured sites, or the pressure at which proteins and fluids may be exuded into the lungs may be lowered, making pulmonary edema more likely.

- The mediators can suppress the immune system, adding insult to injury.
- The leaky endothelial cells of the intestinal vasculature may allow bacteria normally found in the bowel to make its way into the bloodstream (a process known as translocation), causing sepsis, even in the absence of a burn wound infection.
- Cardiac output may also be impaired after a burn injury. Although the mechanism is unclear, myocardial contractility is suppressed after a significant burn injury.

Regardless of the cause, the inflammatory response from a burn injury, although necessary to promote burn healing, may also result in untoward effects.

Classification of Burn Injury

The severity of a burn depends on (1) extent, depth, and location of the burn injury; (2) age of the patient; (3) etiologic agents involved; (4) presence of inhalation injury; and (5) coexisting injuries or preexisting illnesses.

Two classification systems for the depth of burns exist. The system describing first-through fourth-degree burns is widely known and used, but is less predictive of the need for surgical intervention than the simple partial- or full-thickness descriptions **Table 12-1**. Both systems are discussed here.

Burn Extent and Depth

Superficial burns, or first-degree burns, involve only the epidermis and are usually the result of ultraviolet light exposures (sunburn), very minor scald injuries, or flash burns. The skin is hyperemic but not blistered, with healing occurring without scarring in approximately seven days.

TABLE 12-1 Classification of Burns

Depth	Color and Vascularity	Surface Appearance and Pain	Swelling, Healing, and Scarring
Superficial (first degree)	Erythematous, pink and red	No blisters Dry and tender	Slight edema Heals easily without scarring
Superficial to partial thickness (second degree)	Erythematous, bright pink/red, mottled Blanches with brisk capillary refill	Intact blisters, moist when removed Weeping wounds and extremely painful	Moderate edema Easily heals but with skin discoloration
Deep to partial thickness (second degree)	Red, waxy-white Blanches with slow capillary refill	Broken blisters, wet Sensitive to pressure, but not to light touch	Marked edema Heals slowly with hypertrophic scars
Full thickness (third degree)	White, black to red/tan No blanching, vessels thrombosed Poor distal circulation	Dry, leathery Anesthetic Hairs pull out easily	Skin grafting required Scarring likely after healing
Subdermal (fourth degree)	Charred	Obvious subcutaneous tissue involvement Anesthetic	Skin grafting and/or flap required Scarring after healing

Partial-thickness burns, or second-degree burns, are subdivided into superficial and deep burns. In **superficial partial-thickness burns** (superficial second-degree burns) the epidermis and part of the dermis are involved, but the deeper layers of the dermis are spared, including the sweat glands, sebaceous glands, and hair follicles. These burns are typically caused by hot liquids or minimal contact with flame. Blisters form, and the injured skin is red and painful to touch. These burns do not typically require skin grafting unless they are extensive and occur on areas of the body with thin skin such as the face, hands, genitals, and feet. Superficial partial-thickness burns will heal in 14 to 21 days. The extent of the scarring depends on the extent of the burn. **Deep partial-thickness burns** (deep second-degree burns) are most often the result of steam, oil, or flames, and involve the deeper layers of the dermis. They may be difficult to distinguish from full-thickness burns. The skin is blistered but not charred and is painful to touch. Healing takes 21 days or more and may require surgical grafts. Scarring may be moderate and depends on the extent and location of the burn.

Full-thickness burns, or third-degree burns, involve the entire thickness of the dermis down to the subcutaneous fat. All epidermal and dermal structures, including nerve endings in the burned area, are destroyed, resulting in a pale, painless, leathery charred area of skin. Full-thickness burns will not heal spontaneously and surgical skin grafting is necessary. Full-thickness burns result in significant scarring.

Subdermal burns, or fourth-degree burns, involve the deep structures of muscle and bone, larger blood vessels, and nerves. These injuries are severe and life threatening. Like full-thickness burns, they will not heal spontaneously and require surgical intervention.

Superficial, partial-thickness, full-thickness, and subdermal burns are shown in **Figure 12-3**.

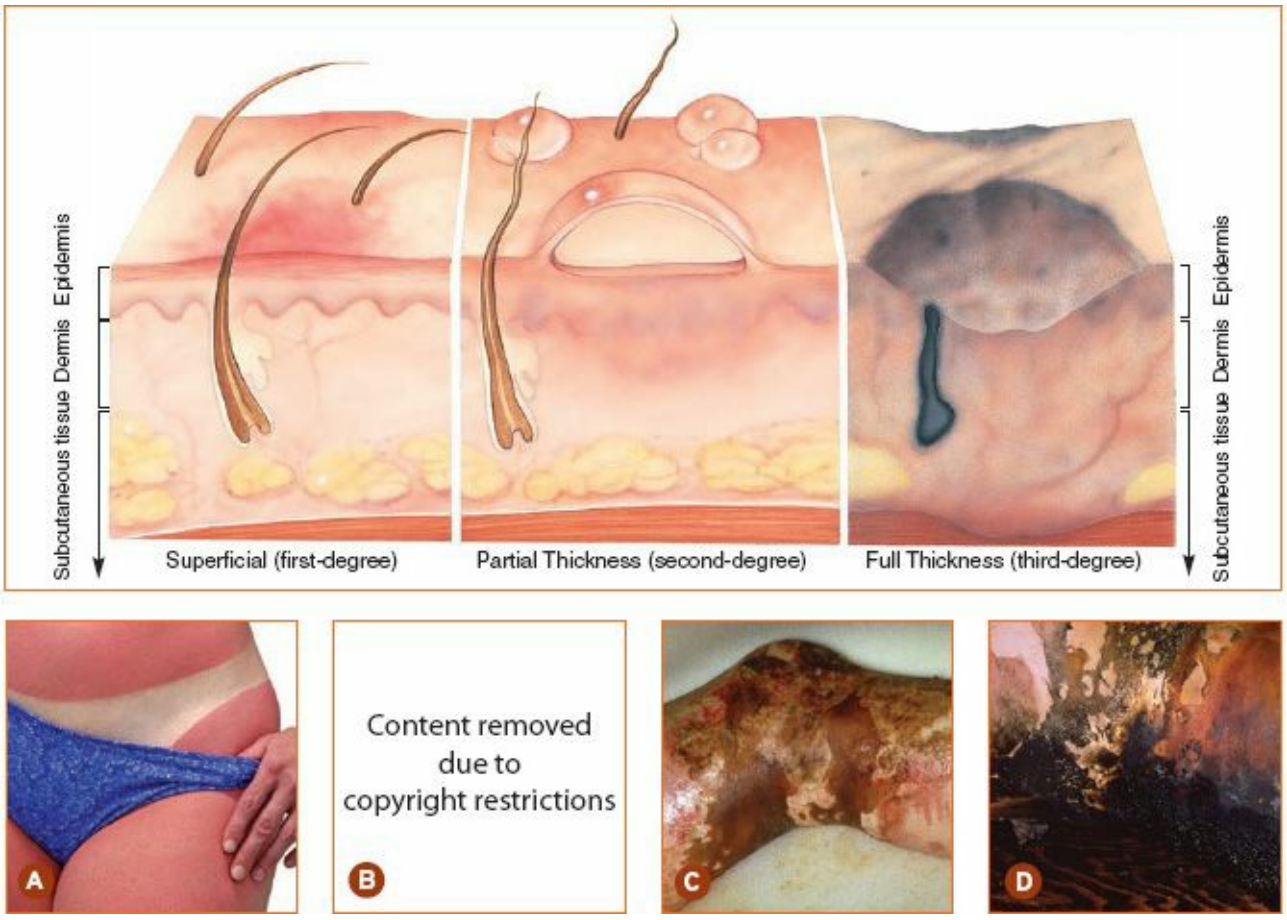

Figure 12-3 Classification of burns. **A.** Superficial (first-degree) burns involve only the epidermis. **B.** Partial-thickness (second-degree) burns involve some of the dermis but do not destroy the entire thickness of the skin. The skin is mottled, white to red, and often blistered. **C.** Full-thickness (third-degree) burns extend through all layers of the skin and may involve subcutaneous tissue and muscle. The skin is dry, leathery, and often white or charred. **D.** Subdermal (fourth-degree) burns involve deep structures such as

muscle, bone, large blood vessels, and nerves.

Burn Size

As stated previously, the depth of the burn is only one factor determining its severity; the size of the burn is also a determining factor. Numerous methods are available to estimate the body surface area involved in a burn. The **rule of nines** is the most common formula and is based on the fact that large regions of the adult body can be divided into areas that represent roughly 9% of the total body surface area or multiples of 9% **Figure 12-4**. For infants and children an amended rule is used that adjusts the rule of nines to account for the relatively large head and small lower extremities. For patients with scattered irregular burns or small burns, the patient's palm may be used to estimate the burn area. In children and adults, the palm (not including fingers) represents 0.5% of the patient's total body surface area. Previously the palm was thought to represent 1% of the body surface area. However, in 1995 Sheridan and coworkers demonstrated that 0.5% is more accurate. Data also demonstrate that the **Lund and Browder chart** **Figure 12-5** is more accurate than the rule of nines for calculating the body surface area burned and is the preferred method in most burn centers. However, the chart is difficult to memorize, making the rule of nines the most common method in the prehospital environment. Regardless of the method used, accuracy improves with experience.

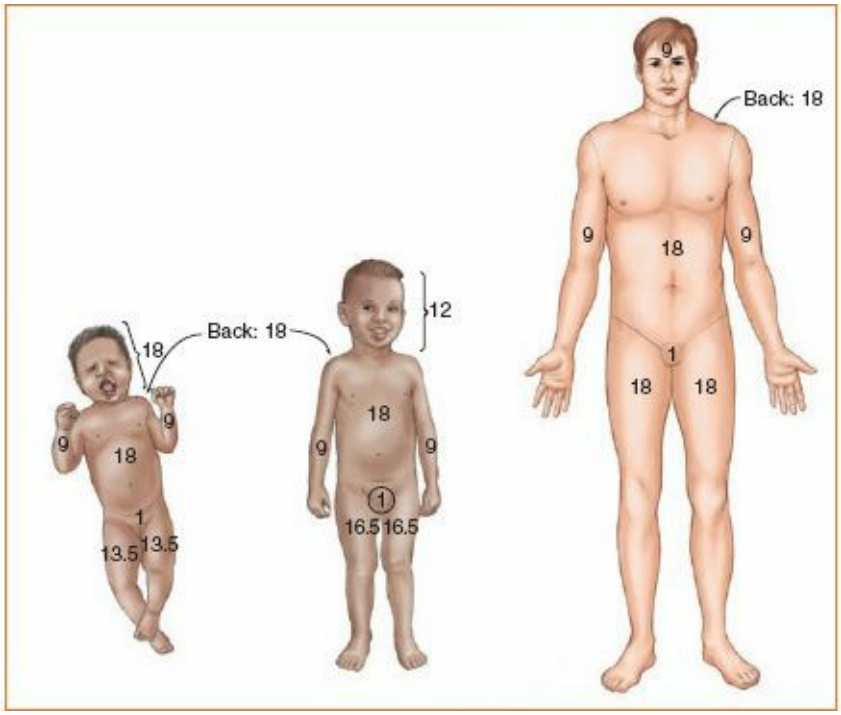

Figure 12-4 The rule of nines. The body is divided into sections, each representing approximately 9% of the total body surface area. The proportions differ for infants, children, and adults.

Special Populations

Fetal mortality is closely linked to maternal mortality when considering burn victims. Generally speaking, a maternal patient with greater than 60% total body surface area burns has a high rate of fetal mortality.

Burn Severity

The American Burn Association classifies burns into three major categories—major, moderate, and minor.

Major Burn Injury

Major burn injuries include:

1. Partial-thickness burns involving more than 25% of BSA in adults or 20% of BSA in children younger than 10 years and adults older than 50 years.
2. Full-thickness burns involving more than 10% of BSA.
3. Burns involving the face, eyes, ears, hands, feet, or perineum that may result in functional or cosmetic impairment.
4. Burns caused by caustic chemical agents.
5. High-voltage electrical injury.
6. Burns complicated by inhalation injury or major trauma.
7. Burns sustained by high-risk patients (eg, patients with debilitating diseases such as diabetes or congestive heart failure).

Moderate Burn Injury

Moderate burn injuries include the following (note that this list excludes high-voltage injury):

1. Partial-thickness burns of 15% to 25% of BSA in adults or more than 10% to 20% of BSA in children and older adults.
2. Full-thickness burns involving 2% to 10% of BSA that do not present a serious threat to functional or cosmetic impairment of the eyes, ears, face, hands, feet, or perineum.

Minor Burn Injury

Minor burn injuries include:

1. Partial-thickness burns involving less that 15% of BSA in adults or 10% of BSA in children and older adults.
2. Full-thickness burns involving less that 2% of BSA that do not present a serious threat of functional or cosmetic risk to the eyes, ears, face, hands, feet, or perineum.

Patients who meet the criteria for major burn injury should be transferred to a specialized burn center to ensure appropriate acute care, rehabilitation, and long-term care. Patients who meet the criteria for moderate burn injury should be hospitalized and consideration given to transferring care to a specialized burn center. Patients with minor burn injuries can usually be managed in the outpatient setting.

Assessment

Assessment for burn patients should be similar to any other patient. However, there are particular complications and findings that must be detected in order to take corrective action **Figure 12-6**.

A complete initial assessment and focused history and physical exam should be performed, always using caution whenever a c-spine injury is suspected. Keep in mind that explosions may produce c-spine injuries that may not be as obvious as the visible multiple burns. The CCTP should not rely on the history and exam of others because their level of training may not be equivalent to that of the CCTP. In addition, the patient's condition may have changed since the last exam. As always during interfacility transfers, an initial evaluation of the patient for life-threatening problems should be conducted and then a history obtained from the patient and/or family members and a report from the nursing staff. In order to avoid excessive delay in initiating transfer, the CCTP should review the chart for the most relevant information. The CCTP can then fill in remaining details by asking the patient, staff, or family. A focused history and physical exam of the patient should be performed to assess for complications that need corrective action and to document the patient's condition. Vital signs, including temperature and oxygen saturation, should also be obtained again prior to transporting the patient. The initial assessment should include the ABCs, and the physical exam should follow the head-to-toe format, with attention paid to each organ system.

Initial Assessment

Airway

The CCTP should pay special attention to the airway of the burned patient, particularly if the patient was burned as the result of a confined space fire. Inhaling heated gases from combustion damages the respiratory tract. Inhaled gases, particles, and other debris damage the respiratory epithelium resulting in increased mucus production, impairment of mucociliary function, and eventual cell death. Inflammatory changes in the airway occur *within 2 hours of injury*. Bacteria colonize the damaged airway and infection is present microscopically within 72 hours. The extent of the inflammatory response is directly proportional to the dose of smoke inhaled and length of exposure.

The CCTP should inspect the airway and face for any evidence of inhalation injury and, if present, consider performing endotracheal intubation after rapid sequence intubation (RSI) if the transport time is

prolonged or if there is any deterioration in the patient's condition. Preemptive airway control is necessary because of the worsening edema that occurs after fluid resuscitation, potentially causing airway obstruction and necessitating a surgical airway. If stridor, progressive hoarseness, or any change in the patient's voice is present, the patient should be intubated *immediately using RSI*, with instruments for performing a surgical airway on hand.

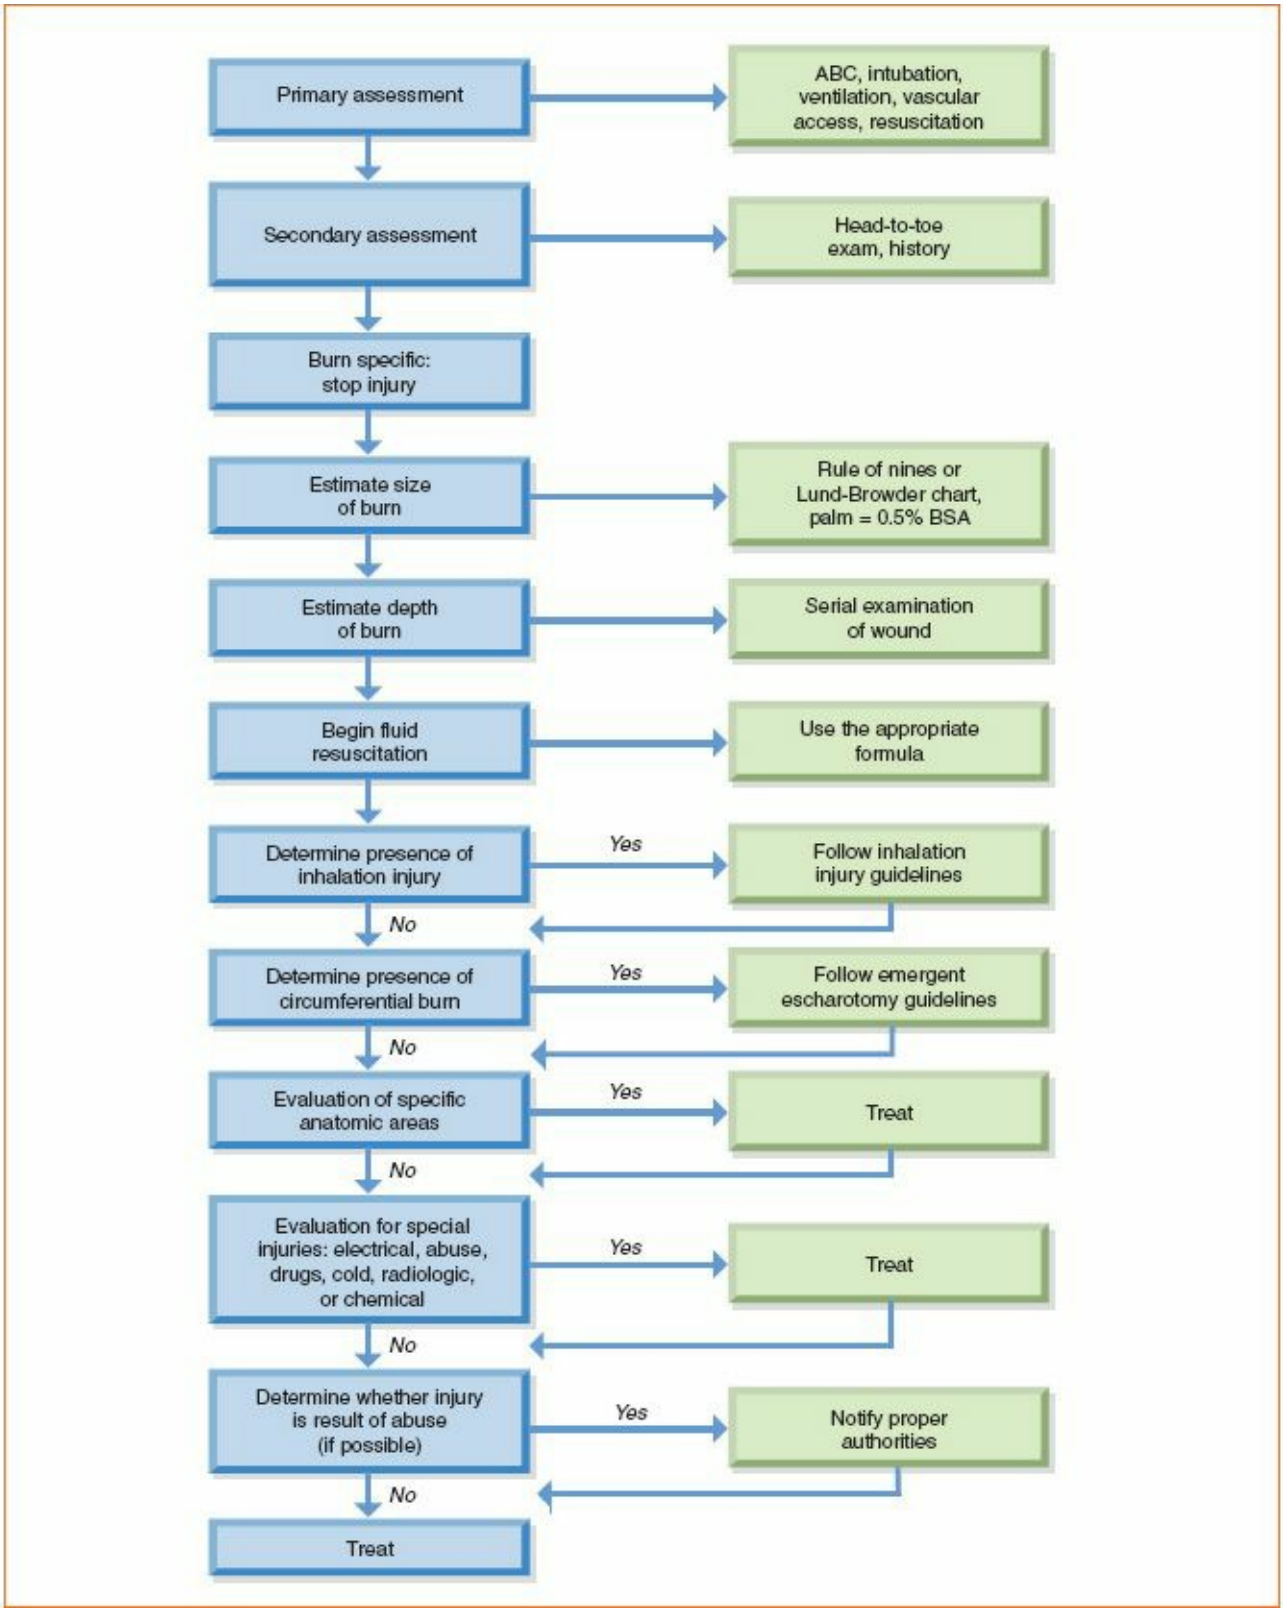

Figure 12-6 Algorithm for initial assessment of a burn injury.

Inhalation injury should be suspected if the patient has any of the following:

1. Facial burns
2. Stridor or progressive hoarseness
3. Singeing of the eyebrows and nasal vibrissae (hairs)
4. Carbon deposits and acute inflammatory changes in the oropharynx
5. Carbonaceous (black) sputum
6. History of impaired mentation and/or confinement in a burning environment
7. Explosion with burns to the head and torso
8. Circumferential neck burns
9. Carboxyhemoglobin level greater than 10% if the patient is involved in a confined space fire
10. Soot around the nose and mouth

The patient's airway should be reevaluated frequently to assess for potential compromise due to edema. In addition, patients with an altered mental status or a Glasgow Coma Scale score of 8 or less after a major burn or any injury should have their airway controlled. If the patient is to be intubated for an elevated carboxyhemoglobin level, water should be used to fill the endotracheal tube cuff in preparation for hyperbaric therapy. However, it is often difficult for the CCTP to predict who will need hyperbaric oxygen, and an air-filled cuff can always be changed to water prior to initiating hyperbaric treatment. It is important to point out that if RSI is not in the scope of practice for the CCTP in your jurisdiction, attempted intubation in the setting of an inhalation injury is likely to result in worsened edema and potentially a failed airway. In this situation a risk/benefit assessment of airway management without RSI must be undertaken. Consideration should be given to delaying the transfer of the patient until the airway can be managed by someone skilled in airway management and capable of RSI.

Breathing

The patient's breathing rate and depth should be assessed along with the lung sounds. Noncardiogenic pulmonary edema may develop as a result of inhalation injury or fluid overload from aggressive fluid replacement, but needed fluids should never be withheld. High-flow oxygen should be started immediately in the patient with major burns, using caution in patients with chronic obstructive pulmonary disease (COPD) due to suppression of the hypoxic drive. Although COPD often causes concern regarding oxygen therapy, a hypoxic patient should never have high-flow oxygen withheld, and the CCTP should be prepared to assist ventilation if needed. Examination of the chest should include a search for full-thickness circumferential burns, which may significantly impair ventilation by impairing expansion of the chest. A field escharotomy is rarely, if ever, needed. Although it takes time for tissues to dessicate (dry out) and a constrictive **eschar** (the leathery covering of a burn injury) to develop, the CCTP will encounter burn patients at varying times after injury and an escharotomy may be necessary. For example, the CCTP may need to perform chest wall escharotomies in extreme cases with extended transport times. Emergent chest wall escharotomy may be performed (if scope of practice allows) to allow for adequate movement of the chest wall. If available, the arterial blood gas levels should be reviewed, paying particular attention to the oxygenation and carboxyhemoglobin levels. Wheezing should be treated with bronchodilators, as is standard. Another therapy to consider includes humidified oxygen for inhalation injuries (in the absence of wheezing) using a nebulizer with normal saline only and no bronchodilators.

Burn patients may have experienced significant trauma from explosions or motor vehicle collisions resulting in fires. In such situations it is easy to overlook conditions such as a pneumothorax or hemothorax while treating the obvious burn. Repeated patient examinations should be aimed at identifying these conditions.

Patients with carbon monoxide poisoning may present with symptoms of hypoxia, but without

cyanosis. The classical teaching is that patients present with cherry red skin, although this is not often identified until postmortem. The CCTP should be aware of the limitations of pulse oximetry in the patient with carbon monoxide poisoning. Carbon monoxide poisoning will be covered in Chapter 20.

Cyanide poisoning should be considered if the assessment of the burn patient reveals intense air hunger, metabolic acidosis, or sudden cardiovascular collapse and the patient has been the victim of a confined space fire. Begin appropriate therapy such as hydroxocobalamin.

Circulation

Burn patients may have impaired cardiac output. The etiology of decreased cardiac output is unclear, but may be from a variety of causes, including high levels of circulating inflammatory mediators, carbon monoxide poisoning, or cyanide poisoning. Assessment of the burned patient should include an evaluation of cardiac output, capillary refill, neck vein distension, lung sounds, pulse rate, and blood pressure. Burn patients who have been victims of other trauma such as motor vehicle collisions or explosions may have myocardial contusions, cardiac tamponade, or abdominal or solid organ injuries. The CCTP should review the lab values to ensure that the hemoglobin level is adequate—a value of more than 10 g/dL is preferred for flight. Consider administering blood transfusions to patients with hemoglobin levels of less than 10 g/dL, patients with major burns, patients with significant comorbidities (such as coronary artery disease), or elderly patients.

Assessment of the patient's circulation should include evaluation of the extremities and digits for circumferential burns that have impaired circulation. Edema in the arms and legs may also impair circulation. Circumferential deep partial-thickness burns cause impairment of circulation because of their tough leathery nature. Impaired circulation may result in an absence of pulses, delayed capillary refill, or mottling and discoloration of the extremity. Early identification of circulatory impairment in the extremities is crucial to prevent tissue necrosis and amputation. Patients with circumferential burns and a lack of distal circulation should have an escharotomy performed if local scope of practice allows.

In the arms and legs, edema may also develop deep in compartments created by the tough nonelastic fascia that surrounds and separates the muscles. Edema can compress the blood vessels and nerves, which impairs blood flow and sensation and results in **compartment syndrome**. The symptoms of compartment syndrome are known as the Five Ps: Pain, Pallor, Paralysis, Paresthesias, and Pulselessness. The affected extremities may also be cold (poikilothermia, sometimes called the sixth P). Pulselessness is a late finding in compartment syndrome. Pain is considered the hallmark of compartment syndrome and is typically out of proportion to the injury or physical findings. Compartment syndrome therefore may be difficult to detect in burn patients because burns are expected to be painful. Patients with compartment syndrome undergo **fasciotomy**, a surgical incision of the tough and fibrous fasciae that separate the compartments to relieve the pressure. Fasciotomies are typically not performed by prehospital providers and should only be performed by properly trained personnel.

The assessment of a patient's circulation should also include determining the adequacy of fluid resuscitation in the burn patient. Fluid resuscitation in burn patients should be guided by formulas such as the Galveston and Parkland formulas, which are discussed later; however, in patients with significant comorbid conditions such as congestive heart failure or renal failure, the assessment of the patient's fluid status may play a greater role in guiding fluid replacement. Pulse rate, oxygen saturation, and lung sounds must all be considered in determining the patient's fluid balance. In patients with adequate renal function, urine output should be monitored closely to ensure an output of at least 50 mL/h (0.5 to 1.0 mL/kg/h) for the adult. Pulse rate is not a good indicator of the adequacy of fluid resuscitation and may remain elevated because of pain and the release of catecholamine. If **myoglobinuria** develops (an accumulation of myoglobin in the renal tubules), additional fluids should be given to reach a urine output of at least 100 mL/h. Myoglobinuria should be suspected if the urine becomes dark, brown, or bloody.

Signs and Symptoms

Compartment Syndrome

- The Five Ps: Pain, Pallor, Paralysis, Paresthesias, and Pulselessness
- The affected extremities may also be cold (poikilothermia)

Transport Management

Compartment Syndrome

- Keep the involved extremity elevated.
- Monitor pulses, sensation, and motor function.
- Do not place anything on the extremity that is compressive, such as splints or bandages.
- Monitor for increased pain (remember pain out of proportion is the hallmark of this syndrome).
- Provide supportive care (ie, maintain body temperature, analgesics, IV fluids, and oxygen).

Signs and Symptoms

Myoglobinuria

- Dark, brown, or bloody urine

Transport Management

Myoglobinuria

- Administer additional fluids so that urine output is at least 100 mL/h.

Focused History and Physical Exam

Disability

A brief neurologic exam is part of the initial assessment, but a more detailed neurologic assessment is necessary. Burn patients are generally awake and alert. Unconscious or confused patients may have other issues affecting their mental status, such as hypoxia, carbon monoxide poisoning, cyanide poisoning (from burning plastics), head injury, or substance abuse. Alcohol is commonly present in burn victims. Patients with carbon monoxide poisoning may exhibit subtle cognitive impairment that may not be detected during initial assessment. The CCTP therefore should be alert to changes in mental status. A patient with altered mental status should have aggressive support of the ABCs while the cause is investigated. The neurologic exam should include pupillary response to light and gross motor activity in the extremities. Patients with additional trauma (for example, injuries from explosions or motor vehicle collisions) should undergo c-spine immobilization until evaluated and cleared by radiograph, or clinical criteria such as the NEXUS or the Canadian c-spine rule, which are the clinical rules used in emergency departments throughout the country.

Exposure

A head-to-toe examination of the patient should be undertaken, noting the depth and size of the burns and other associated injuries. If the patient's wounds have been dressed prior to transport, within reason these should be removed to inspect the wounds and injuries (use your clinical judgment regarding the feasibility of doing this prior to transport). Care should be taken to identify and correct any inappropriate dressings, such as wet dressings. Assess the patient for hypothermia, and take precautions to prevent it.

History

In addition to the initial assessment and physical exam, a detailed history should be obtained. Information about the patient, the incident, and what treatment has been provided must be included, especially the amount of fluids delivered prior to arriving at the hospital and at the referring hospital. This is particularly important for patients who will be transported a long distance from home. If the patient is unconscious or becomes unconscious en route, vital information may not be available to the team that assumes care. The following information should be obtained:

- Patient information (SAMPLE)
  - Signs/symptoms
  - Allergies
  - Medications
  - Past medical and surgical history, and tetanus status
  - Last meal or drink
  - Events leading to injury
- Mechanism of injury
  - Source of burn
  - Closed space and duration of exposure
  - Chemical exposure
  - Related trauma (ie, fall, blast, motor vehicle crash)
- Prior interventions
  - Scene
    - Resuscitation required and fluid administered to patient
    - Field decontamination (ie, method of cooling, eye irrigation)
  - Hospital
    - Tetanus booster
    - Fluids given (amount and type)
    - Other treatments (ie, antibiotics, nebulized medications, diuretics, sedation, and pain medications)
    - Procedures (ie, central line placement, endoscopy, bronchoscopy, fasciotomy, and escharotomy)
- Bring copies of all records and radiographs from the transferring facility

Transport Management

General Burn Management

- Remove the patient from the source of the burn.
- Cool the burn within the first 2 minutes, and no longer than 20 to 30 minutes.

- Irrigate. This should not be done for longer than 30 minutes.
- Administer high-flow oxygen.
- Remove wet clothing, dressings, and linens.
- Provide early, aggressive, sustained fluid management; obtain IV access through unburned skin if possible.
- Consider using warmed IV fluids, especially if large volumes are required.
- Monitor the patient's overall perfusion status, mental status, urine output, and lung sounds.
- Leave blisters intact.
- Administer pain medication. Assess and treat for pain every 10 minutes until the patient is comfortable.
- Check fluid and infusion rates when accepting a transfer.
- Inventory the fluid given already.
- Reconcile urine output since injury.
- Empty the Foley bag at the time of assuming care.
- Keep the patient warm and place him or her in clean, dry linens prior to transport.

Management

Stopping the Burn
